It follows from Eq. (1) that at low pressures ($p \sim 10^{-4}$ torr) the discharge is ignited when the slow electrons resulting from ionization at the axis (the beam region) no longer reach the collector under the influence of the electric field and begin to revolve along an epitrochoid in the azimuthal plane, effectively ionizing the gas. In a strong magnetic field $B \gg B_{cr}$ it is possible to reduce the height of the epitrochoid, ρ, to such an extent that the energy acquired by a slow electron in the field E_r, $\mathcal{E} = e\rho E_r$, becomes lower than the ionization energy eV_i:

$$\rho E_r \leqslant V_i. \tag{2}$$

In this case the discharge is cut off, as can be seen from Fig. 5 (the right-hand branch of the ignition curve). The calculated curve 4, for which inequality (2) holds, is

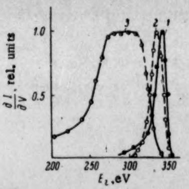

Fig. 4. Ion energy spectrum. Here $\partial I/\partial V$ is the differential functional dependence of the analyzer–collector current on the potential of the analyzer electrode; E_i is the ion energy; E_0 = 1.2 kV; p = $2 \cdot 10^{-4}$ torr; V_c = 350 V; L = 10 cm; I_0 = 2 mA. shown in Fig. 5; it gives a qualitatively correct description of the experimental functional dependence of the ignition potential V_c^* on B.

Similar results are obtained when this annular gun (Fig. 1) is replaced by a Pierce gun, which produces a cylindrical electron beam. In addition to an electron beam, a powerful ion or electromagnetic (laser) beam can be used to evaporate a solid working medium and to cause primary ionization of the vapor or gas. The use of crossed electric and magnetic fields in this case also would presumably permit an increase of the ionization of the working medium, and the electron-beam excited electric discharge, which results would have characteristics similar to those of the discharge which we have studied.

The ignition curves of the discharge which we have studied are similar to those of a magnetron discharge,[6] so that we can call the electron-beam-maintained crossed-field discharge a "beam–magnetron discharge." The discharge which we have studied has certain features in common with a hot-cathode reflex discharge,[7] in which cutoff of the discharge by a strong magnetic field has also been observed (but not explained). Furthermore, in both types of discharges the currents I_c, I_k, and I_i are nonmonotonic functions of B. However, there are important differences between these discharges, which furnish a basis for identifying the electric discharge which we studied as a new type of electron-beam excited discharge. The most important difference is that in a beam–magnetron discharge the cathode is replaced by an electron gun outside the ionization chamber. This difference makes it possible 1) to protect the gun cathode from ion bombardment, 2) to limit the flux of neutral atoms to the cathode, 3) to independently regulate the energy and current of the electron beam over broad ranges, and 4) to use an electron beam to sup-

ply a solid-phase working medium to the ionization chamber.

The structural features of an apparatus which uses a beam—magnetron discharge are governed by the electron gun, the means for supplying working medium, and the direction in which the plasma or ions are collected. When the plasma or ions are collected parallel to the magnetic field, it is preferable to use an annular gun. The entire electron beam (an evaporating collector) or part of the beam can be used to evaporate a solid-phase working medium. In the latter case a rod of the working medium is placed beside the electron beam, and the rate at which the working medium is supplied to the ionization chamber is adjusted by adjusting the immersion of the rod into the beam region.

In conclusion the authors thank V. N. Vasil'kovskii for assistance and A. F. Linev for discussion.

(Submitted June 25, 1973)
Zh. Tekh. Fiz., 44, 1210-1217 (June 1974)

An effective system for extracting synchrotron radiation from a cyclic electron accelerator with a strong magnetic field is described. This system uses a reflector in the accelerating chamber. The gains for a single reflecting surface of revolution and that for a system of two such surfaces are determined. The quality of the image of the electron orbit obtained through the use of a single reflecting surface of revolution is evaluated. Extraction of synchrotron radiation by means of a reflector outside the accelerator chamber and the use of composite reflectors are also examined.

INTRODUCTION

The properties of synchrotron radiation and its applications in vacuum-UV spectroscopy, solid state physics, metrology, and other fields of physical research have been discussed by many authors.[1-3]

In many applications of synchrotron radiation it is important that the intensity be high in the vacuum-UV region. In these cases it is important to extract as much of the radiation as possible from the accelerator chamber. Since the synchrotron radiation is focused near the plane of the electron orbit and since it is directed along a tangent to this orbit, the only way to extract the radiation in many accelerators with iron magnets is to use a vacuum light guide along the tangent to the orbit. In this case radiation from a small part of the orbit is used, so that the radiation-collection coefficient at the entrance to the collector, $\eta = I_c/I_0$, is small (here, I_c is the intensity of the radiation incident on the collector and I_0 is the total intensity of the synchrotron radiation). In the DESY accelerator,[4] this coefficient is 10^{-4}.

A comparatively simple and accessible source of synchrotron radiation can be realized with a cyclic electron accelerator with a strong magnetic field. An effective model for such an accelerator and the corresponding theory are given in refs. 4 and 5; certain aspects of the methods for developing and using such accelerators are discussed in ref. 6. In a cyclic electron accelerator with a strong magnetic field it is possible to construct light guides which can extract synchrotron radiation from all parts of the orbit.

EXTRACTION OF THE SYNCHROTRON RADIATION BY MEANS OF A REFLECTOR IN THE ACCELERATING CHAMBER

Let us consider the construction of the accelerator of refs. 4 and 6 and the light guide for synchrotron radiation (Fig. 1). A massive copper turn 1, which is both the electromagnet and the vacuum chamber of the accelerator, has an inner profile such that a magnetic field similar in shape to the field of an adiabatic trap is produced in the cavity within the turn. The decay index of the magnetic field over a relativistic orbit is 0.2. The electromagnet is fed with pulses from a capacitor bank. The cavity is simultaneously used as a volume resonator to produce a high-frequency accelerating E field in the H_{III} mode. The accelerating field is excited by rf oscillator 6, coupled to the cavity by turn 7. The electron source is a gun 5, which injects a low-voltage (100 eV) electron beam along the axis of the turn. This beam ionizes the residual gas near the axis of the turn. The radiation is extracted by means of reflector 2, in the accelerating chamber. The reflector is a surface of revolution, whose revolution axis coincides with the accelerator axis. Radiation passes through the vacuum light guide 3 to the entrance of collector 4. The use of thin reflecting films of platinum, gold, or tungsten on a glass substrate makes it possible to efficiently extract radiation in the vacuum-UV region up to a wavelength of 400 Å (ref. 7) without interfering with the normal operation of the accelerator.

We now use geometric-optics methods to examine the shape and quality of the image of the electron orbit formed by this reflector. Experiment[1] has shown that the synchrotron radiation from a local part of the orbit has a spherical wave front. Accordingly, a synchrotron reflector can be treated as a radiating circle, from each point of which a fine homocentric beam of rays is emitted along the tangent to the circle at the given point. The angle through which the extreme rays diverge from the central ray (along the tangent), β, for wavelengths near the maximum of the spectral distribution is of order γ^{-1}, where $\gamma = (1 -$

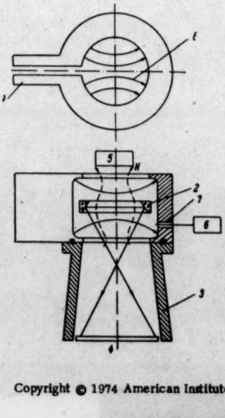

Fig. 1. Diagram of the accelerating chamber and the light guide. 1) Accelerating chamber; 2) reflector; 3) vacuum light guide; 4) radiation collector; 5) electron gun; 6) rf oscillator; 7) rf input.

$v^2/c^2)^{-1/2}$, v is the electron velocity, and c is the speed of light in vacuum. For this accelerator geometry and for a maximum electron energy of 50 MeV we have $\gamma \cong 100$ and thus $\beta \ll 1$. Since the synchrotron radiator is in a symmetric position with respect to the axis of the optical system, it is sufficient to consider the path of a beam of rays from any point of the emitting circle. The image of the other points can be easily found through a rotation around the axis of the system. These rays make an angle of approximately 90° with the optic axis and are not meridian rays; this circumstance rules out the use of the paraxial approximation, so that it is more convenient to use a direct method of constructing the beam paths.

Since this optical system is axially symmetric, the image of the circular electron orbit lies in a plane perpendicular to the optic axis. It is convenient to choose the origin of coordinates at the symmetry axis and to adopt this axis as the oz axis, which we characterize by the unit vector **k**. We locate the origin at the center of the orbit and assume the plane of the orbit to coincide with the xy plane (Fig. 2). We specify the position of the given point of the radiator by the vector A. For simplicity we consider a point radiator on the ox axis; in this case the vector A has the components $\{r, 0, 0\}$, where r is the radius of the electron orbit. We specify the beam of rays emerging from point A by the unit vector **s** with direction cosines $\{p, m, n\}$ $\mathbf{s}^2 = p^2 + m^2 + n^2 = 1$. The central ray of this beam is characterized by a unit vector $S_0\{0, 1, 0\}$, which is parallel to the tangent to the circle of the radiator at point A. In the general case the equation of a surface of revolution whose revolution axis coincides with the oz axis can be written

$$F(u^*, z) = 0;\ 2u^* = x^2 + y^2. \tag{1}$$

We write the vector equations for the ray paths as two systems of equations: 1) a system of two-dimensional equations relating the components of the vectors perpendicular to the oz axis, and 2) a system of equations for the projections of the vectors on the axis. Vectors perpendicular to the oz axis (i.e., vectors which have vanishing components along the oz axis), are denoted by capital letters. We use the vectors A with components $\{x, y, 0\}$ and S with components $\{p, m, 0\}$ so that

$$\mathbf{a} = \mathbf{A} + z\mathbf{k};\quad \mathbf{s} = S + n\mathbf{k}. \tag{2}$$

The path of a fine beam of rays can be determined by considering the path of the central ray, while the image quality can be analyzed by considering the divergence of the extreme rays from the central ray in the image plane. We consider the path of the central ray as shown in Fig. 2.

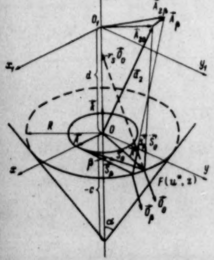

Fig. 2. Ray path for reflection from a conical surface.

With A_0^* as a vector from the origin to the point of incidence and $\mathbf{s}'_0$ as the unit vector along the reflected ray, the equations for calculating the ray path are, according to ref. 8,

$$\mathbf{A}_0^* = \mathbf{A} + l\mathbf{S}_0, \tag{3}$$

$\mathbf{s}'_0 = \mathbf{S}'_0 + \Gamma\mathbf{o}_0$ (the reflection law), and $\Gamma = -2(\mathbf{S}_0\mathbf{o}_0)$ (here $\mathbf{o}_0$ is the unit vector normal to the surface at the point of incidence).

To calculate l we square the first equation in (3):

$$\mathbf{A}_0^{*2} = 2u^* = \mathbf{A}^2 + 2\mathbf{A}\mathbf{S}_0 + l\mathbf{S}_0^2. \tag{4}$$

We consider this equation together with the equation of the reflecting surface, (1). Second-order surfaces of revolution are usually used in optics. We note that the path of the principal and other rays in the plane of the radiator (z = 0) are not affected by the general shape of the reflected surface, only by its curvature in the z = 0 plane, i.e., by the inclination with respect to the axis of the normal to the reflecting surface at any point at which it intersects the z = 0 plane. Accordingly, without any loss of generality we can consider the path of these rays upon reflection from a conical surface tangent to a second-order surface of revolution of a more general type.

The equation of a conical surface of revolution in this coordinate system (Fig. 2) is

$$F(u^*, z) = \frac{2u^*}{R_0^2} - \frac{(z+c)^2}{c^2} = 0;\quad c = R_0\,\mathrm{tg}\,\alpha; \tag{5}$$

where α is the angle between the direction cosine and the axis, and R_0 is the radius of the circle formed by the intersection of the cone with the z = 0 plane. From Eqs. (4) and (5) we find the coordinates of the vector A_0^* to be $\{r, \sqrt{R_0^2 - r^2}, 0\}$. In an axially symmetric system the vector normal to the surface intersects the oz axis so that

$$-r_s\mathbf{o}_0 = -\mathbf{A}_0^* + t\mathbf{k}, \tag{6}$$

where r_s is the sagittal radius of curvature or the distance along the normal from the point of incidence to the point at which the axis is intersected. The components of the normal at the point of incidence are proportional to the derivatives F_u^* and F_z, so that the vector $\mathbf{o}_0$ is parallel to the vector

$$F_{u^*}\mathbf{A}_0^* + F_z\mathbf{k}. \tag{7}$$

From Eqs. (6) and (7) we find the direction cosines of the vector; using Eqs. (1), we find the unit vector of the reflected ray, $\mathbf{s}'_0\{p'_0, m'_0, n'_0\}$:

$$\mathbf{s}'_0 = -\mathbf{i}\frac{2r\sqrt{R_0^2 - r^2}}{R_0^2(1 + \mathrm{tg}^2\alpha)} + \mathbf{j} \times \frac{R_0^2(\mathrm{tg}^2\alpha - 1) + 2r^2}{R_0^2(1 + \mathrm{tg}^2\alpha)} + \mathbf{k}\frac{2\,\mathrm{tg}\,\alpha\sqrt{R_0^2 - r^2}}{R_0(1 + \mathrm{tg}^2\alpha)}. \tag{8}$$

The reflected ray is governed completely by the unit vector $\mathbf{s}'_0$ and by the point of intersection with the z = 0 plane, i.e., by the vector A_0^*. To find the point at which the reflected ray intersects the z = d image plane we must find a vector $\mathbf{a}_2\{x_2, y_2, z\}$ such that

$$\mathbf{a}_2 = \mathbf{A}_0^* + l\mathbf{s}'_0.$$

We write the vector $\mathbf{a}_2$ as $\mathbf{a}_2 = \mathbf{A}_{20} + d\mathbf{k}$, where $\mathbf{A}_{20}$ lies in the z = d plane and runs from the axis of the system to the point at which the reflected ray intersects the z = d plane. Then we find

$$\mathbf{A}_{20} = \mathbf{A}_0^* + \frac{d}{n_0'}\mathbf{s}_0' - d\mathbf{k} = \mathbf{A}_0^* + \frac{d}{n_0'}\mathbf{S}_0', \tag{9}$$

where $\mathbf{s}'_0 = \mathbf{S}'_0 + n'_0\mathbf{k}$.

The length of vector $\mathbf{A}_{20}$ is equal to the radius of the circular image of the radiator, so that K, the magnification of the optical system in the z = d plane, is $K = |\mathbf{A}_{20}|/|\mathbf{A}|$. Squaring (9) and dividing by A^2, we find the square of the magnification in this plane to be

$$K^2 = 1 + \frac{1}{r^2}\Big[d^2 \frac{R_0^2(\mathrm{tg}^2\alpha - 1)^2 + 4r^2\,\mathrm{tg}^2\alpha}{4\,\mathrm{tg}^2\alpha\,(R_0^2 - r^2)} + d\frac{R_0(\mathrm{tg}^2\alpha - 1)}{\mathrm{tg}\,\alpha} + (R_0^2 - r^2)\Big]. \tag{10a}$$

The square of the radius of the image of the electron orbit is

$$R^2 = d^2 \frac{R_0^2(\mathrm{tg}^2\alpha - 1)^2 + 4r^2\,\mathrm{tg}^2\alpha}{4\,\mathrm{tg}^2\alpha\,(R_0^2 - r^2)} + d\frac{R_0(\mathrm{tg}^2\alpha - 1)}{\mathrm{tg}\,\alpha} + R_0^2. \tag{10b}$$

Analysis of the quantity in brackets in Eq. (10a) shows that it is always positive for any d, so that any reflecting surface of revolution provides a magnified image of the synchrotron radiation. From Eq. (10a) we find the value of d at which this magnification is minimized:

$$d_{\min} = \frac{2R_0(R_0^2 - r^2)(1 - \mathrm{tg}^2\alpha)\,\mathrm{tg}\,\alpha}{R_0^2(\mathrm{tg}^2\alpha - 1)^2 + 4r^2\,\mathrm{tg}^2\alpha}. \tag{11}$$

Substituting $d_{\min}$ into (10a) we find the minimum magnification for a single reflecting surface of revolution:

$$K^2_{\min} = 1 + \frac{4\,\mathrm{tg}^2\alpha\,(R_0^2 - r^2)}{R_0^2(\mathrm{tg}^2\alpha - 1)^2 + 4r^2\,\mathrm{tg}^2\alpha}, \tag{12a}$$

and we find the minimum square of the radius of the image of the electron orbit to be

$$R_{\min} = \frac{R_0 r(\mathrm{tg}^2\alpha + 1)}{\sqrt{R_0^2(\mathrm{tg}^2\alpha - 1)^2 + 4(\mathrm{tg}^2\alpha)\,r^2}}. \tag{12b}$$

As noted above, the quality of the image of an orbital point in the case of reflection from a single surface of revolution is independent of the nature of the surface for rays in the orbital plane. Accordingly, analysis of such rays is of general interest. Here it is sufficient to examine a ray in the plane of the synchrotron radiation (z = 0) and to examine its divergence from the central ray in the image plane.

We consider the extreme ray of the beam, which is emitted from point A and lies in the orbital plane. Its direction is governed by the unit vector $\mathbf{S}_\beta$, which makes an angle β with the central ray. The direction cosines of this ray, $\{p_\beta, m_\beta, 0\}$, can be expressed in terms of the angle β:

$$\left.\begin{aligned} p_\beta &= \cos\left(\frac{\pi}{2} - \beta\right) = \sin\beta, \\ m_\beta &= \cos\beta. \end{aligned}\right\} \tag{13}$$

Since $\beta \ll 1$, we expand the sine and cosine in powers of β, retaining only terms of first order in β. We can now write the direction cosines of $\mathbf{S}_\beta$ in the form $\{\beta, 1, 0\}$. Let us consider the reflection of this ray from the conical surface described by Eq. (5). Carrying out calculations analogous to those for the central ray, and retaining only terms of first order in β, we find the coordinates of the point at which the reflected ray (governed by the vector $\mathbf{A}_{2\beta}$; Fig. 2) intersects the image plane, at a distance d from the z = 0 plane. The divergence of this ray from the central ray in this plane is obviously given by $|\mathbf{A}_\beta| = |\mathbf{A}_{2\beta} - \mathbf{A}_{20}|$.

Calculations yield the following values for the projections of $\mathbf{A}_\beta$ onto the o_1x_1 and o_1y_1 axes:

$$\left.\begin{aligned} A_{\beta x} &= \beta\sqrt{R_0^2 - r^2}\Big[1 + d\frac{R_0^2(\mathrm{tg}^2\alpha - 1) + 2r^2}{2(\mathrm{tg}\,\alpha)R_0(R_0^2 - r^2)}\Big], \\ A_{\beta y} &= -r\beta\Big[1 - \frac{d}{R_0\,\mathrm{tg}\,\alpha}\Big]. \end{aligned}\right\} \tag{14}$$

We see from (14) that for no value of d does the quantity $|\mathbf{A}_\beta|$ vanish (its vanishing is the condition for a sharp image of point A). These equations for $|\mathbf{A}_\beta|$ show that $|\mathbf{A}_\beta|$ is a minimum at the value of d given by (11. Here, $|\mathbf{A}_\beta|$ is given to second order in β by

$$|\mathbf{A}_\beta| = \frac{\beta r R_0(1 + \mathrm{tg}^2\alpha)}{\sqrt{R_0^2(1 - \mathrm{tg}^2\alpha)^2 + 4r^2\,\mathrm{tg}^2\alpha}}. \tag{15}$$

We thus conclude that no reflecting surface of revolution can produce a sharp image of the synchrotron radiation. However, in many practical cases (because of the smallness of the angle β), the necessary image quality in the vacuum-UV region can be achieved by means of a conical surface.

Let us consider the possibility of obtaining a reduced image of the synchrotron radiation by introducing a second reflecting surface. Here we do not discuss the use of refraction optics since synchrotron radiation is of interest at wavelengths below 1000 Å, for which there are no transparent optical materials. Obviously, this second reflecting surface of revolution must have a radius of curvature at the point of incidence, which is directed opposite that of the first surface. We consider the reflection of the central ray from a conical surface of revolution with an angle of α_1 between the axis of the system and a line of the cone (Fig. 3). The equation of a conical surface of revolution in the coordinate system x_1y_1z, where the coordinate plane x_1y_1 contains the vector $\mathbf{A}_{20}$ corresponding to the minimal magnification given by the first reflecting surface, i.e.,

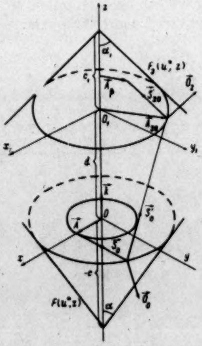

Fig. 3. Path of the central ray through a system of two conical reflecting surfaces.

the square of the length of the vector A_{20}, is governed by Eq. (12b):

$$F_2(u^*,\ z)=\frac{2u^*}{A_{20}^2}-\frac{(z-c_1)^2}{c_1^2}=0, \tag{16}$$

where $\tan\alpha_1 = |A_{20}|/c_1$.

The ray incident on the second surface is specified by the vector A_{20} and the unit vector s'_0. The unit vectors $s'_{20}\{p'_{20},\ m'_{20},\ n'_{20}\}$ and $S'_{20}\{p'_{20},\ m'_{20},\ 0\}$ of the reflected ray are found by analogy with the procedure above. The intersection of the reflected ray with an image plane perpendicular to the axis and at a distance d_2 from the x_1y_1 coordinate plane is given by the vector

$$\mathbf{A}_3=\mathbf{A}_{20}+\frac{d_2}{n'_{20}}S'_{20}. \tag{17}$$

The ratio $K_2 = |A_3|/|A|$ is the magnification of a system consisting of two reflecting conical surfaces of revolution. From Eqs. (12b) and (17) we find the square of the magnification of a system of two reflecting surfaces to be

$$\begin{gathered}K_2^2=1+(ad_2^2+bd_2+c),\\ a=\frac{1}{r^2}\left\{1+\frac{[R_0^2(\mathrm{tg}^2\alpha-1)^2+4r^2\,\mathrm{tg}^2\alpha](1+\mathrm{tg}^2\alpha)^2}{16\,\mathrm{tg}^2\alpha\,\mathrm{tg}^2\alpha_1(R_0^2-r^2)}\right\},\\ b=\frac{2R_0(\mathrm{tg}^2\alpha+1)}{r\sqrt{R_0^2(\mathrm{tg}^2\alpha-1)^2+4r^2\,\mathrm{tg}^2\alpha}},\\ c=\frac{4\,\mathrm{tg}^2\alpha(R_0^2-r^2)}{R_0^2(\mathrm{tg}^2\alpha-1)^2+4r^2\,\mathrm{tg}^2\alpha}.\end{gathered} \tag{18}$$

Analysis of Eq. (18) shows that a reduced image of the synchrotron radiator cannot be obtained for any value of d_2. The maximum magnification can be found by substituting the value $d_2 = -b/2a$ into Eq. (18); the largest magnification is unity at $\tan\alpha_1 = 1$.

USE OF AN EXTERNAL REFLECTOR

In most practical cases it is desirable to have a small image of the synchrotron radiator ($R_{\min} \sim r$) at a large distance from the plane of the electron orbit ($d_{\min} \gg r$). Analysis of Eq. (11) shows that this is the case when

$$R_0 \gg r, \tag{19a}$$

$$\tan < 1. \tag{19b}$$

Since the radius of the accelerator chamber is governed by the frequency of the H_{III} field and is equal to 2r (ref. 6), condition (19a) can be satisfied if the chamber and light guide are constructed as shown in Fig. 4. Here, reflector 4 has dimensions larger than those of the accelerator chamber, so that maximization of the radiation extraction requires that the accelerator chamber be constructed in two parts, separated from the plane of the electron orbit by a distance permitting complete extraction of the radiation from the accelerator to reflector 4 and then to collector 6.

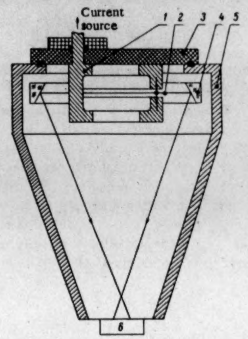

Fig. 4. Radiation-extraction method using a reflector outside the electromagnet–resonator. 1) Electromagnet–resonator; 2) gap in the resonator for extracting the radiation; 3) dielectric flange; 4) reflector; 5) vacuum light guide; 6) radiation collector.

EXTRACTION OF RADIATION BY MEANS OF A COMPOSITE REFLECTOR

A significant reduction of the dimensions of the synchrotron-radiation beam incident on the collector can be achieved by replacing the reflector in Fig. 1 by a composite reflector, e.g., one consisting of n identical plane mirrors, each of which is a distance R_0 from the center of the electron orbit and oriented as shown in Fig. 5a. The central ray of the beam, emerging from point A, strikes the center of mirror m at point M_1; after reflection, it reaches point M_2, which lies on the oz axis, a distance d from the orbital plane. It can be shown that the angle between the xy orbital plane and each element of the reflector is given by

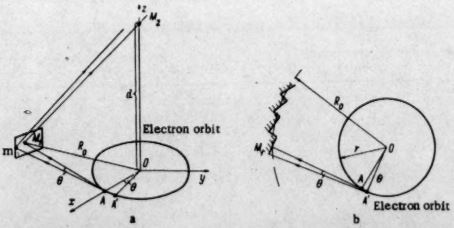

Fig. 5. Composite reflector. a) Reflection of the central ray from an element of the reflector; b) intersection of the surface of the composite reflector with the orbital plane.

$$\cos \varphi = \frac{d}{\sqrt{2}\sqrt{R_0^2 + d^2 + \sqrt{(R_0^2 + d^2)(R_0^2 - r^2)}}}. \quad (20)$$

The angular size of the beam reflected from each element of the reflector is, within terms on the order of β, equal to $2\theta = 2\pi/n$ and equal to the angular size of the electron orbit from which the radiation is incident on the given element. When the number of such elements making up the reflector, n, is sufficiently large, the size of the radiation spot incident on the collector a distance d from the orbital plane is $\simeq 2\pi d/n$. Figure 5b shows the intersection of the composite reflector with the xy plane of the electron orbit. These arguments obviously can be extended to the case of an external composite reflector.

Resonator with azimuthally varying end plates

M. F. Vorogushin and V. I. Petrunin

D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad

(Submitted November 9, 1972; resubmitted October 18, 1973)
Zh. Tekh. Fiz., 4, 1218-1221 (June 1974)

In the design of cyclotrons with an azimuthally varying electric field there is a need for analytic expressions for the field components in a resonator with azimuthally varying end plates. This problem cannot be solved exactly by the usual methods as the variables do not separate in any orthogonal coordinate system. In the present paper convenient expressions for the field components are found by constructing a solution in the form of the product of a certain scalar function of the radius and the vector static field of an azimuthally varying gap. It is shown that this representation is valid if the number of variations aound the azimuth is sufficiently large and the amount of variation is bounded.

The present problem is of interest in connection with the design of cyclotrons with an azimuthally varying electric field.[1] The accelerating system of such cyclotrons can have the form of a cylindrical or coaxial resonator of small height with large inphase variations of the end plates around the azimuth. The electrodynamic problem in this sort of structure cannot be solved exactly by any of the usual methods, e.g., by the method proposed by Kompaneets and Sayasov,[2] as the variables do not separate in any of the orthogonal coordinate systems.

Approximate expressions for the high-frequency fields in a resonator with azimuthally varying end plates are derived in the present paper. Also, it is shown that the field components can be represented as a combination of the static field of an azimuthally varying gap[3] and the high-frequency field of a smooth resonator, for which exact solutions are known.

Indeed, assuming a large number of variations around the azimuth, the solution of the wave equation for the electric field intensity is likely to be of the form

$$E = f(r)\,E_{st}, \tag{1}$$

where $f(r)$ is a scalar function normalized to unity which describes the radial variation of the high-frequency field, and $\bar{E}_{st}$ is the static field of an azimuthally varying gap.

Let us find conditions under which this sort of representation is possible. The wave equation for field (1) is

$$\nabla^2 (fE_{st}) + k_0^2 fE_{st} = 0. \tag{2}$$

Here k_0 is the wave number and ∇^2 is the Laplacian of a vector function

$$\nabla^2 (fE_{st}) = \nabla(\nabla(fE_{st})) - [\nabla[\nabla(fE_{st})]]. \tag{3}$$

Remembering that $(\nabla\bar{E}_{st}) = 0$ and $[\nabla\bar{E}_{st}] = 0$, we have

$$\left.\begin{aligned} \nabla(\nabla(fE_{st})) &= \nabla(f\nabla E_{st} + E_{st}\nabla f) = \nabla(E_{st}\nabla f) = \\ &= (E_{st}\nabla)\nabla f + (\nabla f\nabla)E_{st}, \\ [\nabla[\nabla(fE_{st})]] &= [\nabla(f[\nabla E_{st}] + [\nabla f E_{st}])] = \\ &= [\nabla[\nabla f E_{st}]] = (E_{st}\nabla)\nabla f - (\nabla f\nabla)E_{st} - E_{st}\nabla^2 f. \end{aligned}\right\} \tag{4}$$

Inserting these expressions into Eq. (2) gives

$$2(\nabla f\nabla)E_{st} + E_{st}(\nabla^2 f + k_0^2 f) = 0. \tag{5}$$

If the gradient of the vector $\bar{E}_{st}$ in the direction of the vector ∇f is zero

$$(\nabla f\nabla)E_{st} = 0, \tag{6}$$

then the function f satisfies the one-dimensional wave equation

$$\nabla^2 f + k_0^2 f = 0,$$

whose solution in cylindrical coordinates is expressed through the Bessel functions

$$f = AJ_0(k_0 r) + BN_0(k_0 r). \tag{7}$$

Condition (6) is satisfied, in particular, in a gap with no azimuthal variation of the boundaries; expression (7) along with the boundary conditions, determines the radial distribution of the high-frequency electric field in a cylindrical or coaxial resonator.

In the case of an azimuthally varying gap, condition (6) is satisfied exactly after averaging the fields over the azimuth φ, i.e., it holds in the mean.

Indeed, by definition

$$(\nabla f\nabla)E_{st} = \frac{\partial f}{\partial r}\frac{\partial E_{st}}{\partial r}. \tag{8}$$

Projecting this equality upon the unit vector of a cylindrical system of coordinates and remembering that the azimuth-averaged components of the static field[3] are independent of radius

$$\langle E_r\rangle = 0;\quad \langle E_\varphi\rangle = 0;\quad \langle E_z\rangle = \frac{U_0}{d},$$

we see that condition (6) is satisfied in the mean.

In the general case we represent the vector $\bar{E}_{st}$ in terms of its modulus and unit vector

$$E_{st} = |E_{st}|\,e.$$

Then

$$\frac{\partial E_{st}}{\partial r} = e\frac{\partial|E_{st}|}{\partial r} + B|E_{st}|\frac{\partial\alpha}{\partial r}, \tag{9}$$

where

$$B \perp e,\quad \alpha = \arccos\frac{E_r}{|E_{st}|}.$$

We use (8) and (9) to write Eq. (5) in the form

$$\varepsilon f'' + \frac{f'}{r}\left[\varepsilon + 2\varepsilon\frac{r\partial|\bar{E}_{st}|}{|\bar{E}_{st}|\partial r} + 2Br\frac{\partial\alpha}{\partial r}\right] + \varepsilon k_0^2 f = 0. \tag{10}$$

Let us estimate the terms in the square brackets of expression (10). We find that

$$2r\frac{1}{|\bar{E}_{st}|}\frac{\partial|\bar{E}_{st}|}{\partial r} = 2r\frac{E_r\frac{\partial E_r}{\partial r} + E_\varphi\frac{\partial E_\varphi}{\partial r} + E_z\frac{\partial E_z}{\partial r}}{E_r^2 + E_\varphi^2 + E_z^2}, \tag{11}$$

$$2r\frac{\partial\alpha}{\partial r} = 2r\frac{E_r\left(E_\varphi\frac{\partial E_\varphi}{\partial r} + E_z\frac{\partial E_z}{\partial r}\right) - \frac{\partial E_r}{\partial r}(E_\varphi^2 + E_z^2)}{(E_r^2 + E_\varphi^2 + E_z^2)\sqrt{E_\varphi^2 + E_z^2}}. \tag{12}$$

In a previous paper[3] an exact solution is found to the problem of the static field in a capacitor with azimuthally varying plates and it is shown that over a wide range of variation of the parameters the potential is given by the expression

$$U = U_0\frac{z}{d} + \cos\nu\varphi\frac{U_0\left(1 - \frac{2z_0}{d}\right)}{2\,\mathrm{ch}\frac{\nu z_0}{r}}\mathrm{ch}\frac{\nu z}{r}.$$

Calculating the corresponding derivatives in the midplane (z = 0) and inserting the results into (11) and (12), we obtain

$$\frac{2r}{|\bar{E}_{st}|}\frac{\partial|\bar{E}_{st}|}{\partial r} = -2\frac{\frac{\beta^3}{\nu^2}\mathrm{th}\,\beta\,(2M-1)\cos^2\nu\varphi + (1 - \beta\,\mathrm{th}\,\beta)\sin^2\nu\varphi}{\sin^2\nu\varphi + \Lambda^2 + \frac{\beta^2}{\nu^2}\mathrm{th}^2\beta\cos^2\nu\varphi}, \tag{13}$$

$$2r\frac{\partial\alpha}{\partial r} = -\frac{2\beta^2\cos\nu\varphi}{\nu}\frac{M(\sin^2\nu\varphi + 2\Lambda^2) - \Lambda^2}{\left[\sin^2\nu\varphi + \Lambda^2 + \frac{\beta^2}{\nu^2}\mathrm{th}^2\beta\cos^2\nu\varphi\right]\sqrt{\sin^2\nu\varphi + \Lambda^2}}, \tag{14}$$

where

$$\Lambda = \frac{\mathrm{ch}\beta}{\beta\left(\frac{d}{2z_0} - 1\right)}, \quad M = \frac{1 + \frac{\mathrm{sh}\,2\beta}{2\beta}}{\mathrm{ch}^2\beta}, \quad \beta = \frac{\nu z_0}{r}.$$

It can be seen from these expressions that these terms tend to zero in the limit of large and small radii ($\beta \to 0$, $\beta \to \infty$).

Thus, to estimate the error associated with representing the field in the form (1), we must determine the extremum values of (13) and (14).

It is not hard to show that expression (14), regarded as a function of two variables, has an extremum equal to

$$2r\frac{\partial\alpha}{\partial r}\bigg|_{\substack{\nu\varphi = k\pi \\ \beta = 1.2}} \cong -\frac{2\left(\frac{d}{2z_0} - 1\right)}{\nu}. \tag{15}$$

Similarly, (13) has the extremum

$$\frac{2r}{|\bar{E}_{st}|}\frac{\partial|E_{st}|}{\partial r}\bigg|_{\substack{\nu\varphi = \frac{(2k+1)\pi}{2} \\ \beta = 0.4}} \cong -\frac{1.7}{1 + \left(\frac{2.7}{\frac{d}{2z_0} - 1}\right)^2}. \tag{16}$$

It can be seen from these estimates that condition (6) is obeyed approximately for large ν($\nu > 10$) and $d/2z_0 < 2$, i.e., when the depth of variation is twice the aperture.

We note that this constraint is a consequence of the feature of the initial system of electrodes assuring a single harmonic field, as it is connected with the requirement that there be no satellites[1]. Accordingly, in a real resonator this constraint probably does not have any fundamental significance.

The high-frequency electric field in an azimuthally varying resonator is thus described by expression (1).

The components of the high-frequency magnetic fields in the resonator are found from the Maxwell equation

$$\nabla\bar{E} = -\frac{\partial\bar{B}}{\partial t},$$

where $\bar{E}$ has the form (1).

Remembering that

$$\nabla(f\bar{E}_{st}) = f\nabla\bar{E}_{st} + [\nabla f\bar{E}_{st}],$$
$$\nabla\bar{E}_{st} = 0,$$

we rewrite the vector product in the cylindrical coordinate system

$$\frac{\partial B_r}{\partial t} = 0,$$

$$\frac{\partial B_\varphi}{\partial t} = \frac{\partial f}{\partial r}(E_{st})_z,$$

$$\frac{\partial B_z}{\partial t} = -\frac{\partial f}{\partial r}(E_{st})_\varphi.$$

Assuming a sinusoidal variation of the field with time, we find the components of the high-frequency magnetic fields:

$$B_r = 0,$$
$$B_\varphi = -\frac{1}{\omega}\frac{\partial f}{\partial r}(E_{st})_z\cos(\omega t + \psi), \tag{17}$$

$$B_z = \frac{1}{\omega}\frac{\partial f}{\partial r}(E_{st})_\varphi\cos(\omega t + \psi). \tag{18}$$

In conclusion, we cite the expressions for all the components of the high-frequency fields in an azimuthally varying resonator in the vicinity of the midplane ($z < z_0$) allowing for the time factor:

$$E_r = -\frac{U_0\nu\left(1 - \frac{2z_0}{d}\right)}{2}\frac{f(r)}{r^2\,\mathrm{ch}^2\frac{\nu z_0}{r}}\left[z_0\,\mathrm{ch}\frac{\nu z}{r}\,\mathrm{sh}\frac{\nu z_0}{r} - z\,\mathrm{sh}\frac{\nu z}{r}\,\mathrm{ch}\frac{\nu z_0}{r}\right]$$
$$\times\cos\nu\varphi\sin(\omega t + \psi),$$

$$E_\varphi = \frac{U_0\nu\left(1 - \frac{2z_0}{d}\right)}{2}\frac{f(r)}{r\,\mathrm{ch}\frac{\nu z_0}{r}}\mathrm{ch}\frac{\nu z}{r}\sin\nu\varphi\sin(\omega t - \psi),$$

$$E_z = -f(r)\left[\frac{U_0\nu\left(1 - \frac{2z_0}{d}\right)}{2}\frac{\mathrm{sh}\frac{\nu z}{r}}{r\,\mathrm{ch}\frac{\nu z_0}{r}}\cos\nu\varphi + \frac{U_0}{d}\right]\sin(\omega t + \psi),$$

$$B_r = 0,$$

$$B_\varphi = \frac{1}{\omega}\frac{\partial f(r)}{\partial r}\left[\frac{U_0\nu\left(1 - \frac{2z_0}{d}\right)}{2}\frac{\mathrm{sh}\frac{\nu z}{r}}{r\,\mathrm{ch}\frac{\nu z_0}{r}}\cos\nu\varphi + \frac{U_0}{d}\right]\cos(\omega t + \psi),$$

$$B_z = \frac{1}{\omega}\frac{\partial f(r)}{\partial r}\frac{U_0\nu\left(1 - \frac{2z_0}{d}\right)}{2}\frac{\mathrm{ch}\frac{\nu z}{r}}{r\,\mathrm{ch}\frac{\nu z_0}{r}}\sin\nu\varphi\cos(\omega t + \psi, \tag{19}$$

where f(r) satisfies the Bessel equation. In particular, if $\nu = 0$ (no azimuthal variations), these expressions give the components B_φ and E_z defining the fields in a smooth resonator.

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 1222-1227 (June 1974)

Power-series and Fourier-series expansions of the potential in an azimuthally varying accelerating structure which satisfies general symmetry conditions are used to derive simple relationships for the index of electrical focusing and the per-orbit energy increment. The advantage of using rectangular variations of the gap boundaries to optimize these parameters is indicated.

The motion of particles in high-frequency fields varying in the azimuthal direction has been studied in previous papers[1-3] on the basis of a model with a single azimuthal harmonic in the midplane (a monoharmonic field[1]). However, the required variation in gap boundary to give rise to such a field is quite complex as far as practical realization is concerned. This is especially true near the center of the structure, where an electrode discontinuity is necessary in order to meet the requirement that the field be monoharmonic.[2] On the other hand, a monoharmonic field is not the optimum field for particle acceleration and focusing.

Accordingly, it is of interest to investigate the particle dynamics in the more general case of an arbitrary variation of gap boundaries in the azimuth direction.

In a cylindrical coordinate system the electric potential U(r, φ, z) near the midplane is described[1] by the two-dimensional Laplace equation with a parameteric dependence on radius

$$U(r,\ \varphi,\ z)=f(r)\,U(\varphi,\ z);\quad \frac{\partial^2 U}{r^2\partial\varphi^2}+\frac{\partial^2 U}{\partial z^2}=0. \tag{1}$$

We substitute the power expansion[4] for U(φ, z)

$$U(\varphi,\ z)=\sum_{k=0}^{\infty} z^k U_k(\varphi) \tag{2}$$

into Eq. (1) and express the unknown functions U_k in terms of the potential U(φ, 0) = $U_0(\varphi)$ and the field in the midplane as $\partial U(\varphi, z)/\partial z|_{z=0} = U_1(\varphi)$. This gives

$$U(\varphi,\ z)=U_0(\varphi)+zU_1(\varphi)-\frac{z^2}{2r^2}U_0''(\varphi)-\frac{z^3}{6r^2}U_1''(\varphi)+\ldots. \tag{3}$$

The phase motion of the particles and possible stabilization are discussed in a previous paper.[3] The motion of the particles will thus be regarded here as isochronic, which in the earlier notation is equivalent to the condition

$$\psi_0=\psi-\nu(\varphi-\theta)=\text{const}. \tag{4}$$

Differentiating with respect to θ the equation for the instantaneous energy of the particle $U_m = m_0\omega_0^2 r^2/2e$ and utilizing expression (14) from ref. 3, we find the energy increment per orbit of a charge moving at a distance $z < z_0$ from the midplane:

$$U_{\mathrm{orb}}=-\int_0^{2\pi}\frac{\partial U(\varphi,\ z)}{\partial\varphi}\sin(\nu\theta+\psi)\,d\varphi.$$

Since the azimuthally varying boundaries must conform to a symmetry like

$$U(\varphi,\ z)=U(-\varphi,\ z);\quad U(\varphi,\ z)=U(\varphi+2\pi,\ z), \tag{5}$$

utilizing power expansion (3) and expression (4), we see that the integral above can be expressed as a sum of parts

$$U_{\mathrm{orb}}=\nu\cos\psi_0\int_0^{2\pi}\cos\nu\varphi\,[U_0(\varphi)+zU_1(\varphi)-\ldots]\,d\varphi.$$

The functions $U_0(\varphi)$ and $U_1(\varphi)$ are periodic in azimuth with a multiplicity (number of variations around the azimuth) ν. Accordingly, when they are expanded as Fourier series and integrated the orthogonality of the trigonometric functions means that the only contribution to the integral comes from the first harmonics. The other terms of the series convolute into the hyperbolic functions

$$U_{\mathrm{orb}}=\pi\nu\delta U_0\cos\psi_0\left[b_1\,\mathrm{ch}\,\frac{\nu z}{r}+a_1\frac{r}{\nu}\,\mathrm{sh}\,\frac{\nu z}{r}\right], \tag{6}$$

where the first coefficients of the Fourier expansion of $U_0(\varphi)$ and $U_1(\varphi)$ are respectively

$$b_1=\frac{\nu}{\pi\delta U_0}\int_0^{2\pi/\nu}U_0(\varphi)\cos\nu\varphi\,d\varphi, \tag{7}$$

$$a_1=\frac{\nu}{\pi\delta U_0}\int_0^{2\pi/\nu}U_1(\varphi)\cos\nu\varphi\,d\varphi. \tag{8}$$

The coefficients a_1 and b_1 are made dimensionless by means of scaling factors U_0 and δ, the significance of which will be explained below.

For antiphase variation of the gap boundaries the potential satisfies the condition

$$U(\varphi,\ z)=-U(\varphi,\ -z).$$

This condition, in conjunction with expression (3), implies that $U_0(\varphi) = 0$, $b_1 = 0$, and the energy increment per orbit is given by

$$U_{\mathrm{orb}}=\pi a_1\delta rU_0\cos\psi_0\,\mathrm{sh}\,\frac{\nu z}{r}. \tag{9}$$

The sign of the energy increment in this structure depends on the location of the particle relative to the midplane, a feature which may find practical application.

For inphase variation of the gap boundaries

$$U(\varphi,\ z)=-U\left[\varphi\pm(2k-1)\frac{\pi}{\nu},\ -z\right];\quad k=1,\ 2,3\ \ldots\ .$$

The component of the electric field in the midplane E_z is also symmetric

$$U_1(\varphi)=U_1\left[\varphi\pm(2k-1)\frac{\pi}{\nu}\right], \qquad (10)$$

which, in conjunction with the evenness of this function, determines its double periodicity $U_1(\varphi+\pi/\nu)=U_1(\varphi)$. Accordingly $a_1 = 0$, and the energy increment is given by

$$U_{\text{orb}}=\pi b_1\nu\delta U_0\cos\psi_0\,\text{ch}\,\frac{\nu z}{r}. \qquad (11)$$

It follows from (11) that the energy increment per orbit will be greatest in a structure with a rectangular variation of the boundaries, in which the limiting value of the coefficient b_1 is $4/\pi$.

We introduce two parameters characterizing the accelerating structure. The aperture coefficient

$$\delta=\frac{2\,|U_0(\varphi)|_{\max}}{U_0} \qquad (12)$$

and, in analogy with linear accelerators,[5] the time-of-flight factor η, which is the ratio of the first-harmonic amplitudes corresponding to the real and a stepwise variation of the potential in the midplane

$$\eta=\frac{\int\limits_0^{2\pi/\nu} s(\varphi)\cos\nu\varphi\,d\varphi}{\int\limits_0^{2\pi/\nu} s_{\text{st}}(\varphi)\cos\nu\varphi\,d\varphi}=\frac{\nu}{2}\int\limits_0^{\pi/\nu} s(\varphi)\cos\nu\varphi\,d\varphi. \qquad (13)$$

Here, U_0 is the peak high-frequency voltage across the gap, $s(\varphi) = U_0(\varphi)/|U_0(\varphi)|_{\max}$ is the dimensionless potential, and $s_{\text{ST}}(\varphi)$ is an even function of unit amplitude with the period of the structure. A change of variable in integral (13) shows that η is independent of ν.

Finally, utilizing (1), we find the energy increment per orbit:

$$U_{\text{orb}}=2\nu\delta\eta U_0 f(r)\cos\psi_0\,\text{ch}\,\frac{\nu z}{r}, \qquad (14)$$

where the parameters η and δ are determined by an electrolytic bath or by a numerical method.

For a monoharmonic field, in particular, these parameters are given analytically by

$$\eta=\frac{\pi}{4},\quad \delta=\frac{1-\frac{2z_0}{d}}{\text{ch}\,\frac{\nu z_0}{r}},$$

when U_{orb} coincides with the corresponding equation of ref. 2.

The vertical motion of a particle, which is described by the equation

$$\frac{d^2z}{d\theta^2}=\frac{ef(r)}{m_0\omega_0^2}\frac{\partial U(\varphi,\,z)}{\partial z}\sin(\nu\varphi+\psi_0)$$

is investigated through the power expansion (3) for the potential and the isochronicity condition (4). This leads, in the linear approximation in z, to an inhomogeneous Mathieu–Hill equation for the independent variable φ:

$$z''+Q(\varphi)\,z=-\frac{ef(r)}{m_0\omega_0^2}U_1(\varphi)\sin(\nu\varphi+\psi_0).$$

Here

$$Q(\varphi)=-\frac{f(r)}{2U_m}U_0''(\varphi)\sin(\nu\varphi+\psi_0).$$

The frequency of the vertical oscillations can be found from the homogeneous equation by the method of averaging.[6]

Following Kapchinskii,[7] we write the solution in the form

$$z(\varphi)=[1+q(\varphi)]\,X(\varphi), \qquad (15)$$

where $X(\varphi)$ is a slowly varying function, and $q(\varphi)$ is a rapidly oscillating function satisfying the equation

$$\frac{d^2q}{d\varphi^2}=\overline{Q(\varphi)}-Q(\varphi). \qquad (16)$$

Here, q and q' must not contain constant components, and $\overline{Q(\varphi)}$ is the mean value of the function over the period of the structure.

In successive integration of Eq. (16) we subtract the constant components from q and q':

$$q(\varphi)=\iint\overline{Q(\varphi)}\,d^2\varphi-\iint Q(\varphi)\,d^2\varphi$$

$$-\frac{\nu}{2\pi}\int\int\limits_0^{\frac{2\pi}{\nu}}\int\overline{Q(\varphi)}\,d^3\varphi+\frac{\nu}{2\pi}\int\int\limits_0^{\frac{2\pi}{\nu}}\int Q(\varphi)\,d^3\varphi$$

$$\frac{\nu}{2\pi}\int\limits_0^{\frac{2\pi}{\nu}}\iint\overline{Q(\varphi)}\,d^3\varphi+\frac{\nu}{2\pi}\int\limits_0^{\frac{2\pi}{\nu}}\iint Q(\varphi)\,d^3\varphi$$

$$+\frac{\nu^2}{4\pi^2}\int\limits_0^{\frac{2\pi}{\nu}}\int\int\limits_0^{\frac{2\pi}{\nu}}\int\overline{Q(\varphi)}\,d^4\varphi-\frac{\nu^2}{4\pi^2}\int\limits_0^{\frac{2\pi}{\nu}}\int\int\limits_0^{\frac{2\pi}{\nu}}\int Q(\varphi)\,d^4\varphi.$$

In order to evaluate $\overline{Q(\varphi)}$ and $q(\varphi)$ we expand $U_0(\varphi)$ as a Fourier series in orthogonal trigonometric functions. Finally

$$\begin{aligned}\overline{Q(\varphi)}&=-\frac{\nu\delta U_0 f(r)}{8\pi U_m}\int\limits_0^{2\pi/\nu}\left[\frac{d^2}{d\varphi^2}\sum_{n=1}^{\infty}b_n\cos n\nu\varphi\right]\sin(\nu\varphi+\psi_0)\,d\varphi\\&=\frac{b_1\nu^2\delta U_0 f(r)}{8U_m}\sin\psi_0,\end{aligned} \qquad (17)$$

$$\begin{aligned}q(\varphi)=\frac{Kb_1}{8\nu^2}\sin(2\nu\varphi+\psi_0)+\frac{K}{2\nu^2}\sum_{n=2}^{\infty}n^2b_n\Bigg\{&\frac{\sin[(n+1)\nu\varphi+\psi_0]}{(n+1)^2}\\&-\frac{\sin[(n-1)\nu\varphi-\psi_0]}{(n-1)^2}\Bigg\},\end{aligned} \qquad (18)$$

In accordance with ref. 7, the function $X(\varphi)$ is found from the equation

$$K=\frac{\delta\nu^2U_0}{4U_m}f(r).$$

where

$$\frac{d^2X}{d\varphi^2}+\mu^2X=0.$$

The number of vertical oscillations performed by the particle per orbit μ is given by the equation

$$\mu^2=\overline{Q(\varphi)}+\frac{\nu}{2\pi}\int_0^{2\pi/\nu} q(\varphi)Q(\varphi)\,d\varphi. \tag{19}$$

We use (16) to transform the integral in this expression

$$\int_0^{2\pi/\nu} qQd\varphi=\bar{Q}\int_0^{2\pi/\nu} qd\varphi-\int_0^{2\pi/\nu} qq''d\varphi.$$

The first term here vanishes, since $q(\varphi)$ has no constant component. Then, integrating the second term by parts and recalling the periodicity of $q(\varphi)$ and $q'(\varphi)$, we obtain

$$\int_0^{2\pi/\nu} qQd\varphi=\int_0^{2\pi/\nu}(q')^2\,d\varphi. \tag{20}$$

Differentiating (18), taking the first term under the summation sign, and utilizing the equality

$$\sum_{n=2}^{\infty}\frac{n^2b_n}{n-1}\cos\left[(n-1)\nu\varphi-\psi_0\right]=\sum_{n=0}^{\infty}\frac{(n+2)^2b_{n+2}}{n+1}\cos\left[(n+1)\nu\varphi-\psi_0\right],$$

we obtain the following expression for q':

$$q'=\frac{K}{2\nu}\sum_{n=0}^{\infty}\left\{\frac{n^2b_n}{n+1}\cos\left[(n+1)\nu\varphi+\psi_0\right]\right.$$
$$\left.-\frac{(n+2)^2b_{n+2}}{n+1}\cos\left[(n+1)\nu\varphi-\varphi_0\right]\right\}.$$

Integral (20), after some straightforward manipulations, can now be brought to the form

$$\int_0^{2\pi/\nu} qQd\varphi=\frac{K^2}{4\nu^2}\left\{\int_0^{2\pi/\nu}\sum_{n=0}^{\infty}\frac{[n^2b_n-(n+2)^2b_{n+2}]^2}{(n+1)^2}\cos^2\psi_0\cos^2(n+1)\nu\varphi d\varphi\right.$$
$$2\int_0^{2\pi/\nu}\sum_{n=0}^{\infty}\frac{[n^2b_n-(n+2)^2b_{n+2}]}{n+1}\cos\psi_0\cos(n+1)\nu\varphi$$
$$\times\left(\sum_{n=0}^{\infty}\frac{n^2b_n+(n+2)^2b_{n+2}}{n+1}\sin\psi_0\sin(n+1)\nu\varphi\right)d\varphi$$
$$\left.+\int_0^{2\pi/\nu}\sum_{n=0}^{\infty}\frac{[n^2b_n+(n+2)^2b_{n+2}]^2}{(n+1)^2}\sin^2\psi_0\sin^2(n+1)\nu\varphi d\varphi\right\}.$$

In this expression the second integral reduces to zero by orthogonality. Working out the remaining integrals and in using the results in (19), utilizing (1), we obtain

$$\mu^2=\frac{\nu^2b_1\delta U_0f(r)}{8U_m}\sin\psi_0+\frac{\nu^2\delta^2U_0^2f^2(r)}{128U_m^2}$$
$$\times\sum_{n=0}^{\infty}\frac{1}{(n+1)^2}\left[n^4b_n^2+(n+2)^4b_{n+2}^2-2n^2(n+2)^2b_nb_{n+2}\cos 2\psi_0\right]. \tag{21}$$

An analysis of this expression shows that the first term, which depends on the particle phase ψ_θ, corresponds to soft focusing and is proportional to the coefficient of the first harmonic in the expansion of the potential in the midplane. This term has a dominant effect on the focusing at large particle energies.

The terms independent of the phase ψ_θ correspond to hard focusing by the corresponding field harmonics. They can become predominant at low energies.

The expression in the square brackets of (21) is always greater than zero. Accordingly, within the limits of applicability of the method of averaging ($\mu \ll \nu$), the higher harmonics have the effect of increasing μ.

For a monoharmonic field[1] we have $b_1 = 1$ and $b_{n|n\neq 1} = 0$, and expression (21) reduces to

$$\mu^2=\frac{\nu^2\delta U_0f(r)}{8U_m}\sin\psi_0+\frac{\nu^2\delta^2U_0^2f^2(r)}{512U_m^2}.$$

The main contribution comes from the first term, which coincides with the index of electrical focusing n_{el} (see ref. 3). The second term is responsible for the hard-focusing effect.

Thus, for gap boundaries varying according to an arbitrary law subject to general symmetry conditions we see that the per-orbit energy increment (14) and number of vertical oscillations (21) are determined with adequate accuracy by the first harmonic of the Fourier expansion of the potential in azimuth. In particular, the use of an accelerating structure with a rectangular variation of the boundaries gives an increase of these parameters by a factor of $4/\pi$ compared with the monoharmonic case.

Spatial and energy parameters of the relativistic electron beam of the Rius-5 accelerator

A. T. Altyntsev and V. I. Koroteev

(Submitted July 17, 1973)
Zh. Tekh. Fiz., 44, 1228-1231 (June 1974)

The parameters of the relativistic electron beam in the Rius-5 accelerator have been studied in an effort to evaluate the use of this accelerator in plasma-heating experiments. The optimum conditions correspond to a beam energy of 450-500 J, a maximum electron energy of ~2 MeV, a beam particle density $n_e \sim 5 \cdot 10^{10}$ cm^{-3}, a beam divergence of ~ 6-7°, and a pulse length ~60 nsec.

A detailed study of the parameters of the electron beam of the Rius-5 accelerator,[1] built at the Institute of Nuclear Physics, Siberian Branch, Academy of Sciences of the USSR, has been undertaken in an effort to evaluate the use of this accelerator in plasma-heating experiments.[2] Theory[3] predicts that the effective transfer of beam energy to a plasma requires a highly dense beam (beam density comparable to that of the plasma) and a low beam divergence as the beam enters the plasma and moves through it.

Figure 1 shows the experimental apparatus. The electron beam is extracted from the accelerator through anode 2 (made of Al or Ti foil 10-50 μ thick) into a stainless steel cylinder 9, 160 mm in diameter and 250 mm long. Anode holder 4 is designed to accommodate anodes of various shapes (flat, concave, or convex). In addition, there are sector apertures 5 in the anode which connect the evacuated volumes of the discharge tube of the accelerator and the experimental apparatus.

The detectors which measure the beam parameters are mounted on disk 7. Disk holder 14 is designed so that the detectors can be moved along the axis of the chamber and the disk can be rotated around its axis without disruption of the vacuum. Phosphor bronze leaves 8 provide a reliable contact between the disk and the inner surface of the chamber.

The average charge density and the radial density profile are studied with 50 Faraday cups 10, 2.5 mm in diameter, arranged in a cross on the disk. The cups are loaded with low-leakage, low-inductance capacitors 11.

The voltage from the capacitors is measured through the use of a sequential scanner by an S1-29 storage oscilloscope. The signals from the series of detectors are displayed in a row on the oscilloscope; the charge-density profile along any direction can be monitored visually on the oscilloscope screen when the appropriate reading sequence is chosen.

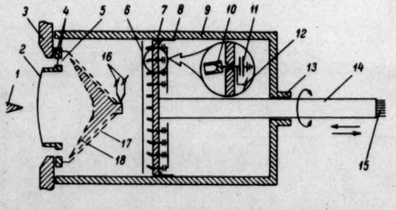

Fig. 1. 1) Cathode; 2) anode; 3) accelerator flange; 4) anode holder; 5) sector apertures in the anode holder; 6) shielding foil; 7) metal disk used as a support for the detectors; 8) phosphor bronze leaves; 9) housing; 10) Faraday cup; 11) capacitor; 12) capacitor terminal; 13) seal; 14) disk holder; 15) electrical leads from the detector elements to the external circuit; 16) leads to a copper–constantan thermocouple; 17) return conductor of the calorimeter; 18) calorimeter.

The Faraday cups are shielded by a grounded thin metal foil (copper, 30 μ thick) 6, and a positive potential (+100 V) is supplied to the capacitors before a pulse. In this manner signal distortion due to secondary-electron emission is avoided. Only the flux of electrons backscattered by the detector, some 15-20% of the basic flux,[4] is taken into account.

The total beam energy is measured by a calorimetric detector, a massive copper calorimeter 18 connected to the accelerator by a stainless steel return conductor 17, 0.05 mm thick. The change in the collector temperature is measured by a copper–constantan thermocouple 16 in a comparison circuit. The thermocouple indications go to a PSR1-13 electronic chart recorder.

Transparent films of chlorovinylmethylmethacrylate, darkened by bombardment by high-energy electrons, are used to obtain a qualitative estimate of the density and energy distributions of the electron beam integrated over a pulse (see ref. 5 for a detailed discussion). The films are arranged in a packet or sandwich and stacked with 7 μ aluminum foil, connected to the anode, to remove space charge. The sandwiches are placed behind the anode, and the relative density distribution and the maximum energy of the electrons in the beam can be determined from the shape and depth of the position of the darkening boundary.

The electron energy is measured with a high time resolution (~10^{-9} sec) by current collectors covered by foils of various thicknesses. The energy measurements are reliable and accurate because the accelerator beam is monoenergetic at each measurement time, as expected on the basis of the method used to extract the beam.

Cathodes of three types are used in the experiments: conical, three-ring (20 mm in diameter, consisting of a point and three concentric rings with acute vertices), and multi-ring (20 mm in diameter, consisting of six rings). The most efficient and stable operation results from the use of the three-ring cathode combined with an anode of aluminum foil, convex toward the cathode (radius of curvature of R ~13 cm).

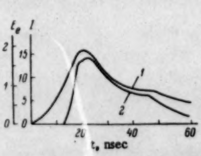

Fig. 2. Electron energy E_e (MeV) (1) and beam current I (kA) (2) as functions of the time.

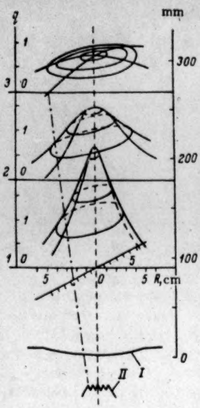

Fig. 3. Transformation of the charge-density distribution, averaged over a pulse, as the beam moves through the experimental chamber. The right-hand ordinate shows the distance to the anode, and the left-hand ordinate shows the cross sections (1, 2, 3) in which the measurements are made and the integrated surface-charge density q (relative units per square centimeter). I) Anode; II) cathode.

Experiments show that the total electron energy should be 2 MeV for prolonged maintenance-free use of the Rius-5 (several thousand pulses). The electron-current pulse, having a sharp front (5-10 nsec) and a slower decay (Fig. 2), has a length of the order of 50 nsec and is delayed ~10 nsec with respect to the voltage pulse. The delay apparently results from the fact that a critical electric field ($\sim 10^6$ V/cm) must be reached at the accelerator cathode for explosive field emission to occur.[6]

The electron density distribution is axially symmetric; the current density reaches 220 A/cm^2 (at the axis in the second cross section; Fig. 3), corresponding to a beam density of $n_e \sim 5 \cdot 10^{10}$ cm^{-3}.

Figure 3 illustrates the transformation of the charge-density distribution, averaged over a pulse, as the beam moves through the experimental chamber. The average density distribution is shown isometrically and has a Gaussian cross section. The beam divergence is taken to be half the magnitude of the plane angle at the vertex of the solid angle containing half the charge detected at the anode. With an aluminum-foil anode 50 μ thick the divergence does not exceed 7°. Calculations show that the divergence is due primarily to scattering by the foil, since[7] the corresponding scattering angle for electrons at ~1 MeV is ~6°.

As the maximum electric field in the discharge gap is raised (above 1 MeV/cm), electron-density rings appear in the distribution function along with the main peak. In this case the electron distribution is a multipeak curve (in cross section), whose shape hinders an evaluation of the beam divergence.

The experiments with the Rius-5 beam show that the basic beam parameters [the total energy (~450-500 J), the maximum electron energy (~2 MeV), the beam density ($n_e \sim 5 \cdot 10^{10}$ cm^{-3}), the length of the current pulse (~60 nsec), and the beam divergence (~7°)] are adequate for the initiation of an experimental study of the interaction of a relativistic electron beam with a plasma.

The authors thank R. Kh. Kurtmullaev for interest in this work and for useful discussion; they also thank E. A. Abramyan and S. B. Vasserman for the opportunity to use the Rius-5 accelerator.

General

Kinetics of gasdynamic lasers. Effect of nozzle geometry on inversion

A. S. Biryukov and L. A. Shelepin

P. N. Lebedev Physics Institute, Academy of Sciences of the USSR, Moscow

(Submitted June 8, 1973; resubmitted November 16, 1973)
Zh. Tekh. Fiz., 44, 1232-1243 (June 1974)

A detailed analysis is made of the effect of supersonic nozzle geometry on the parameters of a CO_2 gasdynamic laser. It is shown that each of the elements characterizing the nozzle (throat half-height or radius, divergence angle of expansion section, length and shape of expansion section, character of the transition from subsonic to supersonic flow, and so on) has its own specific effect on the population inversion and the kinetics of vibrational relaxation. A study is also made of the case of high (up to ~ 4000°K) initial temperatures, allowing for the variation of the composition and the gasdynamic parameters as a result of chemical reactions. It is shown that equilibrium reactions do not lead to additional nonequilibrium effects in the vibrational levels. Such nonequilibrium effects can result from the combustion of carbon-containing mixtures.

I. INTRODUCTION

Gasdynamic lasers have received much attention in recent years. Vibrational relaxation and laser action on the 00^01-02^00 and 00^01-10^00 transitions of the CO_2 molecule have been studied in many papers, both theoretical[1-13] and experimental[14-20] (see also the reviews in refs. 21 and 22). Gasdynamic lasers can be divided into two types, depending on the mechanism of operation and the characteristics of the kinetic processes: lasers operating in the low-temperature region at an initial temperature of the gas mixture $T_0 < 2500°K$, and high-temperature lasers $T_0 > 2500°K$).

The manner in which the population inversion depends on the initial parameters (stagnation temperature and pressure, mixture composition) has been investigated thoroughly in the case of low-temperature lasers. Work remains to be done, however, on the role played by nozzle size and geometry, factors which are often crucial in design. In most papers the work pertains to one particular nozzle geometry. Thus, Basov et al.[4] investigated the relaxation of a binary CO_2-N_2 mixture in a Laval nozzle. Generalov et al.[11] varied the temperature and the pressure, and, to some extent, the shape of the nozzle (Laval nozzle going over into a cylinder, a two-dimensional hyperbolic nozzle going over into a plane-parallel channel). Anderson and Harris[12] used a simplified relaxation scheme to calculate the variation of the gain along the flow axis of a $CO_2-N_2-H_2O$ mixture in a nozzle having a somewhat different profile than in refs. 4 and 11.

Of the various experimental papers[14-20] that by Kuehn[20] contains the most complete description of the effect of nozzle geometry on the output power of a gasdynamic laser (GDL). These papers are rather disconnected in character, however, and even when taken together do not lend themselves to systematic study of the effect of the nozzle.

In the present paper we have carried out a detailed study of the effect of nozzle geometry on the kinetics of vibrational relaxation and the appearance of an inverted population in low-temperature gasdynamic lasers. The nozzle is divided into separate sections and the effect of each (in particular, the dimensions and shape of the throat, the angle of divergence, the geometry of the transition to the expansion section, the presence or absence of a constant-area duct) is investigated with a view to drawing conclusions concerning the operation and usefulness of particular nozzles.

Little work has been done on high-temperature gasdynamic lasers. The kinetics of the physical processes in such lasers can differ strongly from the low-temperature case ($T_0 \leqslant 2500°K$). In particular, the CO_2 can be more than half dissociated, and thermal ionization begins to play a role ($T_0 > 3000°K$). Yushchenkova and Kalenov[6] noted that, upon expansion of the mixture, the chemical composition differs from the equilibrium value as a result of the "freezing" of the chemistry. The effect of chemical reactions on the vibrational kinetics in the low-temperature region ($T_0 \leqslant 3000°K$) is considered in refs. 8 and 13. The role of nonequilibrium recombination reactions is studied in ref. 23. Tulip and Seguin[10] calculated the inverse population distribution along the nozzle axis at temperatures up to ~4000°K but ignored the chemistry. The output power at high stagnation temperatures (up to ~4000°K) has been measured by Kuehn[20] but no explanation of his results is given.

Another aim of the work reported here is to investigate the role of chemical processes at temperatures $T_0 \geqslant 3000°K$ and to explain the operation of high-temperature gasdynamic lasers.

II. BASIC EQUATIONS AND METHOD OF CALCULATION

The analysis of the kinetics in a moving and expanding gas at high initial temperatures require the simultaneous consideration of the gas dynamics, the chemical processes and the chemical kinetics. Let us being with the chemical kinetics.

All chemical conversions in the ternary mixture CO_2-N_2-He at initial temperatures 2500-4000°K involve only the CO_2 molecule (N_2 dissociates to some extent at higher temperatures). Accordingly, the six main components of interest are O_2, CO, O, CO_2, N_2, and He. We denote the molar fractions by $\gamma_i = n_i/n$, where n_i is the concentration of the i-th component and n is the total number of particles per unit volume. To determine the six unknowns γ_i we have the following four relationships:

$$\left.\begin{array}{c}\sum_i \gamma_i(t)=1,\ \dfrac{\gamma_{CO}(t)+\gamma_{CO_2}(t)}{\gamma_{CO}(t)+\gamma_O(t)+2\gamma_{O_2}(t)+2\gamma_{CO_2}(t)}=b,\\ \gamma_{N_2}(t)=\dfrac{\mu(t)}{\mu_{N_2}}\alpha_{N_2},\ \gamma_{He}(t)=\dfrac{\mu(t)}{\mu_{He}}\alpha_{He},\end{array}\right\} \qquad (1)$$

where $\mu(t)$ is the molecular weight of the mixture; b, α_{N_2}, α_{He} are constants that depend on the initial conditions. The first of relationships (1) comes from the definition of γ_i; the second reflects the fact that the ratio of the number of carbon atoms to the number of oxygen atoms is a constant for all chemical conversions; the third and the fourth are connected with the fact that N_2 and He do not participate in the chemical reactions and that the mass of each relative to the total mass of gas must remain constant.

For a mixture of equilibrium chemical composition b = 1/2. If a composition with definite ratios of the molar fractions at some (initial) time is in a state of nonequilibrium, we have for α_{N_2}, α_{He}, b

$$\alpha_{N_2}=\frac{\gamma_{N_2}(0)\,\mu_{N_2}}{\sum\limits_i \gamma_i(0)\,\mu_i},\quad \alpha_{He}=\frac{\gamma_{He}(0)\,\mu_{He}}{\sum\limits_i \gamma_i(0)\,\mu_i},$$
$$b=\frac{\gamma_{CO}(0)+\gamma_{CO_2}(0)}{\gamma_{CO}(0)+\gamma_O(t)+2\gamma_{O_2}(0)+2\gamma_{CO_2}(0)}. \tag{2}$$

Thus, having four relationships with which to find the six unknown molar fractions, we must solve a set of two equations in all. For definiteness, let us take γ_{O_2} and γ_{CO_2} to be the independent variables in this set. We write the equations determining γ_{O_2} and γ_{CO_2} as a result of gasdynamic expansion in the presence of chemical reactions. Under these conditions, the concentration of the i-th component n_i is given by the equation[24]

$$\frac{d\gamma_i}{dt}=\frac{1}{n}\left(\frac{dn_i}{dt}\right)_*+\frac{\gamma_i}{\mu}\frac{d\mu}{dt}, \tag{3}$$

where $(dn_i/dt)_*$ is the rate of change of the i-th component as a result of the chemical reactions. The required set of equations can now, with the aid of (1), be represented in the form[25]

$$\left.\begin{aligned}\frac{d\gamma_{O_2}}{dt}&=\frac{1+\gamma_{O_2}}{n}\left(\frac{dn_{O_2}}{dt}\right)_*+\frac{\gamma_{O_2}}{n}\left(\frac{dn_{CO_2}}{dt}\right)_*,\\ \frac{d\gamma_{CO_2}}{dt}&=\frac{\gamma_{CO_2}}{n}\left(\frac{dn_{O_2}}{dt}\right)_*+\frac{1+\gamma_{CO_2}}{n}\left(\frac{dn_{CO_2}}{dt}\right)_*.\end{aligned}\right\} \tag{4}$$

To make (4) more specific we must restrict the discussion to a definite set of reactions responsible for the variation of the chemical composition. The most important reactions in this case include[25]

$$\left.\begin{aligned}&CO_2+M \underset{k_{-1}^M}{\overset{k_1^M}{\rightleftarrows}} CO+O+M,\\ &CO_2+O \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} CO+O_2,\\ &O_2+M \underset{k_{-3}^M}{\overset{k_3^M}{\rightleftarrows}} O+O+M.\end{aligned}\right\} \tag{5}$$

Here M is any of the six components of the mixture; k_i^M, k_{-i}^M are the rate constants of the forward and reverse reactions respectively. The particle-number balance equations determining the right sides of (4) have the form

$$\left.\begin{aligned}\frac{1}{n}\left(\frac{dn_{O_2}}{dt}\right)_*=\frac{P}{kT}\Big(&\frac{P}{kT}\gamma_O^2\sum_M k_{-3}^M\gamma_M+\gamma_{CO_2}\gamma_O k_2\\ &-\gamma_{O_2}\sum_M k_3^M\gamma_M-\gamma_{CO}\gamma_{O_2}k_{-2}\Big),\\ \frac{1}{n}\left(\frac{dn_{CO_2}}{dt}\right)_*=\frac{P}{kT}\Big(&\frac{P}{kT}\gamma_{CO}\gamma_O\sum_M k_{-1}^M\gamma_M\\ &+\gamma_{CO}\gamma_{O_2}k_{-2}-\gamma_{CO_2}\sum_M k_1^M\gamma_M-\gamma_{CO_2}\gamma_O k_2\Big),\end{aligned}\right\} \tag{6}$$

where P is the pressure and T the temperature of the gas.

The variation of the gasdynamic parameters is described by the equations of motion, energy conservation, and continuity. The analysis of the motion of a mixture of gases in a supersonic nozzle usually proceeds on the assumption that the flow is one-dimensional and that the gasdynamic parameters depend only on the one coordinate, x, along the axis of the nozzle. This assumption is usually justified in the great majority of cases (see also ref. 12).

We assume further that the rotational degrees of freedom are in equilibrium with the translational degrees of freedom and utilize the equation of state $P = \rho RT/\mu$. The set of gasdynamic equations then becomes

$$\left.\begin{aligned}&\frac{P\mu Vf}{RT}=\text{const},\\ &\frac{dP}{dx}=-\frac{P\mu V}{RT}\frac{dV}{dx},\\ &\frac{RT}{\mu}\left(\frac{5}{2}+\sum_i\gamma_i\right)+\sum_i e_v^i+\frac{V^2}{2}=\text{const},\end{aligned}\right\} \tag{7}$$

where $\rho(x)$ is the mass per unit volume of the gas; $f(x)$ is the ratio of the cross-sectional area at x to the nozzle area at the throat; R is the gas constant; e_v^i is the vibrational energy per unit mass of the i-th component. In (7) and in all relationships of this section the summation is taken over the molecular components.

The system (7) can be solved for the derivatives, and the equations determining the gasdynamic parameters take the form

$$\left.\begin{aligned}\frac{dT}{dx}&=-T\,\frac{\left\{(1-z)\sum\limits_i\frac{d\gamma_i}{dx}+\frac{1-z}{zV^2}\sum\limits_i\frac{de_v^i}{dx}+\frac{1}{f}\frac{df}{dx}-\left[\left(\frac{5}{2}+\sum\limits_i\gamma_i\right)(1-z)-1\right]\frac{1}{\mu}\frac{d\mu}{dx}\right\}}{\left(\frac{5}{2}+\sum\limits_i\gamma_i\right)(1-z)-1},\\ \frac{dV}{dx}&=V\,\frac{z\sum\limits_i\frac{d\gamma_i}{dx}+\frac{1}{V^2}\sum\limits_i\frac{de_v^i}{dx}+z\left(\frac{5}{2}+\sum\limits_i\gamma_i\right)\frac{1}{f}\frac{df}{dx}}{\left(\frac{5}{2}+\sum\limits_i\gamma_i\right)(1-z)-1},\\ \frac{dP}{dx}&=-\frac{P}{Vz}\frac{dV}{dx},\quad z=\frac{RT}{\mu V^2}.\end{aligned}\right\} \tag{8}$$

It can be seen from (8) that the nozzle geometry can have a significant effect on the rate of change of the gasdynamic parameters of the flow, which, in turn, determine the rates of all relaxation processes. The geometry of the nozzle is not only important beyond the throat, but also before it.

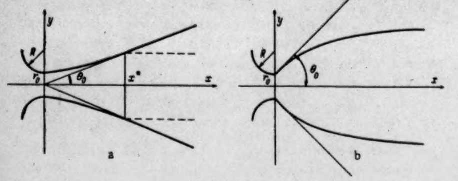

Fig. 1. Nozzle profiles.

The calculations were performed for two nozzle geometries, hyperbolic and logarithmic (see Fig. 1 for the shape for $x \geq 0$).

For a hyperbolic nozzle, in (x, y) coordinates (Fig. 1a) we have

$$y = r_0\sqrt{1+\left(\frac{x}{r_0}\operatorname{tg}\theta_0\right)^2}, \tag{9}$$

where r_0 is the half-height (or radius) of the throat, and θ_0 is the limiting angle of divergence of the nozzle. The area ratio f can be represented by a common expression for both circular and rectangular nozzle cross sections:

$$f = \sqrt{1+\left(\frac{x}{r_{01}}\operatorname{tg}\theta_{01}\right)^2}\sqrt{1+\left(\frac{x}{r_{02}}\operatorname{tg}\theta_{02}\right)^2}. \tag{10}$$

For $r_{01} = r_{02} = r_0$ and $\theta_{01} = \theta_{02} = \theta_0$ this expression corresponds to a circular (throat radius r_0) or square (half-height at throat r_0) nozzle, and otherwise to a rectangular-section nozzle.

It is of interest to consider a nozzle (10) going over, at some distance x^* from the throat, into a duct of constant cross-sectional area, i.e., f = const for $x \geq x^*$.

The nozzle geometry of Fig. 1b is most conveniently represented by an expression of the form

$$y = m\ln(ax + c). \tag{11}$$

The constants a and c are expressed in terms of m and the usual characteristics r_0 and θ_0 by

$$a = c\,\frac{\operatorname{tg}\theta_0}{m}, \quad c = e^{\frac{r_0}{m}}.$$

For large angles $\theta_0(\sim 45°)$ nozzles of this type resemble a slit with a half-height r_0 treated by us in ref. 5. For angles greater than this the quasi-one-dimensional character of the flow can be violated.

It can be seen from (10) and (11) that nozzles a and b differ fundamentally from each other in the manner in which the transition to expansion occurs.

The nozzle input profile is taken to be the same in both cases, a quarter arc of a circle of radius $R = 2r_0$ (Fig. 1).

For the chosen mixture composition and chemical reactions (5), we deal with only four molecular components: CO_2, CO, O_2, and N_2. Accordingly, besides those considered in ref. 26, the main channels of vibrational relaxation are the following:

$$\left.\begin{aligned}
&CO_2(00^01) + CO(v=0) \rightleftarrows CO_2(00^00) + CO(v=1), && W_{3.5},\\
&CO_2(00^00) + CO(v=1) \rightleftarrows \begin{cases} CO_2(11^10) + CO(v=0), & W_{5.12},\\ CO_2(03^10) + CO(v=0), & W_{5.2},\end{cases}\\
&CO_2(00^00) + O_2(v=1) \rightleftarrows CO_2(10^00) + O_2(v=0), && W_{6.1},\\
&N_2(v=1) + CO(v=0) \rightleftarrows N_2(v=0) + CO(v=1), && W_{4.5},\\
&N_2(v=1) + O \rightleftarrows N_2(v=0) + O, && W_{4.0},\\
&O_2(v=1) + M \rightleftarrows O_2(v=0) + M, && W^{M}_{6.0}.
\end{aligned}\right\} \tag{12}$$

The probabilities of the forward basic processes are indicated on the right; the indices from 1 to 3 denote respectively the symmetric stretching, the bending, and the asymmetric stretching modes of vibration of CO_2; the index 4 refers to the N_2 molecule, the index 5 to the CO molecule, and the index 6 to O_2.

When the chemical reactions occur in a moving flow of gas the variation of the average energy stored per unit mass in the i-th vibrational degree of freedom is given by the equation[27]

$$\frac{de_v^i}{dt} = \frac{\theta_i R}{\mu_i}\left[\frac{d\varepsilon_v^i}{dt} + \sum_j \left(\varepsilon_{i*}^{(j)} - \varepsilon_v^i\right)\frac{1}{n_i}\left(\frac{dn_i}{dt}\right)_*^{(j)}\right], \tag{13}$$

where the summation is understood to extend over all chemical reactions in which a given molecule participates; $\varepsilon_{i*}^{(j)}$ is the average energy, expressed in the number of photons $h\nu_i$ going into the i-th oscillator as a result of a single act of the j-th reaction; $\theta_i = h\nu_i/k$; k is Boltzmann's constant; $e_v^i = \varepsilon_v^i(\theta_i R/\mu_i)$; ε_v^i is the mean energy (number of photons) stored in the i-th vibration.[26]

Let us assume further that the reactions of dissociation and recombination go mainly through the upper vibrational levels. The magnitude of the vibrational energy lost or acquired by molecules participating in these processes is then approximately equal to the dissociation energy. In the case of the exchange reaction in (5) we set $\varepsilon_{i*} = 0$ for simplicity for all the components CO, O_2, CO_2. We assume that the vibrational energy of the chemical reactions in the case of CO_2 is uniformly distributed over its four vibrational modes, i.e., $\varepsilon_{i*} = D\alpha_i$, where D is the dissociation energy of CO_2, $\alpha_i = 0.25$ for the asymmetric and symmetric stretching modes, $\alpha_2 = 0.5$ for the doubly degenerate bending mode.

The rates of change of the concentrations of the mixture components are described by equations of the form (6)[24] but with the rate constants of the reactions (5) taken from ref. 28. The first term on the right side of (13) describes the normal collisional relaxation over the vibrational levels. The general expression for this process is obtained in ref. 26.

Thus, Eqs. (4), (8), and (13) along with (6) completely determine vibrational relaxation in a gas expanding through a nozzle and in which chemical reactions (5) can take place.

The calculations are performed on a computer, first for low-temperature mixtures ($T_0 \leqslant 2300°K$). It turns out that even at high pressures the chemical reactions are weak and their effect on the vibrational relaxation can be neglected. The acceleration of the gas from the nozzle input to the throat, as shown in ref. 11, can be regarded as taking place in complete thermodynamic equilibrium (an isentropic process). This is confirmed by our calculation, as the maximum deviation of the vibrational temperature from the gas temperature is less than ~80°K at T ~2000°K. The flow up to the throat is thus regarded as independent of the input geometry, and the parameters in the throat are found from the equations[29]

$$P_{\text{th}} = P_0\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{(\gamma-1)}}, \quad T_{\text{th}} = T_0\frac{2}{\gamma+1}. \tag{14}$$

Here, P_0 and T_0 are the stagnation parameters; γ is the adiabatic ratio, defined in our case as

$$\gamma = \left(\frac{5}{2} + \sum_i \gamma_i\right) / \left(\frac{3}{2} + \sum_i \gamma_i\right).$$

This expression leads to a temperature-independent γ for a fixed chemical composition of the mixture, as it ignores the contribution to the specific heat of the gas from the vibrational degrees of freedom. The drop of gas temperature accompanying the acceleration of the gas from the input to the throat causes the adiabatic ratio to increase slightly. However, estimates allowing for the possible contribution from the symmetric and bending modes for a mixture containing He in a quantity $\gamma_{\text{He}} \gtrsim 0.5$ in the temperature range $T_0 = 3500$–2500°K show that the variation of γ is less than ~5%.

It can be seen from (8) that in supersonic operation of the nozzle the numerator and the denominator in the equations for T and V change sign simultaneously. This change occurs at a critical point x_1 located slightly downstream from the throat for nozzles of type a (Fig. 1a) and, as a rule, directly in the throat for nozzles of type b. For equilibrium initial stagnation conditions the distance x_1 is very small; accordingly, in the low-temperature calculations, the origin is taken to be in the throat. The equilibrium composition at P_{th}, T_{th} is calculated for various assigned α_{N_2}, α_{He} through (4) and (1) with the derivatives set equal to zero. The composition of the mixture and the temperature are used to find the initial velocity of the gas, which is assumed to be equal to the local (in the throat) velocity of sound.

The calculations for high-temperature mixtures are carried out for both equilibrium and nonequilibrium composition stagnation conditions. A type b nozzle geometry is used in both cases. At temperature T > 3000°K the chemical reactions can proceed intensively and the composition vary rapidly (especially under nonequilibrium conditions), and accordingly the choice of the initial value of the velocity in (8) is not a trivial one. It is chosen by the "ranging method" (see refs. 4, 24).

The probabilities of the processes entering into Eqs. (13) are taken from the data of ref. 30 with allowance for ref. 31.

III. RELAXATION PROCESSES AND MECHANISM OF OPERATION OF GASDYNAMIC LASERS

Our calculations on low-temperature mixtures demonstrate the profound effect of nozzle geometry on the parameters of gasdynamic lasers. This effect is systematically studied by dividing the nozzle into separate elements: the section up to the throat; the shape of the throat (circular or rectangular); the half-height (radius) of the throat r_0; the angle of divergence of the expansion section θ_0; the character of the transition to expansion (nozzle type *a* or b); length of expansion section x*.

It can be seen from (10) and (11) that each of these elements has its own specific effect on the laser characteristics, the maximum inversion, the position of this maximum along the nozzle axis, the width of the region in which inversion ΔN exists, and the manner in which the inversion depends on pressure and temperature. The calculations have the aim of investigating the effect of each of these closely interrelated factors for different stagnation conditions in order to permit an appraisal of the possibilities of particular nozzles as a whole. The results of the calculations are presented in Figs. 2–7. The effect of the character of the transition from the throat to the expansion section is analyzed on the basis of a type-*a* nozzle (Fig. 1a).

Figure 2 shows typical on-axis variations of the inversion $\Delta N = N_{00^01} - N_{10^00}$, and the vibrational and gas temperatures for complete thermodynamic equilibrium in the throat. It can be seen (the dashed curves) that at a certain distance from the throat the vibrational temperatures in N_2 and in the asymmetric CO_2 mode are "frozen," while T_2 continues to fall. The inversion, which occurs when the difference between T_3 and T_2 reaches a certain value (the ratio T_3/T_2 must be ~1.73), passes through a maximum and subsequently falls. The presence of a maximum is due, on the one hand, to the increase in the difference between T_3 and T_2 and, on the other, to the reduction in density upon expansion.

Calculations have also been performed for the same conditions but with the nozzle going over, at a distance x* from the throat, into a constant-area cylindrical duct (the solid curves). The picture here is somewhat different. Commencing from this point the gas temperature T increases as a result of the termination of expansion and the arrival of energy from the vibrational degrees of freedom to the translational. This increase of T enables T_2 to continue falling, and subsequently leads to a speeding up of the relaxation of T_3 and T_4. The region of increasing difference between T_3 and T_2 can be much more drawn out in this case, and since the particle density for x ≥ x* is constant it follows that the maximum inversion, under otherwise equal conditions, can be much higher than in the first case. The fall-off in inversion is due not to a reduction in density, but to a diminution in the rate of decrease of T_2 and its subsequent increase for a simultane-

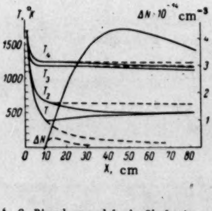

Fig. 2. Variation of inversion ΔN and vibrational and gas temperatures along axis of axially symmetric nozzle (type a). $T_{\text{th}} = 2000$°K, $P_{\text{th}} = 15$ atm, $\tan \theta_0/k_0 = 1.25$, $\alpha_{N_2} = 0.6$, $\alpha_{\text{He}} = 0.085$.

ous relaxation of T_3 and T_4. The process whereby T_3 and T_2 approach is a comparatively slow one, and accordingly the region in which the inversion is high can extend over a considerable distance (sometimes more than 1-2 m). The chosen values of α_{N_2} and α_{He} correspond under our conditions to a composition $CO_2:N_2:He \approx 1:3:3$ (the remaining components amount on the whole to less than one percent).

Figure 3a shows plots of the inversion along the axis of a nozzle going over into a constant-area duct for various values of the pressure in the throat P_{th}. It can be seen that for the specified parameters of the system the optimum value of $P_{th} \approx 27$ atm. This is due to the increase in the number of working particles with increasing pressure and to the accompanying speeding up of vibrational relaxation. The increase in the relaxation rate leads to a more rapid rise of the gas temperature, and as a result the region in which inversion exists contracts greatly with increasing P_{th}.

The role played by the expansion parameter tan θ_0/r_0 can be seen from Fig. 3b, which shows similar plots for a nozzle with larger tan θ_0/r_0. The optimum value of the inversion now occurs in the expansion section of the nozzle. However, inclusion of a transition to a constant-area duct enables the CO_2 bending modes to continue relaxing and the difference between T_3 and T_2 to increase, which, for a constant density, results in an increase in the inversion and attainment of a higher second maximum. The maximum value of ΔN increases up to pressures $P_{th} \sim 300$ atm and approaches x* with increasing pressure. The region in which inversion exists correspondingly contracts, as in the case of Fig. 3a.

With a view to establishing the effect of throat shape, we calculate the inversion along the axis of a two-dimensional type-*a* nozzle. The vibrational temperatures and the inversion in this case are distributed along the axis in much the same manner as in Fig. 2. However, the region of optimum pressures (Fig. 4a) occurs at much lower values of P_{th} as a result of the smaller rate of expansion. It can be seen from Fig. 4a that the higher the expansion parameter tan θ_0/r_0 the higher the pressure corresponding to optimum inversion and the greater the absolute value of the latter (the solid curves).

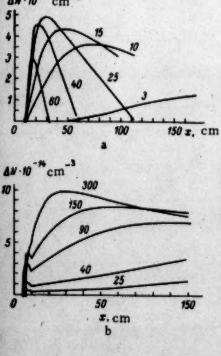

Fig. 3. Plots of inversion ΔN versus distance along axis of axially symmetric type-*a* nozzle for various throat pressures P_{th}. $T_{th} = 2000$°K, $\alpha_{N_2} = 0.6$, $\alpha_{He} = 0.085$, x* = 10 cm; tan θ_0/r_0: a) 1.25; b) 2.5.

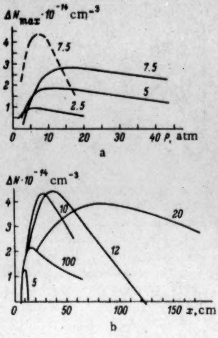

Fig. 4. a) Plots of a maximum inversion ΔN_{max} versus pressure P_{th} for two-dimensional type-*a* nozzle for various values of the expansion parameter tan θ_0/r_0 (solid curves). The dashed curves correspond to the same conditions but for a nozzle going over at x* = 10 cm into a constant-area duct. b) Plots of inversion along axis of two-dimensional type-*a* nozzle going over at x = x* into a constant area channel for various values of x*. $R_{th} = 7.65$ atm, tan $\theta_0/r_0 = 7.5$. In both cases $T_{th} = 2000$°K, $\alpha_{N_2} = 0.6$, $\alpha_{He} = 0.085$.

Figure 4b shows the variation of the inversion along the axis for various lengths x* of the expansion section of the nozzle. The presence of an optimum value x^*_{opt} is explained, on the one hand, by the fact that at $x^* < x^*_{opt}$ the role of relaxation is large, while at $x^* > x^*_{opt}$ the number of working particles is small on account of the appreciable expansion. As in the case of Fig. 3, the maximum inversion can be greater than for a nozzle with $x^* \to \infty$.

The effect of the manner in which the throat goes over into the expansion section can be seen by comparison with the results obtained for type-b nozzles (Fig. 1b). High initial cooling rates can occur here. As can be seen from Fig. 5, no "freezing" of T_3 and T_4 occurs. The difference between t_3 and t_2, established even at x ~ 1-2 cm, proves, however, to be sufficient for the occurrence of inversion. The subsequent increase of this difference resulting from the different relaxation times of the vibrational degrees of freedom of CO_2 leads, for a weakly varying density, to an increasing inversion ΔN (Fig. 6a). As the expansion rate of the nozzle falls off the gas temperature not only ceases to drop, but indeed even begins to rise on account of the accelerated relaxation of T_3 and T_4 (T_2 here is already close to T). This, along with a weak diminution of density, results in the inversion ΔN falling off.

Figure 6b shows plots of maximum inversion versus throat pressure for various nozzle characteristics. Curves 1 and 2 differ in the value of m by a factor of 3, the higher the value of m the more the optimum values of ΔN_{max} are displaced towards higher pressures. Calculations show

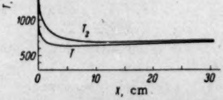

Fig. 5. Vibrational temperatures and gas temperature versus distance along axis of logarithmic type-b nozzle. $T_{th} = 2000$°K, $P_{th} = 15$ atm, tan $\theta_0/m = 2.663$, $/m = 0.0525$, $\alpha_{N_2} = 0.6$, $\alpha_{He} = 0.085$.

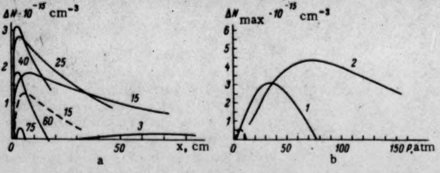

Fig. 6. a) Plots of inversion ΔN along axis of type-b nozzle for various values of the pressure in the throat. T_{th} = 2000°K, $\tan\theta_0/m$ = 2.663, r_0/m = 0.0525, α_{N_2} = 0.631, α_{He} = 0.1122 (corresponds to a composition $CO_2 : N_2 : He$ = 1 : 4 : 5). The dashed curve corresponds to α_{N_2} = 0.6, α_{He} = 0.085 (composition 1 : 3 : 3). b) Maximum inversion ΔN_{max} achieved on axis of logarithmic nozzle versus throat pressure T_{th} = 2000°K, α_{N_2} = 0.631, α_{He} = 0.122; $\tan\theta_0/m$: 1) 2.663; 2) 0.888; r_0/m: 1) 0.0525, 2) 0.0175. Dashed curve corresponds to $\tan\theta_0/m$ = 0.662, r_0/m = 0.065.

that the greater the ratio $\tan\theta_0/r_0$, the more efficiently is the gas cooled (compare, for example, with the dashed curve of Fig. 6b). Also, higher initial temperatures call for larger values of m (to achieve a sufficient depth of cooling). The absolute values of the optimum ΔN are around four to eight times greater than in the best variants of hyperbolic nozzles (correct to the small difference in the compositions of the mixtures).

Initial temperatures $T_0 \sim 1800$°K appear to be the optimum for gasdynamic lasers; higher values are regarded as inefficient on account of the high relaxation rate. The theoretical analysis ignores, however, a number of physical processes (for example the dissociation of CO_2, thermal ionization). Each of these factors demands a detailed study of the kinetics. To investigate the effect of the chemistry on the operation of high-temperature gasdynamic lasers, the inversion is calculated allowing for the chemical kinetics in a type-b nozzle at high temperatures T_0 = 3200-4000°K. The calculations are performed for equilibrium (in chemical composition) conditions at P_0, T_0 and also for a deliberately introduced degree of nonequilibrium. Velocity "ranging" is carried out for r_0 = 0.025 and 0.05 cm in both cases. In the case of equilibrium stagnation conditions over a wide range of pressures, the vibrational temperatures fall monotonically for both values of r_0 and, for $x = 2r_0$, are very close to the gas temperature (difference is ~90-120°K); the chemical compositions, however, are close to the equilibrium compositions at (P_{th}, T_{th}). This means that reactions (5) are able to establish a state of chemical equilibrium under conditions of varying gasdynamic parameters in the entire distance from x = 0 to $x = 2r_0$. The variation of the composition as a result of chemical reactions for a temperature drop from T_0 to T_{th} is small.[24]

In the case of a nonequilibrium chemical composition at (P_0, T_0), the temperature is found to vary in a nonmonotonic manner along the axis as a result of the reactions. A temperature difference between T_3 and T_2 of ~100°K is achieved, which is far from sufficient to obtain inversion.[24] Even this difference, however, is not maintained up to the throat, as T_3 and T_2 approach T as a result of intense relaxation. The absolute values of the temperatures in the throat are $T_{th} \sim 2800$-2900°K for T_0 = 3200°K (for T_0 = 4000°K, $T_{th} \sim 3500$-3700°K).

The subsequent motion of the mixture of almost equilibrium composition through the nozzle is accompanied, as a result of the sharp drop in P and T, by a rapid (for $x \gtrsim 1$ cm) "freezing" of the chemical reactions. In both cases therefore, equilibrium and nonequilibrium at (P_0, T_0, the composition at distances x ~1 cm differs from that at the throat by not more than 2% (in terms of the amount of CO_2). Thus, one can assume with good accuracy that the gas from the throat is a mixture of constant chemical composition in almost complete thermodynamic equilibrium.

As in low-temperature gasdynamic lasers, the use in the high-temperature case of a type-b nozzle does not result in the appearance of inversion since, for otherwise equal conditions, larger T_{th} calls for larger m. Figure 7 illustrates how the parameter m affects the maximum inversion in the case of high initial temperatures of the gas. This effect is significant for nozzles with small r_0, and better results are obtained with m ~5-7. Increasing r_0 requires larger m, and conversely. The optimum values of the inversion are smaller than at $T_0 \sim 2000$°K.

The above calculations, in which reactions (5) are taken into account, still do not permit a complete estimate to be made of the role of the chemistry. The fact is that real GDL mixtures contain a certain amount of water vapor, which can radically affect the chemical kinetics. The CO oxidation reaction catalyzed by water has the character of a chain reaction, and proceeds according to quite a different scheme than (5) (see ref. 32, for example). Also, it is exothermal, and probably makes a large energy contribution to the vibrational degrees of freedom of the CO_2 molecules formed as a result of the reaction. A detailed analysis of the kinetics of this reaction and of its effect on the vibrational relaxation is rendered difficult by several factors, namely, the fraction of the energy of the reaction going into vibrations is unknown, there are no rate constants for the various links of the reaction, and the role of the bounding surfaces, on which active centers may be created, is unclear. Under such conditions one can only make qualitative estimates, and these showed[24] that inversion can be an order greater than in the case of the ordinary oxidation reaction of CO. This may be the theoretical explanation of the experimental fact[20] that the output power of a gasdynamic laser increases with increasing stagnation temperature.

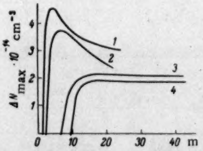

Fig. 7. Plots of ΔN_{max} versus the parameter m (logarithmic type-b nozzle). Curves 2 (r_0 = 0.025 cm and(r_0 = 0.025cm) and (R_0 = 0.05 cm) pertain to equilibrium stagnation conditions will α_{N_2} = 0, α_{He} = 0.178 (corresponds to composition $CO_2 : CO : O : O_2 : N_2 : He$ = 1 : 0.37 : 0.02 : 0.17 : 0 : 3.26 at P_0, T_0). Curves 1(r_0 = 0.025 cm) and 3 (r_0 = 0.05 cm) pertain to nonequilibrium composition $CO_2:CO:O:O_2:N_2:He$ = 1 : 2 : 1 : 1 : 0 : 8 at P_0, T_0. T_0 = 3200°K, P_0 = 90 atm, and θ_0 = 45°.

We note that in the high-temperature laser, on account of the high degree of thermal ionization, a discharge can be used to effect additional excitation of the working gas (in the throat the degree of thermal ionization amounts to 10^{-6}–10^{-7} at $P'_{th} \sim 10^2$ atm and $T_{th} \approx 3500°K$). Also, the large number of electrons greatly facilitates the striking of a discharge across the flow and gives rise to the electrical gasdynamic laser. The kinetics of the physical processes in such lasers at low initial temperatures ($T_0 \leqslant 2000°K$) are discussed in ref. 33.

On the whole, the data obtained in the present work on the dependence of the inversion on the individual elements of the nozzle in the low-temperature case can be used to obtain semiquantitative characteristics for a broad class of specific nozzles. The results can be refined by allowing for possible differences between the real and the calculated flows. Our analysis also shows the possibilities of high-temperature lasers based on the reactions of combustion.

In conclusion we should like to thank B. F. Gordiets for a useful discussion.

Processes which are related to the propagation of blast waves in a gaseous medium characterized by a branch-chain conversion mechanism are considered. It is shown that under certain conditions the wave velocity exceeds substantially the wave velocity of nonbranching chain reactions. Expressions are found for the wave profile. These expressions differ from expressions for both the photolysis wave and the photochemical wave when no branching occurs.

I. INTRODUCTION

The propagation of photodissociation waves in gaseous media has been considered in refs. 1-3. Several papers[4-7] have reported on investigations of photochemical waves which propagate in gaseous media characterized by a chain conversion mechanism. The present work is a theoretical investigation of similar waves in media in which branch-chain reactions can take place. The interest in these waves results from the fact that chain reactions with branching (oxidation of hydrogen, burning of carbon dioxide in the presence of hydrogen-containing compounds, chlorination of acetylene, etc.) are characteristic of a large number of gas mixtures.

According to the theoretical concepts developed by Semenov and his school,[8-10] two basic chemical branching reactions can be distinguished. In the first type the branching of chains takes place without formation of induced particles ("material" branching), and the mechanism of the process proper consists of the formation of two active centers (radical and biradical) in the interaction of the radical with the initial molecule).

In the second type of chemical branching reaction the branching process takes place at the expense of the energy liberated during a chain reaction which is localized at a certain bond of the reaction product. In principle, monomolecular decomposition of an excited product can result in the branching of chains. Obviously, a rather low binding energy is associated with this process. If the excitation energy does not suffice for the rupture of bonds according to the monomolecular mechanism, branching can take place in a bimolecular reaction of an excited molecule on the one hand and one of the initial agents on the other. It is emphasized in refs. 9 and 10 that the branching process occurs in this case through formation of a chemical complex and through a strong perturbation of the energy levels of the interacting particles, rather than at the expense of migration of excitation energy to the bond of the initial agent and subsequent decomposition of the same.

2. FORMATION OF THE PROBLEM

The present work deals with photochemical waves in gaseous media which are characterized by a mechanism of bimolecular energy branching.

As in previous papers,[4-7] we assume that the mixture of gases A_2-B_2 is irradiated by quasimonochromatic radiation of frequency ν and intensity I_0, and that the B_2 molecules and the reaction products do not absorb radiation at this frequency. It is assumed that the reactions in the medium occur according to the following scheme:

$$\left.\begin{aligned}
A_2+h\nu &\xrightarrow{\sigma} 2A,\\
A+B_2 &\xrightarrow{k_1} AB+B,\\
B+A_2 &\xrightarrow{k_2} (1-\mu)\,AB+\mu AB^{+}+A,\\
AB^{+}+A_2 &\xrightarrow{k_3} AB+2A,\\
B+R &\xrightarrow{\gamma} BR,\\
A+Q &\xrightarrow{\gamma_1} AQ.
\end{aligned}\right\} \qquad (2.1)$$

The first link of Eq. (2.1) corresponds to the photoinitiation processs;the following two links correspond to the development of the chain; the fourth link corresponds to the branching process; the chain rupture is described by the next two links. The following notation is introduced in the scheme (2.1): A_2 and B_2 denote the molecules of the initial agents; A and B denote active centers; AB^+ and AB correspond to excited and nonexcited products of the chain reaction, respectively; R and Q are inhibitors; BR and AQ are inhibition products; σ denotes the cross section of photolysis; k_1 and k_2 denote the constants of the links in the chain reaction; k_3 denotes the constant of branching; μ denotes the probability of the appearance of an excited product; γ and γ_1 denote the constants of the chain-rupture processes. In our ensuing discussion, square brackets will be used to denote the densities of the corresponding agents, e.g., $[A_2]$, $[B_2]$, etc.

Thermal effects are ignored in the present paper.[1)]

To describe the propagation of a photochemical wave we used the radiation-transfer equation and equations of chemical kinetics. A solution to the system in the form of a stationary wave is determined, i.e., it is assumed that all dynamic variables depend upon the argument $x' = x - Dt$, where D denotes the wave velocity, which is to be determined. The system of ordinary differential equations which describes this wave has the form

$$\left.\begin{aligned}
u' &= -\sigma a_2 u,\\
a_2' &= \sigma a_2 u + b a_2 + \delta_3\varphi_2 a_2,\\
b_2' &= \delta_1 a b_2,\\
a' &= -2\sigma a_2 u + \delta_1 a b_2 - b a_2 - 2\delta_3\varphi_2 a_2,\\
b' &= -\delta_1 a b_2 + b a_2 + \delta_2 b r,\\
\varphi_1' &= -\delta_1 a b_2 - (1-\mu)\,b a_2 - \delta_3\varphi_2 a_2,\\
\varphi_2' &= -\mu b a_2 + \delta_3\varphi_2 a_2,\\
r' &= \delta_2 b r,\\
\psi' &= -\delta_2 b r,\\
q' &= \delta_4 a q,\\
\psi_1' &= -\delta_4 a q,
\end{aligned}\right\} \qquad (2.2)$$

where differentiation with respect to $\eta = x'(k_2[A_2^0])/D$ is performed; the following notation is introduced:

$$\left.\begin{gathered}\alpha=\sigma D/k_2,\ \delta_1=k_1/k_2,\ \delta_3=k_3/k_2,\ \delta_2=\gamma/k_2,\\ \delta_4=\gamma_1/k_2,\ a_2=[A_2]/[A_2^0],\ b_2=[B_2]/[A_2^0],\\ a=[A]/[A_2^0],\ b=[B]/[A_2^0],\ \varphi_1=[AB]/[A_2^0],\\ \varphi_2=[AB^+]/[A_2^0],\ r=[R]/[A_2^0],\\ \psi=[BR]/[A_2^0],\ q=[Q]/[A_2^0],\ \psi_1=[AQ]/[A_2^0],\ u=I/D[A_2^0]\end{gathered}\right\}$$

with I denoting the radiation flux expressed in photons $\cdot$ $cm^{-2} \cdot sec^{-1}$.

The solution of the problem is reduced to the integration of system (2.2) under the following boundary conditions:

$$\left.\begin{gathered}\eta=+\infty:u=0,\ a_2=1,\ r=r_0,\ q=q_0,\\ a=b=\varphi_1=\varphi_2=\psi=\psi_1=0,\\ b_2=b_2^0.\ \eta=-\infty:u=u_0,\ a_2=0.\end{gathered}\right\}$$

3. STABILITY OF THE UNPERTURBED GAS

We assume in our formulation of the problem that the front of the photochemical wave moves toward the gas medium which has not entered into the reaction. According to the theory of Semenov, this involves a situation in which the image point of the unperturbed state of the mixture is beyond the region of spontaneous (self-) ignition. Let us determine the conditions which the parameters of the problem must satisfy for the initial medium to be stable in this sense. To do this, we consider the front of the wave in the region of large $\eta > 0$ values, where the inequalities $(1-a_2) \ll 1$, $(b_2^0-b_2) \ll b_2^0$, $(r_0-r) \ll r_0$, $(q_0-q) \ll q_0$ hold. By linearizing the equations of the initial system in the neighborhood of the point corresponding to the unperturbed state, we obtain a relation between the intensity and the concentration of the active centers A:

$$2\alpha u=a\frac{(\alpha+\delta_2r_0)(\alpha+\delta_3)(\alpha+\delta_1b_2^0+\delta_4q_0)+{}+(\alpha+\delta_3)(\alpha+\delta_4q_0)-2\mu\delta_1\delta_3b_2^0}{(1+\alpha+\delta_2r_0)(\alpha+\delta_3)}. \tag{3.1}$$

Obviously, the proportionality coefficient in a linear relation between a and $2\alpha u$ must be positive. Since the stability condition is independent of the velocity of the wave propagating toward the gas, the minimum of the coefficient, which obtains for $\alpha = 0$ (i.e., $D = 0$), must be nonvanishing. Thus, the general stability condition, for the initial mixture corresponding to the reaction scheme (2.1), has the following form:

$$F=\frac{\gamma[R_0]}{k_2[A_2^0]}+\frac{\gamma_1[Q_0]}{k_1[B_2^0]}+\frac{\gamma_1[Q_0]}{k_1[B_2^0]}\frac{\gamma[R_0]}{k_2[A_2^0]}-2\mu>0. \tag{3.2}$$

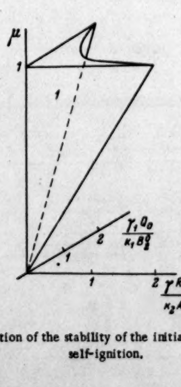

Fig. 1. Determination of the stability of the initial mixture. 1) Region of self-ignition.

The surface F = 0 splits the phase space into two regions: a region of self-ignition and a region of stability (Fig. 1).

To simplify the analysis we will restrict our considerations to cases in which chain rupture occurs only by virtue of the reaction of an active center B with an admixture R. In this case, inequality (3.2) assumes the simpler form

$$\gamma[R_0]-2\mu k_2[A_2^0]>0, \tag{3.3}$$

i.e., the chain length is bounded by the value $1/2\ \mu$.

4. CONDITIONS FOR A FAST TRANSITION INTO THE SELF-IGNITION REGION

The system of equations (2.2) (with Q = 0), which describes a stationary wave, has four integrals. This means that three types of particles and photon-particles are conserved:

$$\left.\begin{gathered}\psi=r_0-r,\\ (1+\mu)b=u+(1+\mu)(b_2^0-b_2)\\ -(1-a_2)-(1+\mu)(r_0-r)-\varphi_2,\\ a=2(1-a_2)+b-2(b_2^0-b_2)+(r_0-r),\\ \varphi_1=2(1-a_2)-a-\varphi_2.\end{gathered}\right\} \tag{4.1}$$

Equations (4.1) make it possible to reduce the initial system to the simpler system

$$\left.\begin{gathered}u'=-\alpha a_2u,\\ a_2'=\alpha a_2u+ba_2+\delta_3\varphi_2a_2,\\ \varphi_2'=-\mu ba_2+\delta_3\varphi_2a_2,\\ r'=\delta_2br,\\ \varepsilon b_2'=ab_2,\end{gathered}\right\} \tag{4.2}$$

where $\varepsilon = 1/\delta_1 = k_2/k_1$. The solution is greatly simplified when the reaction rate in one of the links of the chain reactions greatly exceeds the reaction rate in another link. This situation is frequently encountered in practice. In our subsequent discussion, we consider the case $\varepsilon = k_2/k_1 \ll 1$. It is possible to show[11] that for sufficiently small ε, the solution of the system resembles the solution of the system in which the last equation is replaced by

$$0=ab_2. \tag{4.3}$$

When an excess of agent B_2 is present (first condition of ref. 6), $a = 0$ is the solution to (4.3). This situation is of greatest interest. As a matter of fact, in the case of the second condition (B_2 deficiency), it is possible to show for a sufficiently small concentration of the inhibitor ($[R_0] \ll I_0/D$) that the wave velocity differs only slightly from the wave velocity of photodissociation of products from the instantaneously occurring chemical reactions, i.e., from the wave velocity $D = I_0/([A_2^0]-(1+\mu)[B_2^0])$ (it is assumed that $\xi = 2K_2[A_2^0]/\sigma I_0 \gg 1$, ref. 6). We consider below the first condition in which the wave propagation process is described by a system including the first four equations of (4.2), the integrals (4.1), and the equality $a = 0$.

The behavior of a medium characterized by a branch-chain conversion mechanism depends upon the form in which the concentration of the active centers changes. The following differential equation for the active center B can be obtained from system (2.2) (taking into account that $a = 0$):

$$b' = -2\alpha a_2 u + \delta_2 br - 2\delta_3\varphi_2 a_2. \tag{4.4}$$

In order to make our considerations clearer we assume for the time being $\delta_3 = k_3/k_2 \gg 1$ (fast branching reaction); then Eq. (4.4) assumes the form

$$b' = -2\alpha a_2 u + b(\delta_2 r - 2\mu a_2). \tag{4.5}$$

When we assume that Eq. (4.5) describes the kinetics of a reaction which occurs at some fixed point $x = x_1$ and when we recall the equality $\partial/(\partial t) = -Dd/(d\eta)$, it becomes obvious that Eq. (4.5) is equivalent to the equation which was obtained by Semenov.[9] It is shown in ref. 9 that self-ignition of the gas does not occur when the inequality $l_0 = \delta_2 r_0 - 2\mu > 0$ is satisfied. This coincides with the particular case of the previously considered stability condition (3.3) of the mixture.

The quantity $l = \delta_2 r - 2\mu a_2$ which appears in parentheses in Eq. (4.5) can be treated as "distance" between the image point and the region of self-ignition. As has been noted above, the inequality $l \approx l_0 > 0$ must be satisfied for large $\eta > 0$. The concentrations of both agent A_2 and admixture R decrease in the wave front and, hence, a cross section $\eta \equiv 0$, in which the representing point reaches the region of self-ignition, must not necessarily exist. This situation $[l(\eta) > 0, -\infty < \eta < \infty]$ corresponds to a wave propagating in a medium in which chain reactions with rupture occur.[6,12]

When we use the solution of the linearized system (4.2), (4.4), we can in the general case (arbitrary δ_3 value) determine the change in the distance L between the representing point and the region of self-ignition during changes in the dynamic variables in the wave front:

$$L = \delta_2 br - 2\delta_3\varphi_2 a_2 = \frac{2\alpha a_2 u}{(\delta_2 r_0 + \alpha)(\delta_3 + \alpha) - 2\delta_3\mu}[\delta_2 r_0(\delta_3 + \alpha)a_2^{\varkappa-1} - 2\delta_3\mu], \tag{4.6}$$

where

$$\varkappa = \frac{\frac{\gamma}{k_2}}{1 + \frac{1}{2}\left(\frac{\gamma R_0}{k_2 A_2^0} + \frac{\sigma D}{k_2}\right)}.$$

If $\varkappa < 1$, the decrease in the concentration of A_2 only enhances the inequality $L > 0$. If the inequality $\varkappa \gg 1$ is satisfied, a slight reduction of a_2 sharply reduces the term which in Eq. (4.6) corresponds to chain rupture, i.e., the representing point rapidly "enters" into the region of autoignition. We assume the point $\eta = 0$ at which L tends to zero $[L(o) = 0]$ as the origin of the coordinate system. For positive L values, the number of active centers in the medium is smaller than twice the number of absorbed photons; in the region of negative L values, active centers are generated by the medium. This implies that b(t), the number of active centers which are present at a particular time in a unit volume of the gas, can greatly exceed the number of photons N(t) absorbed by this volume. The quantity b(t) depends to a larger extent upon the time $\tau(t)$ during which the image point of the volume is within the self-ignition region than upon N(t). The quantity b(t) increases qualitatively in exponential form with increasing $\tau(t)$ (the factor before the exponential is $\sim N(t)$).

5. PROFILE AND VELOCITY OF THE WAVE

In order to investigate in explicit form the details of the waves which depend upon the properties of the branching reaction, it is interesting to consider the case in which the main fraction of agent A_2 is annihilated in the region of negative η values. To do this we consider a mixture which is close to the self-ignition region due to the presence of a small amount of a chemically active inhibitor R in the gas. We assume that the developing active centers B rapidly enter into reactions with molecules R, as long as molecules R are present in the gas. This means that the wave profile in the region of positive η values is of the photolysis type:

$$\eta > 0: r = r_0 - 2u,\ a_2 = 1 - u,\ \psi = 2u,$$

$$\varphi_1 = 2u,\ b_2 = b_2^0 = 2u,\ b = \varphi_2 = a = 0.$$

In the region of negative values of wave front coordinates, the concentration of admixture R becomes zero and the wave is described by a system which comprises the first three equations of (4.3) and the integrals

$$\left.\begin{aligned} &r = a = 0;\ \psi = r_0;\ \varphi_1 = 2(1 - a_2) - \varphi_2;\\ &b_2 = b_2^0 - \frac{1+2\mu}{1+\mu}(1 - a_2) - \frac{u}{1+\mu} + \frac{\varphi_2}{1+\mu},\\ &b = \frac{2u}{1+\mu} + \frac{2\mu}{1+\mu}(1 - a_2) - \frac{2}{1+\mu}\varphi_2 - r_0. \end{aligned}\right\}$$

The boundary conditions of this system are as follows: $\eta = 0$; $u = r_0/2$, $a_2 = 1 - r_0/2$, $r_2 = 0$.

We introduce for convenience $r_2 \equiv r_0/2$.

We obtain the following equation from Eq. (4.2):

$$\frac{d^2a_2}{du^2} + \frac{c_1}{u}\frac{da_2}{du} + \frac{c_2}{u^2}a_2 = \frac{c_3}{u} + \frac{c_4}{u^2} \tag{5.1}$$

with the boundary conditions

$$a_2(u = r_2) = 1 - r_2,$$

$$(da_2/du)(u = r_2) = -1,$$

where

$$\left.\begin{aligned} &c_1 = 1 + \frac{\delta}{z};\ c_2 = -\frac{\mu\delta}{z^2};\ c_3 = -\left(1 + \frac{\delta}{z}\right)\left(1 + \frac{1}{z}\right);\\ &c_4 = [r_2(1+\mu) - \mu]\frac{\delta}{z^2};\ \delta = \frac{k_3}{2k_2};\ \xi = \frac{2k_2[A_2^0]}{\sigma I_0};\ z = \frac{D}{\frac{2k_2}{\sigma}}. \end{aligned}\right\}$$

The solution of Eq. (5.1) has the form

$$a_2 = 1 - r_2 - \frac{r_2}{\mu} - m_1 u + \frac{r_2}{y_1 - y_2}\left\{\left(m_1 + \frac{1}{\mu}\right)\left[y_1\left(\frac{u}{r_2}\right)^{y_2} - y_2\left(\frac{u}{r_2}\right)^{y_1}\right] + (m_1 - 1)\left[\left(\frac{u}{r_2}\right)^{y_2} - \left(\frac{u}{r_2}\right)^{y_1}\right]\right\}, \tag{5.2}$$

where

$$m_1 = \frac{(z+\delta)(z+1)}{z^2 + \delta z - \mu\delta};\ y_{1,2} = \frac{\delta}{2z}\left(-1 \pm \sqrt{1 + \frac{4\mu}{\delta}}\right).$$

When we use the well-known conditions for $\eta = -\infty$: $u = u_0 = 1/\xi z$, and $a_2 = 0$, we can obtain, from Eq. (5.2), an equation establishing a relation between the velocity of the photochemical wave and the parameters of our problem:

$$E(z, \xi, \delta, \mu, r_2) = 0. \tag{5.3}$$

It is possible to show that Eq. (5.3) has two roots, one of which is

$$z^* = \frac{\delta}{2}\left[-1 + \sqrt{1 + \frac{4\mu}{\delta}}\right].$$

This root is independent of the intensity of the external radiation flux. Obviously, this root has no physical meaning. The velocity of the wave is given by the second root of Eq. (5.3).

Nonbranching chain reactions occur in the gas for $k_3 = 0$ or $\mu = 0$ in the region of negative η values. It is then possible to show that Eq. (5.3) is reduced to the following equation for the wave velocity:

$$0 = 1 - r_2 - \left(1 + \frac{1}{z}\right)\left(\frac{1}{\xi z} - r_2\right) + \frac{r_2}{z}\ln\left(\frac{1}{r_2 \xi z}\right). \tag{5.4}$$

In the limit $r_2 \to 0$, we obtain the well-known expression for the velocity[6,7]

$$D = \frac{1}{2}\frac{I_0}{[A_2^0]} + \sqrt{\left(\frac{1}{2}\frac{I_0}{[A_2^0]}\right)^2 + \frac{2k_2 I_0}{\sigma [A_2^0]}}. \tag{5.5}$$

It follows from a numerical solution of Eq. (5.4) that even for $r_2 = 10^{-4}$–10^{-6} the wave velocity differs only slightly from the limit value defined by Eq. (5.5).

The results of a numerical solution of the general equation (5.3) are displayed in Fig. 2 [a family of curves $D/D_0 = f_\delta(\xi)$ is shown for $\mu = 1$ and $r_2 = 10^{-4}$, $D_0 \equiv I_0/[A_2^0]$ denotes the velocity of the photodissociation wave[1]].

First of all, let us note that when the intensity decreases (ξ increases), the influence of branching upon the wave velocity increases. The branching effect in the reaction becomes important in this case, provided that the branching constant amounts to at least one per cent of the constant of the chain reaction. When the branching constant increases in the interval $0 < k_3 \leqslant k_2$ $(0 < \delta \leqslant 1)$, the wave velocity increases sharply and a further change in k_3 does not lead to a substantial increase in the velocity [for $\delta \geqslant 5$ the wave velocity is close to the limit value $D \approx D$ $(\delta = \infty)$]. When the branching constant is unbounded ($\delta \to \infty$) Eq. (5.3) assumes the simpler form

$$0 = 1 - r_2 - \frac{r_2}{\mu} - \frac{z+1}{z-\mu}\frac{1}{\xi z} + r_2 \frac{z(1+\mu)}{\mu(z-\mu)}(r_2 \xi z)^{-\mu/z}. \tag{5.6}$$

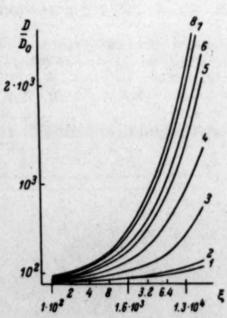

Fig. 2. Family of curves which define the velocity of the wave for various $\delta = \bar{k}_3/2\bar{k}_2$ values. $r_2 = 10^{-4}$, $\mu = 1$; 1) $\delta = 0$; 2) $\delta = 10^{-4}$; 3) $\delta = 10^{-2}$; 4) $\delta = 10^{-1}$; 5) $\delta = 0.5$; 6) $\delta = 1$; 7) $\delta = 5$; 8) $\delta = \infty$.

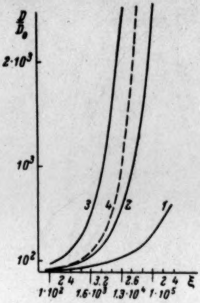

Fig. 3. Family of curves which determine the wave velocity for $\bar{k}_3 = \infty$. $r_2 = 10^{-4}$, 1) $\mu = 0$; 2) $\mu = 0.1$; 3) $\mu = 1$; 4) $r_2 = 10^{-6}$, $\mu = 0.1$.

It follows from reaction scheme (2.1) that in this case, the quantity 2μ has the meaning of the number of active centers generated by the medium per link of the chain reaction. By varying μ we can observe the way the degree of branching in the chain reaction affects the characteristics of the wave. Figure 3 displays the numerical solution of Eq. (5.6) for $r_2 = 10^{-4}$ and $\mu = 0$, 0.1, and 1. When the branching is "switched on", the velocity of the wave is greatly increased. For example we have for $\xi = 10^4$ the results $D(\mu = 0) = 10^2 D_0$, $D(\mu = 0.1) = 5 \cdot 10^2 D_0$, and $D(\mu = 1) = 2 \cdot 10^3 D_0$. Figure 2 includes the curve which corresponds to $r_2 = 10^{-6}$ and $\mu = 0.1$. In contrast with the nonbranching chain reactions, the velocity of the wave increases sharply with increasing concentration of the admixtures, even when the admixture concentration is low. This detail can be understood when we consider a unit volume of the gas located at a large distance before the wave front. The number of photons which are absorbed by the unit volume must decrease with decreasing admixture concentration for a branching chain reaction to be initiated in that volume. The time between the beginning of the reaction and the moment at which the wave front arrives at the particular point of the medium increases. The exponential increase in the rate of the branching reaction overcomes the reduction of the initiation rate with increasing η. One can show that when r_2 is decreased the wave velocity defined by Eq. (5.6) tends to the value D_{lim}:

$$D_{\mathrm{lim}} = \frac{1}{2}\frac{I_0}{[A_2^0]} + \mu\frac{k_2}{\sigma} + \sqrt{\left(\frac{1}{2}\frac{I_0}{[A_2^0]}\right)^2 + \frac{(2+\mu)k_2 I_0}{\sigma [A_2^0]} + \left(\mu\frac{k_2}{\sigma}\right)^2}. \tag{5.7}$$

However, let us note that the stability condition (Eq. 3.3) for the initial mixture implies a restriction of the minimum of the concentration of admixtures R, because the rate of the rupture reaction cannot exceed the gas-ki-

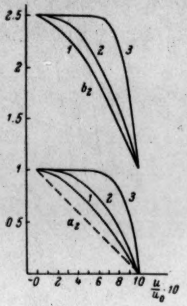

Fig. 4. Wave profiles ($\mu = 1$, $r_2 = 10^{-4}$). ξ values: 1) 100; 2) 800; 3) 10^5.

netic collision frequency ($r_0 > r_{0\,\min} = 2\gamma k_2/\gamma_{\max}$). The order of magnitude of $r_{0\min}$ is 10^{-2}–10^{-4} in fast chain reactions ($\mu k_2 \simeq 10^{-12}$–10^{-14} cm^3/sec). Figure 3 displays the curves which correspond to the greatest possible wave velocities in a medium which is characterized by a branch-type conversion mechanism. In the limit ($k_3 \gg k_2$), the expressions determining the wave profile have the form

$$\left.\begin{array}{c} a_2 = 1 - r_2 - \dfrac{r_2}{\mu} - \dfrac{z+1}{z-\mu}u + r_2\dfrac{z(1+\mu)}{\mu(z-\mu)}\left(\dfrac{u}{r_2}\right)^{\mu/z}; \\ r = \varphi_2 = a = 0;\ \psi = r_0;\ \varphi_1 = 2(1-a_2), \\ b_2 = b_2^0 - \dfrac{1+2\mu}{1+\mu}(1-a_2) - \dfrac{u}{1+\mu}, \\ b = \dfrac{2u}{1+\mu} + \dfrac{2\mu}{1+\mu}(1-a_2) - r_0, \\ \eta = -\dfrac{1}{a}\displaystyle\int_{r_2}^{\infty}\dfrac{du}{a_2(u)\,u}. \end{array}\right\}$$

Figure 4 shows the functions $a_2 = a_2(u/u_0)$, $b_2 = b_2(u/u_0)$. In the case of nonbranching reactions, the wave front is not distinguished from the front of the photolysis wave, and the relation between a_2 and u is linear: $a_2 = 1 - (u/u_0)$. When branching is "switched on", the wave front is distorted, i.e., the wave front begins to depend upon the ratio of the rate of chemical reactions to the rate of photolysis. When the intensity decreases, the wave front section on which the photons initiate reactions is more clearly separated. A considerable fraction of the photons are spent for the initiation process, and the change in the concentration of the agents is small in this range. The photodissociating agent is basically annihilated on the rear wave front section, where the rate of the chemical reaction reaches high values. For example, for $\xi = 10^5$, the concentration of A_2 and B_2 decreases less than 1% at the wave front point at which $u = u_0/2$.

6. CONCLUSION

It follows from our analysis that, in principle, the wave velocity in a medium characterized by a branch-chain conversion mechanism can be very high. The wave velocity can exceed by one order of magnitude the velocity of the corresponding wave in a medium without branching. However, for this to occur the image point of the initial gas mixture must be close to the region of self-ignition (the mixture is stabilized with the aid of a small amount of a chemically active inhibitor $\gamma > k_2$). When the medium is intensively heated by the heat liberated during the reaction, the condition for the entry of the representing point into the self-ignition region is less rigorous. The reason is that chain rupture frequently occurs as a consequence of triple collisions with activation energy zero, i.e., chain rupture depends only slightly upon temperature, contrary to the exponential temperature dependence of the rate of a chain reaction. The gas-dynamic motions which are caused by the external radiation flux and the possible formation of shock and explosion waves before the front of the photochemical wave are other interesting aspects of the problem. We propose that these specific questions be investigated in future work.

Spontaneous parametric scattering of light (PSL) is a source of noise in parametric lasers and infrared frequency converters with nonlinear crystals. The present paper investigates the characteristics of four-photon PSL in one of the most interesting nonlinear crystals, $LiIO_3$. The results of experiments on the pumping of this crystal by a He−Ne laser ($\lambda_1 = 0.63\ \mu$) are presented. In noncentrosymmetric media, to which $LiIO_3$ belongs, three four-photon PSL mechanisms are possible: direct scattering on the cubic nonlinearity and two cascade processes on the quadratic nonlinearity through second-harmonic and idler generation. The principal aim of the work is to establish the dominant mechanism responsible for the scattering in $LiIO_3$. The effect is recorded using a coincidence-circuit technique. This technique gives a great improvement in the sensitivity of the measuring system over the usual one-channel recording, and enables pairs of correlated four-photon PSL photons to be distinguished against background phenomena. The experimental results in conjunction with a theoretical calculation indicate that the main scattering mechanism in the present case is a cascade process going through generation of an idler frequency.

INTRODUCTION. FORMULATION OF THE PROBLEM

Experimental investigations on the parametric scattering of light (PSL) date from 1967.[1-3] Since the publication of these papers much work has been carried out on this phenomenon in media with quadratic ($\hat{\chi}$) and cubic ($\hat{\theta}$) nonlinear susceptibilities. There are a number of reasons for the interest in PSL. First, it is a convenient tool for measuring the magnitudes of the nonlinear susceptibilities and their dispersion. This phenomenon can also be used to determine the tuning curves of parametric lasers, in which it plays the role of the initiating sources. Also, PSL limits the sensitivity of optical detectors that use nonlinear frequency conversion.

In connection with the interest manifest in recent times in processes involving nonlinear susceptibilities of higher order, considerable importance attaches to the question of the competition of different cascade transformations in multiphoton processes. For example, the magnitude of the pump threshold in four-photon parametric lasers utilizing cascade processes can be appreciably less than in the case of direct four-photon processes.[4-6]

Three-photon PSL processes are associated with the quadratic nonlinearity $\hat{\chi}$ of the medium, and four-photon processes with the cubic nonlinearity $\hat{\theta}$. Of the latter processes we mention in particular the process

$$\omega_1+\omega_1=\omega_s+\omega_a,\quad 2\mathbf{k}=\mathbf{k}_s+\mathbf{k}_a+\Delta, \tag{1}$$

where ω_1 is the pump frequency, ω_s and ω_a are the Stokes and antistokes frequencies of the scattered radiation, k_j are the wave numbers and Δ is the wave vector mismatch. Processes like (1) have been observed experimentally in refs. 7-12.

In noncentrosymmetric crystals ($\hat{\chi} \neq 0$) in addition to (1), there is the so-called cascade mechanism of four-photon scattering. This process is the result of two successive three-photon PSL processes. Such processes can go through excitation of the second harmonic ω_2

$$\left.\begin{aligned} &2\omega_1=\omega_2, && 2\mathbf{k}_1=\mathbf{k}_2+\Delta_2;\\ &\omega_2=\omega_s+\omega_a, && \mathbf{k}_2=\mathbf{k}_s+\mathbf{k}_a+\Delta' \end{aligned}\right\} \tag{2}$$

or through generation of the idler frequency ω_0

$$\left.\begin{aligned} &\omega_1=\omega_0+\omega_s, && \mathbf{k}_1=\mathbf{k}_s+\mathbf{k}_0+\Delta_s;\\ &\omega_0+\omega_1=\omega_a, && \mathbf{k}_0+\mathbf{k}_1=\mathbf{k}_a+\Delta_a. \end{aligned}\right\} \tag{3}$$

Process (3) in the ADP crystal has been studied by Andrews et al.[13] A detailed theoretical discussion of processes of the form (2) and (3) is given by Klyshko and Nazarova.[4] These authors also estimate the ratio of the scattering amplitudes in processes (1) and (3) and conclude that in certain cases cascade scattering on $\hat{\chi}$ is more efficient compared with direct scattering on θ.

Very little has been published on the experimental aspects of this problem. It is therefore of interest to establish the mechanism of four-photon PSL in one of the most promising nonlinear crystals, lithium iodate ($LiIO_3$). The bulk of the work reported in the present paper is devoted to this topic.

Another aim of the work is to develop a sensitive recording system for PSL processes. The usual single-channel photoelectric recording system makes essentially no use of such properties of PSL as the creation of completely correlated photon pairs. Single-channel detection does not offer much promise as far as improvement of the sensitivity is concerned. On the other hand, the correlation of the photon pairs can be used to experimentally distinguish PSL from other forms of scattering and to determine the specific scattering mechanism. Accordingly,

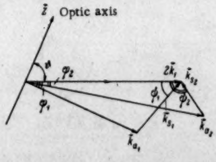

Fig. 1. Four-photon wavevector matching in principal plane of crystal for a varying frequency ω_a. φ_1, φ_2 are the angles between the direction of propagation of the pump wave $\mathbf{k}_1$ and the antistokes wave $\mathbf{k}_a$ for the different values of ω_a; ψ_1, ψ_2 are the angles for the Stokes wave; θ is the angle between the optic axis of the crystal $\mathbf{z}$ and $\mathbf{k}_1$.

in the present work we utilize a two-channel counting technique with subsequent application of a coincidence circuit. As a result, we can experimentally record four-photon PSL in $\mathrm{LiIO_3}$ using pumping with a cw He–Ne laser ($\lambda_1 = 0.63\mu$) with a power of 20 mW. (For comparison we mention that to date, on account of the small conversion coefficient, four-photon PSL has been investigated only in the field of pulsed Q-switched lasers with powers of the order of several megawatts). The scattering power at the antistokes frequency ω_a is $P_a = 9 \cdot 10^{-16}$ W. A corresponding theoretical calculation of the tuning and power characteristics of the various four-photon PSL mechanisms implies that the detected P_a corresponds to cascade PSL on the quadratic nonlinearity, the scattering proceeding through generation of the idler frequency.

TUNING CURVES

This section deals with the tuning curves for four-photon parametric scattering in $\mathrm{LiIO_3}$. As is well known, in PSL the intensity of the radiation at a given frequency has a sharp maximum in directions defined by the phase-matching condition (1)-(3). The parametric frequencies ω_s and ω_a are arbitrary in principle and lie in the transparency bands of the medium. For noncollinear interaction, when the direction of the radiation at the scattered frequency makes a certain angle φ with the direction of the pump radiation, a continuous spectrum of frequencies is emitted in the φ direction. This contrasts with the case of collinear interaction ($\varphi = 0$), in which the frequencies ω_s and ω_a are determined by the orientation of the nonlinear medium relative to the direction of propagation of the pump wave.

The tuning curves for direct four-photon PSL (1) are calculated from the condition that $\Delta = 0$, which determines a certain conical surface. This condition limits the possible frequencies of emitted photons. Formally, this follows from the requirement that $|\cos \varphi| \leq 1$; the sign of the equality corresponds to the limiting values of the frequencies for photons emitted along the direction of the incident light.

1. First we consider the tuning curves when the interacting waves have the same polarization; this analysis also holds for an isotropic medium. If all the interacting waves have ordinary polarization, the phase-match surface $\Delta = 0$ is a circular cone whose axis is directed in the direction of propagation of the pump wave. A straightforward analysis leads to the following picture of the emission of the parametric frequencies ω_s and ω_a in the region of transparency of the crystal. When $\omega_s = \omega_a = \omega_1$ both the created photons are emitted in the forward direction (degenerate collinear interaction). As ω_a is increased a deviation from this direction is observed: With increasing ω_a the angle φ first increases and then decreases (Fig. 1). Finally, at a certain frequency $\omega_a' = \omega_1 + \tilde{\omega}$ ($\tilde{\omega} > 0$) determined by the scalar condition $k_a(\omega_1 + \tilde{\omega}) - k_s(\omega_1 - \tilde{\omega}) = 2k_1(\omega_1)$, the wave vectors $\mathbf{k}_a$ and $\mathbf{k}_s$ are antiparallel. The angle ψ between the directions of propagation of the photons ω_s and ω_1 varies from 0 to 180°; scattering for $\psi > 90°$ is called backward-wave scattering. (This sort of scattering was observed by Weinberg[8] in water). A frequency $\omega_a'(\omega_a' \leq 2\omega_1)$ at which scattering occurs at an angle $\psi = 180°$ always exists for transparent media.

2. If waves of different polarization participate in four-photon PSL, the region of variation of the antistokes frequencies ω_a is reduced as compared with the case considered above. Separate allowed regions of ω_a are possible here; the boundaries are given for values below ω_a'. In all these cases the boundary value of the frequencies ω_a and ω_s corresponds to propagation of the scattered waves in the pump direction.

The family of calculated tuning curves for process (1) in the $\mathrm{LiIO_3}$ crystal at a pump wavelength $\lambda_1 = 0.63\,\mu$ is shown in Fig. 2a (collinear interaction) and in Fig. 2b (noncollinear interaction). In the first case tuning is accomplished by varying the angle θ between the crystal optic axis and the direction of propagation of the pump wave. In the second, tuning is accomplished by varying the angles of observation φ and ψ. The curves of Fig. 2 are calculated utilizing the refractive index values of Nath and Haussühl.[14]

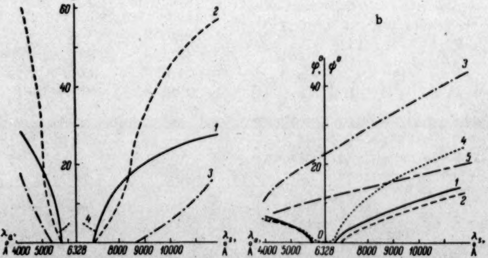

Fig. 2. a) Tuning curves for direct four-photon parametric scattering for different types of collinear interaction in $\mathrm{LiIO_3}$ crystal ($\lambda_1 = 0.63\ \mu$): $2k_1^0$: 1) $k_s^0 + k_a^e$; 2) $k_s^e + k_a^0$; 3) $k_s^e + k_a^e$; 4) $k_s^0 + k_a^0$; o and e denote ordinary and extraordinary waves respectively. b) Case of noncollinear interaction ($\lambda_1 = 0.63\ \mu$): 1) $2\mathbf{k}_1^e = \mathbf{k}_s^e + \mathbf{k}_a^e$, $\vartheta = 45°$; 2) $2\mathbf{k}_1^e = \mathbf{k}_s^e + \mathbf{k}_a^e$, $\vartheta = 90°$; 3) $2\mathbf{k}_1^e = \mathbf{k}_s^0 = \mathbf{k}_a^0$, $\vartheta = 90°$; 4) $2\mathbf{k}_1^0 = \mathbf{k}_s^0 + \mathbf{k}_a^0$, ϑ arbitrary; 5) $2\mathbf{k}_1^e = \mathbf{k}_s^0 + \mathbf{k}_a^e$, $\vartheta = 45°$; the values of the angles are given internal to the crystal.

In order to obtain a wide tuning range for collinear interaction in negative crystals ($LiIO_3$, for example), a pump wave with ordinary polarization must be used; for positive crystals, the pump wave must be polarized as an extraordinary wave.[10]

3. For the same pump waves and Stokes and antistokes waves, an obvious relationship holds between the wave-vector mismatches in the case of processes (1) and (2), (3), namely: $\Delta = \Delta_s + \Delta_a = \Delta_2 + \Delta'$. The tuning curves of process (1) ($\Delta = 0$) are thus the locus of points satisfying the condition $\Delta_s = -\Delta_a$ and $\Delta_2 = -\Delta'$. For processes (2) and (3) the case of double resonance is possible, when $\Delta_s = \Delta_a = 0$ and $\Delta_2 = \Delta' = 0$, which occurs on the curve of the intersection of the matching surfaces $\Delta_a = 0$ and $\Delta_s = 0$ or $\Delta_2 = 0$ and $\Delta' = 0$. In this case the matching condition of process (1) is automatically satisfied on this curve (compare with ref. 13). Thus, situations are possible in which the same frequencies ω_a and ω_s are created synchronously at the same angles for the cascade and the direct mechanisms of four-photon PSL.

It should be noted that in cascade processes (2) and (3), the frequency ω_0 or ω_2 may fall within the absorption band of the medium, making the calculation of the tuning curves more difficult.

EXPERIMENTAL METHOD AND RESULTS

1. As mentioned in the introduction, we measure four-photon parametric scattering in the $LiIO_3$ crystal by a photocounting technique in which signals at the frequencies ω_s and ω_a are recorded through separate channels with subsequent extraction of time-correlated pulses from both channels by a coincidence circuit.[15-17] A great improvement in the sensitivity of the system over the usual single-channel recording method is achieved by reduction of the noise level through the use of the coincidence circuit. An especially important feature of the present method is that the Stokes and anti-Stokes frequencies created simultaneously in the one event can be recorded. This becomes very significant in the case of cascade processes, when the scattering intensity at the frequency ω_a appearing in the second stage of the scattering is much smaller than the scattering intensity at frequency ω_s.

It should be noted that three-photon parametric scattering can not give coincidences; both the photons created in this case are Stokes photons and, after the spectrograph used in the experiment, they enter the same channel of the recording system. What is recorded in fact is the scattering power at the anti-Stokes frequency as the coincidence circuit generates a useful pulse only when an antistokes photon appears in one of the channels; this photon is correlated with the Stokes photon in the other channel. The detectors are two FÉU-79 photomultipliers, the measured quantum efficiencies of which are 5 and 1%, respectively. The resolving time of the coincidence circuit is 6 nsec.

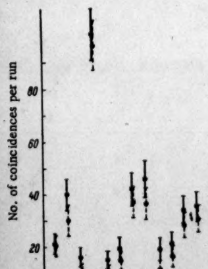

Fig. 3. Number of coincidences with crystal n_0 (solid bars) and normalized number of (noise) coincidences without crystal n_N (dashed bars) in various runs. The lengths of the bars correspond to the dispersion of the number of coincidences $2\sqrt{n_0}$ and $2\sqrt{n_N}$.

The sensitivity threshold of the recording system (the signal/noise ratio is unity) is determined in the experiment by the level of stray illumination from the laser, being 10^{-19} W for red light ($\hbar\omega = 3 \cdot 10^{-19}$ w). With this sensitivity it is possible to use the beam from a cw He–Ne laser ($\lambda_1 = 0.63\ \mu$); the power at the input to the nonlinear crystal $P_1 = 18$ mW.

2. In the experiment we observe the transformation $2\mathbf{k}_1 \rightarrow \mathbf{k}_s + \mathbf{k}_a$ in the $LiIO_3$ crystal. The optic axis of the crystal subtends an angle of 45° with the direction of propagation of the pump wave, which is an extraordinary wave. The geometry of the experiment is dictated by the need to satisfy two conditions: First, the frequencies ω_a and ω_s, for which the matching condition is satisfied, must lie within the region of sensitivity of the recording system; second, the magnitude of the working component of the nonlinear susceptibility tensor must be a maximum. The latter condition is satisfied when the parametric waves are also waves of extraordinary polarization. Accordingly, the main difficulty consists of reducing the stray illumination from the laser to a level comparable with the intrinsic noise of the photomultipliers. Two successive Fabry–Perot reflection etalons are used as a narrow-band light filter with selective absorption at the pump frequency. This reduces the number of coincidences from laser illumination by eight orders of magnitude. The illumination is reduced further by using a high-transmission spectrograph, at the output of which is located a mirror slot tuned for transmission of the pump radiation. The parametric radiation reflected from the planes of the slot goes to the photomultipliers through bandpass interference filters. The transmission coefficient of the entire optical system (the attenuation of the signal by the system) is 800 for the parametric frequencies.

The scattered radiation is collected in the range of angles from $\varphi_0 \simeq 0.3$ to $\varphi \simeq 3°$ within the crystal, which corresponds to wavelengths 0.68–0.75 μ for the Stokes components and to wavelengths 0.53–0.58 μ (Fig. 2b) for the anti-Stokes components.

3. The experimental procedure requires statistical processing of the results. The experiment consists of several runs of 45 min each. We measure the total number of coincidences n_0 (i.e., including both true coincidences from the parametric frequencies and noise coincidences) and the number of coincidences without the crystal n_N (noise coincidences). The intensity of the anti-Stokes scattering is determined from the amount by which n_0 exceeds n_N, i.e., from $n_a = n_0 - n_N$. The quantities n_0 and n_N are normalized to the same value of the product[1)] $n_{N1}n_{N2}$, where n_{Nj} is the number of noise pulses in each recording channel. (The number of coincidences n_N de-

pends only on the product $n_{N1}n_{N2}$ for small loading of the channels[18].

The experimental values of n_0 and n_N in various runs are given in Fig. 3. The value of n_a averaged over all runs is six coincidences per run. An estimate of the reliability of this experimental quantity n_a using Student's criterion (see ref. 18) gives a 98% confidence limit. We can thus assert that $n_a = 6$ coincidences per run is statistically significant. This value of n_a corresponds to a scattering power at the anti-Stokes frequency ω_a of $P_a^{\exp} = 9 \cdot 10^{-16}$ W measured immediately after the crystal (pump power $P_1 = 18$ mW). When allowance is made for the accuracy of measurement of the transmission coefficient of the optical system and the accuracy with which the quantum efficiency of the radiation detectors is determined, we find $P_a^{\exp} = (9 \pm 3) \cdot 10^{-16}$ W.

We conclude this section by pointing out an important experimental fact: Within the limits of accuracy of the experiment, the observed scattering power does not depend on the focusing of the pump radiation in the crystal.

DISCUSSION

In order to interpret the experimentally obtained value of the scattering power and to ascertain the specific scattering mechanism, the conditions of the experiment must be analyzed and the scattering intensity for the various four-photon parametric-scattering mechanisms (1)-(3) estimated.

However, we recall that our coincidence system discriminates against other possible mechanisms of creating both Stokes and anti-Stokes light photons in addition to (1)-(3) (thermal noise processes,[4,19] for example, which give rise to uncorrelated photons).

Let us now consider the power characteristics of four-photon PSL.

1. In the case of direct four-photon PSL on the cubic nonlinearity $\hat{\theta}$, the power P_Ω scattered per unit solid angle at the anti-Stokes frequency is given by the expression[20] (in the approximation of plane monochromatic waves)

$$P_\Omega = \frac{4\pi^2 \hbar \omega_a^4 \omega_s n(\omega_a) \theta^2 |v|}{c^6 n^2(\omega_1) n(\omega_s)} V S_1^2, \tag{4}$$

where $\theta = \Sigma e_{ai}\theta_{ijkl}e_{1j}e_{1k}e_{sl}$, e_m are the components of the unit polarization vector; $v = [(1/v_a)\cos(\varphi + \psi) - (1/v_s)]^{-1}$; v_s, v_a are the group velocities of the Stokes and anti-Stokes waves; V is the scattering volume; S_1 is the pump intensity and $S_1 = P_1/\pi r^2$, where P_1 is the pump power; πr^2 is the cross-sectional area of the pump beam; and $n(\omega)$ are the indices of refraction. The scattering power is thus proportional to the square of the pump power, is linearly dependent on the length of the nonlinear medium, and is inversely proportional to the area of the pump beam. Focusing of the pump beam can thus be used to increase the scattering intensity, unlike the case of three-photon PSL. For noncollinear interaction, however, the situation is complicated by the emergence of the rays from the interaction volume, which leads to a reduction of the coherence length in focusing. Allowance must be made for the effect of these two factors. Figure 4a shows the general form of the variation of anti-Stokes scattering power P_Ω with angle of observation φ for noncollinear interaction.

The total power P_a emitted at all anti-Stokes frequencies within a given receiver solid angle $\Delta\Omega$ is obtained by integrating expression (4). For small φ, allowing for the emergence of the rays from the interaction volume, we obtain

$$P_a = \frac{64\pi\hbar\omega_a^4\omega_s n(\omega_a)}{3c^5 n^2(\omega_s) n^2(\omega_1)} \left(\frac{1}{\varphi_0} - \frac{1}{\varphi}\right) \frac{\theta^2}{2r} P_1^2, \tag{5}$$

where P_1 is the power of the pump wave, 2r is the diameter of the pump beam, and φ_0 is the lower limit of integration (it is assumed that $\varphi_0 \geq 2r/L$, where L is the length of the crystal).

The quantity P_a represents the integrated scattering power collected in the angular range from φ_0 to φ. It can be seen from (5) that the scattering power can be increased by focusing the pump beam (compare with ref. 4). Figure 4b shows a plot of P_a as a function of the parameter φ/φ_0. Evidently, 90% of the total scattering power lies within an angle $\varphi \simeq 10\,\varphi_0$. Under the conditions of our experiment ($r = 60\,\mu$ and L = 3 cm) this corresponds to an angle $\varphi \simeq 3°$ (angles are given within the crystal).

2. For the case of cascade four-photon PSL on the quadratic nonlinearity $\hat{\chi}$, the scattering power does not depend on the focusing.[4] A theoretical comparison of the efficiency of cascade and direct four-photon PSL is given in refs. 4 and 21. It is shown in ref. 4 that for a transparent medium and a planar monochromatic pump wave, the ratio of the scattering amplitudes at the anti-Stokes frequency due to $\hat{\chi}$ (for example, through the idler wave λ_0) and due to $\hat{\theta}$ is given (for $\Delta = 0$) by

$$\frac{A_\chi}{A_\theta} = \frac{4\pi^2}{n(\omega_0)\Delta_a\lambda_0} \frac{\chi^2}{\theta} \tag{6}$$

(for $\Delta_a = 0$ the quantity Δ_a^{-1} is formally replaced by L/2).

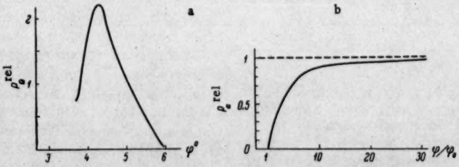

Fig. 4. a) Relative scattering power per unit solid angle P_Ω^{rel} versus angle of observation φ within $LiIO_3$ crystal for propagation of pump wave ($\lambda_1 = 0.63\,\mu$) along optic axis. b) Relative integral scattering power P_a^{rel} collected from scattering angles from φ_0 to φ versus ratio φ/φ_0.

Cascade conversion through the second harmonic [process (2)] in the present case goes more efficiently than conversion through the idler wave [process (3)] because of the joint effect of the strong absorption at the harmonic wavelength and the large wavevector mismatch in the $LiIO_3$ crystal at double the frequency of the pump wave $\lambda_1 = 0.63\ \mu$. Accordingly, we compare the efficiencies of the cascade process through the idler wave λ_0 and of direct four-photon PSL.

When all the interacting waves are extraordinary,[2] the maximum values of the working components of the nonlinear susceptibility tensors of $LiIO_3$ are $\chi \simeq 2.4 \cdot 10^{-8}$ cgs esu for the cascade process through the idler wave λ_0, and $\theta \simeq 2.1 \cdot 10^{-13}$ cgs esu for direct scattering. (The numerical values of the components of tensors $\hat{\chi}$ and $\hat{\theta}$ are taken from refs. 22-24; dispersion is ignored). These estimates assume that the Stokes and anti-Stokes photons are created at small angles relative to the direction of propagation of the pump wave. The angle between the direction of emission of the idler frequency and the pump frequency for $\Delta_a = \Delta_s = 0_s$ is about 10°, and the refractive index at the idler frequency (for example, $\lambda_0 \simeq 6\ \mu$) $n(\omega_0) \simeq 1.9$.

In the present case (6) is given by

$$\frac{A_\chi}{A_\theta} \simeq 1.4 \cdot 10^2. \tag{7}$$

Estimate (7) shows that in the present case cascade conversion in $LiIO_3$ goes much more efficiently than direct scattering.

3. Let us now compare the experimentally measured scattering power, $P_a^{\exp}$, with the powers calculated for direct scattering (P_a) and for cascade scattering through the idler wave ($P_{a,\chi}$).

In the case of four-photon parametric scattering on the cubic nonlinearity $\hat{\theta}$, the power of the radiation at the anti-Stokes frequency is given by expression (5). Under the conditions of the experiment [$P_1 = 18$ mW, $r = 60\ \mu$, $\theta = 2.1 \cdot 10^{-13}$ cgs esu, $\varphi_0 = 0.3°$, $\varphi = 3°$, $\omega_a \simeq \omega_s \simeq 3 \cdot 10^{15}\ \sec^{-1}$, $n(\omega_1) \simeq n(\omega_s) \simeq 1.8$] this leads to the value $P_a \simeq 2.5 \cdot 10^{-19}$ W. Thus, the experimentally measured power exceeds the power of scattering on $\hat{\theta}$ by more than three orders of magnitude:

$$P_a^{\exp}/P_a \simeq 3.6 \cdot 10^3. \tag{8}$$

A theoretical estimate for $P_{a,\chi}$ can be obtained with the aid of (7). In the cascade process, if the double matching condition is satisfied for one set of frequencies ω_s, ω_a, and ω_0, the power of the anti-Stokes emission is determined[20] by the angular width of the tuning curve $\Delta\theta$; in the direct process it is determined by the detection solid angle $\Delta\Omega$. As a result, for $\varphi \simeq 3°$

$$\frac{P_{a,\chi}}{P_a} = \frac{A_\chi^2}{A_\theta^2} \frac{\Delta\theta}{\Delta\Omega} \simeq 4.8 \cdot 10^3. \tag{9}$$

It can be seen that (8) and (9) are close in value. The difference is probably due to the fact that absorption at the idler frequency is ignored in (9). (For $LiIO_3$ the absorption coefficient is around $0.8\ \text{cm}^{-1}$ at $\lambda \simeq 6.0\ \mu$).

Thus, the measured power $P_a^{\exp}$ agrees with the model of a cascade process going through the idler wave.

The above estimates assume that cascade process (3) proceeds synchronously ($\Delta_a = \Delta_s = 0$); as already mentioned, this condition is satisfied if the refractive index $n(\omega_0) \simeq 1.9$ at $\lambda_0 \simeq 6\ \mu$, for example. Further, the $LiIO_3$ crystal has an absorption band from $\simeq 5.6$ to $6.5\ \mu$, for which the value of $n(\omega)$ is unknown; however, near the absorption band, at $\lambda \simeq 5.0\ \mu$, the refractive index $n \simeq 1.82$ (see ref. 25).

The double-matching conditions $\Delta_a = \Delta_s = 0$ must be satisfied, however, on account of the anomalous dispersion in the absorption region and the broad recorded spectrum of scattered waves, corresponding to a range of idler wavelengths from 3.3 to 6.7 μ. Also, an idler wave satisfying the double-matching condition can have extraordinary or ordinary polarization. However, for a cascade process involving an ordinary idler wave, the working component of the tensor $\chi = 2.8 \cdot 10^{-9}$ cgs esu is less than for an extraordinary wave $\chi = 2.4 \cdot 10^{-8}$ cgs esu. Thus, the main process in four-photon PSL in $LiIO_3$ is a cascade process going through an idler wave with extraordinary polization.

CONCLUSION

The results of our experiments can be summarized as follows.

1. The anti-Stokes and Stokes frequencies ω_a and ω_s are recorded by the measuring system. The corresponding photons go to different channels of the system (inorcoporating two photomultipliers) after separation in the spectrograph.

2. The frequencies ω_a and ω_s are correlated in time by feeding the signals from the photomultiplier outputs to a coincidence circuit.

3. The scattering power is determined from the amount by which the total number of coincidences exceeds the number of coincidences obtained with the crystal removed; it is $P_a^{\exp} = (6\text{–}12) \cdot 10^{-16}$ W. Within the limits of experimental error $P_a^{\exp}$ does not depend on the focusing of the pump radiation in the crystal.

These facts, in conjunction with the theoretical estimates (8) and (9), indicate that the recorded process in $LiIO_3$ is one of cascade parametric scattering through the idler wave [process (3)].

In order to observe direct scattering on the cubic nonlinearity $\hat{\theta}$, one must use a centrosymmetric medium, in which $\hat{\chi} = 0$ (see refs. 8-12), or a different experimental geometry such that two pump quanta are directed at a large angle to each other.[7] The experimental value of the observed scattering power coincides in this case with estimates via expression (5).

We thank S. A. Akhmanov for critical remarks and assitance, and D. N. Klyshko for discussion.

---

[1] The values of n_{N1} and n_{N2} averaged over 10 sec are measured in turn in the course of each run. Even slight drifts in laser power in the time of a run can be monitored in this manner.

[2)] It is shown later in this section that in our experiment the matching conditions for three-photon processes can be satisfied for such waves as a result of anomalous dispersion.

Vaporization and boiling of liquid metal in an exploding wire

M. M. Martynyuk

Patrice Lumumba People's Friendship University, Moscow

(Submitted November 28, 1972; resubmitted August 9, 1973)
Zh. Tekh. Fiz., 44, 1262-1270 (June 1974)

Using the thermodynamics and kinetics of vaporization and boiling it is shown that the main factor in the electrical explosion of a wire is explosive boiling of superheated liquid metal. When certain conditions are satisfied the initial point of the electrical explosion must be in the neighborhood of the boundary for thermodynamic stability of the liquid metal phase.

Electrical explosion of a wire occurs in heating by a sufficiently strong current pulse. Thus far, there is no single theory which can explain all the phenomena observed in this process. At the same time, an explanation of the nature of an electrical explosion is important not only from the purely scientific point of view, but for the practical use of exploding wires (plasmotrons, pulsed tubes for laser pumping).

The experimental data indicate that the electrical explosion of a wire is associated with the conversion of a portion of the liquid metal into vapor and then into the plasma state; therefore, it is important to consider this phenomenon from the viewpoint of the thermodynamics and kinetics of the liquid–vapor phase transition, which is the purpose of the present study. To simplify the problem, we first neglect many factors which accompany the pulsed heating of a wire by a current (skin effect, magnetic pressure, and MHD instabilities); their effect will be discussed at the end of the paper in a description of the nature of an electrical explosion. The one factor on which we concentrate is the heating rate. It will be shown that for a given rate of heating considerable superheating of the liquid metal phase above its boiling point is possible; we therefore consider first certain problems in the thermodynamics of superheated liquids.

1. SUPERHEATED LIQUID AND ITS THERMODYNAMIC STABILITY BOUNDARY

According to Gibbs' thermodynamic theory,[1] there are two upper limits to the existence of the liquid phase; the binodal line, the equilibrium curve for the liquid and vapor, and the spinodal line, the boundary of thermodynamic stability of the liquid phase in continuous change. Between these boundaries there is a region of metastable (superheated, overexpanded) liquid. In crossing the spinodal line loss of stability of the liquid phase occurs; therefore at points on the spinodal line the thermodynamic stability coefficients go through zero:[2]

$$-\left(\frac{\partial p}{\partial V}\right)_T=0,\quad \left(\frac{\partial T}{\partial S}\right)_p=0 \tag{1.1}$$

(T is the temperature, S the entropy, p the pressure, and V the volume).

Since these coefficients are inversely proportional to the fluctuations[3]

$$-\left(\frac{\partial p}{\partial V}\right)_T=\frac{kT}{\overline{V^2}-\overline{V}^2},\quad \left(\frac{\partial T}{\partial S}\right)_p=\frac{kT^3}{\overline{H^2}-\overline{H}^2} \tag{1.2}$$

(k is the Boltzmann constant and H is the enthalpy), a sharp rise in the fluctuations in the liquid occurs near the spinodal line, which is also a reason for its breakdown over the entire volume. In the neighborhood of the spinodal line the electrical resistance of a liquid metal should rise sharply because of electron scattering by density fluctuations and because of localization of electron conductivity in small volumes of the liquid. To the right of the spinodal line (see Fig. 1) there is a region of unstable states for which the phase stability coefficients are negative; these states can only be realized in pronounced nonequilibrium processes such as explosions.

The van der Waals equation

$$\pi=\frac{8\tau}{3\varphi-1}-\frac{3}{\varphi^2} \tag{1.3}$$

($\pi = p/p_k$, $\tau = T/T_k$, $\varphi = V/V_k$; the subscript "k" refers to critical parameters) according to Eq. (1.1) yields the following equation for the spinodal line;

$$4\tau_c\varphi_c^3-9\varphi_c^2+6\varphi_c-1=0 \tag{1.4}$$

(the subscript "c" refers to the spinodal line). Fürth[4] obtained the following expression for the spinodal line on the basis of the statistical theory for vacancies in a superheated liquid:

$$p-p_c=1.32\sigma^{3/2}(kT)^{-1/2}, \tag{1.5}$$

where p and p_c are the pressures at points on the binodal and spinodal lines for the temperature T; σ is the surface tension at the vapor–liquid boundary for that temperature. Skripov has pointed out a number of important properties of the spinodal line.[5]

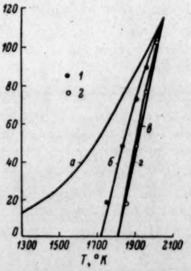

Fig. 1. State diagram for cesium in the high-temperature region. a) Binodal line from experimental data[6]; b) van der Waals spinodal line; c) Fürth spinodal line; d) straight-line approximation to spinodal line. Points are calculated from the theory for homogeneous nucleation; 1) 1; 2) $4\cdot10^{23}$.

Figure 1 is a state diagram for liquid cesium showing the binodal line according to experimental data[6] and the spinodal lines calculated from the van der Waals and Fürth equations. The values of σ needed for the calculation are obtained by linear extrapolation of data from ref. 7. As is evident, the Fürth and van der Waals lines in the figure do not coincide. It has been shown[5] that the Fürth spinodal line agrees better with experimental data in the case of organic liquids and thus one can assume that the Fürth spinodal line is also closer to reality in the case of liquid metals. The cesium spinodal line can be closely approximated by a straight line passing through the intersection of the Fürth spinodal line with the T axis (T_c = 1806°K = $0.9T_k$) and through the critical point (see Fig. 1). [For cesium, T_k = 2033°K and p_k = 116 bars (ref. 6).] The slope of this line in the reduced coordinates π, τ is 10, which is in practical agreement with the slope of the experimentally measured line for maximum superheating of organic liquids.[5] Thus one can write for the cesium spinodal line

$$\frac{p_c}{p_k}=\frac{10T_c}{T_k}-9. \tag{1.6}$$

For cesium, the melting temperature T_f = 301.8°K and the temperature for normal boiling T_0 = 955°K; Eq. (1.6) indicates that the maximum relative superheating for a continuous change in the liquid phase of cesium at p = 1 atm is $\beta_c = (T_c - T_0)/T_0 = (\tau_c - \tau_0)/\tau_0 = 0.89$; in this case the temperature range of the liquid state increases by a factor $(T_c - T_f)/(T_0 - T_f) = 2.3$ as compared to the range for discontinuous change.

2. HOMOGENEOUS NUCLEATION IN A SUPERHEATED LIQUID AND REALIZATION BY PULSED HEATING

The creation of homogeneous vapor nuclei in a defect-free volume of superheated liquid is accompanied by an increase in the Gibbs free energy; this process is possible because of fluctuations in the superheated liquid. In the formation of a spherical critical nucleus this increase is[8]

$$\Delta G_k=\frac{16\pi\sigma^3}{3g^2}, \tag{2.1}$$

where g is the difference between G_L the free energy per unit mass of the superheated liquid and G the free energy of the vapor, calculated per unit volume of the vapor; the parameter g characterizes the depth of penetration into the region of metastable states.

A given metastable state at the point (p_0, T) can be reached in two ways: a) by reducing the pressure from p to p_0 at constant T (p is the pressure of saturated vapor at the temperature T); b) by raising the temperature from T_0 to T at constant p_0 (T_0 is the boiling point at the pressure p_0). In the first case we obtain an expression for g by expansion of G_L and G in a series at the point (p, T) over the range ($p - P_0$); the linear approximation yields

$$\Delta G_k=\frac{16\pi\sigma^3}{3\left[\left(1-\frac{\rho}{\rho_L}\right)(p-p_0)\right]^2}, \tag{2.2}$$

where ρ_L and ρ are the liquid and vapor densities at the point (p, T). For the second case, a similar expansion of G_L and G at the point (p_0, T_0) over the range $T - T_0$ with $p = p_0$ constant leads to

$$\Delta G_k=\frac{16\pi\sigma^3}{(3\rho_0\lambda_0\beta)^2}, \tag{2.3}$$

where ρ_0 is the density of saturated vapor, λ_0 is the specific heat of vaporization at the point (p_0, T_0) and $\beta = (T - T_0)/T_0$ is the relative superheat. Equation (2.3) indicates that a reduction in G_k occurs as the superheating increases; consequently the probability for the formation of a homogeneous nucleus increases.

The rate of homogeneous nucleation at a temperature T is, according to classical theory,[9]

$$I=B\exp\left[-\frac{\Delta G_k}{kT}\right], \tag{2.4}$$

where B is a function which depends weakly on temperature and pressure in comparison with the exponential factor; only the order of magnitude of B is important in the calculation of I. The Becker–Dehring–Volmer theory[9] using experimental data for Fürth spinodal points far from the cesium critical point gives $B = 1.5 \cdot 10^{32}$ cm^{-3} · sec^{-1}. For this value of B two series of points on the cesium p–T diagram are calculated using Eqs. (2.2) and (2.4) (see Fig. 1) for two values of I; in the calculation, experimental data are used for σ (ref. 7), λ (ref. 10), ρ and ρ_L (refs. 6, 11). The first series corresponds to a value I = 1 cm^{-3} · sec^{-1} and the second to I = $4 \cdot 10^{23}$ cm^{-3} · sec^{-1} (for the laser value of I, there arises in liquid Cs in 1 μsec a number of homogeneous nuclei which is 0.01% of the total number of atoms and approximately corresponds to the condition for an electrical explosion). In the first case the points fall on the van der Waals spinodal line and in the second case, on the Fürth spinodal line. These calculations show that I increases rapidly during heating of a superheated liquid: for p = 1 atm, I for Cs varies from 1 to $4 \cdot 10^{23}$ · cm^{-3} · sec^{-1} over the comparatively narrow temperature range from 1720 to 1806°K. The calculations also show that considerable superheating above the boiling point is necessary for the realization of homogeneous nucleation in liquid metal ($I \geq 1$ cm^{-3} · sec^{-1}).

Equation (2.4) is applicable to stationary homogeneous nucleation. The nucleation rate I(t) under nonstationary conditions is related to I by[12]

$$I(t)=I\exp\left[-\frac{\tau}{t}\right], \tag{2.5}$$

where t is time and τ is the time for establishment of stationary nucleation after instantaneous superheating of the liquid. For ordinary liquids and moderate superheating, estimates[5,8] of τ give value of 10^{-8}–10^{-7} sec.

Significant superheating of the liquid and homogeneous nucleation are not achieved at low rates of heat deposition, since practically all the heat goes into the growth of heterogeneous vapor nuclei (ordinary boiling) which arise in the liquid at already existing centers (for example, gaseous inclusions) at insignificant superheating. The number of these centers in the liquid is comparatively small and depends weakly on temperature. At a sufficiently high heating rate the time for superheating the liquid is small and the mass of material which is vaporized within heterogeneous nuclei will be insignificant; therfore, the achievement of high superheating and intense homogeneous nucleation is possible. This boiling mode (shock mode) is discussed by Skripov and Pavlov.[13] In organic liquids and water this mode is realized by through pulsed heating of a platinum wire submerged in the liquid; in this case the points of violent boiling of the superheated liquid are in good agreement with the Fürth spinodal line.

We estimate the heating rate for which significant superheating of the liquid metal is achieved along with explosive boiling created by a sharp increase in the number of homogeneous vapor nuclei. We assume that the growth rate of the vapor bubbles is limited only by the vaporization kinetics; this assumption is obviously completely valid for an exploding wire. According to the Hertz–Knudsen equation,J, the molecular flux of material vaporized from the surface of a liquid at temperature T is[8]

$$J=\frac{\alpha(p-p_0)}{(2\pi mkT)^{1/2}}, \tag{2.6}$$

where α is the vaporization coefficient, m is the mass of the vapor molecule, k is the Boltzmann constant, p is the pressure of saturated vapor at the temperature T, and p_0 is the vapor pressure above the surface of the liquid. If the liquid is superheated instantaneously from the boiling point T_0 to T with $p = p_0 = \text{const}$, Eqs. (2.2) and (2.6) show that the rate of vaporization within a spherical bubble produced far from the critical point is

$$\frac{dM}{dt}\frac{\alpha m\lambda_0\rho_0 S\beta}{(2\pi mkT)^{1/2}},$$

where dM is the mass of material vaporized in time dt. If the volume of the bubble is V and the mass of vapor is M, the surface area S is

$$S=(36\pi V^2)^{1/3}=\left(\frac{36\pi}{\rho^2}\right)^{1/3}M^{2/3},$$

where ρ is the vapor density in the bubble at a temperature T. Making the substitution $\beta = \gamma t^n/T_0$ (t is the time taken in heating liquid metal from T_0 to T; γ and n are constant), we obtain

$$M^{-2/3}dM=\frac{K\gamma t^n}{T_0}dt, \tag{2.7}$$

where

$$K=\frac{\alpha m\lambda_0\rho_0(36\pi)^{1/3}}{(2\pi mkT)^{1/2}\rho^{2/3}}, \tag{2.8}$$

K is a weakly varying function of T and we shall take it to be a constant. Through integration of Eq. (2.7) we obtain an expression for ε, the fraction of the liquid which is vaporized within all heterogeneous nuclei in heating from T_0 to T,

$$\varepsilon=C\left[\frac{3K\gamma}{T_0(n+1)}\right]^3 t^{3(n+1)}, \tag{2.9}$$

where C is the number of identical heterogeneous nuclei per unit mass of liquid; it is assumed C is independent of temperature. If ε_0 is the maximum permissible value of ε, then for $\varepsilon \le \varepsilon_0$ and $n = 1$ we find a condition for the heating rate γ for which a superheat β_C close to the maximum is possible,

$$\gamma \geqslant \frac{3kT_0C^{1/3}\beta_c^2}{2\varepsilon_0^{1/3}}. \tag{2.10}$$

When cesium is heated at a pressure p = 1 atm, $\beta_C = 0.89$ and $k = 5.2\cdot10^4\ \text{deg}^{1/3}\cdot\text{sec}^{-1}$ (for $\alpha = 1$). Assuming $C = 10^2\ \text{deg}^{-1}$ and $\varepsilon \le 10^{-2}$, from Eq. (2.10) we find that $\gamma \ge 10^9$ deg/sec, which corresponds to a pulse heating time of about 1 μsec.

To evaluate the sufficiency of the condition $\gamma \ge 10^9$ deg/sec it still is necessary to consider vaporization from the free surface of the metal. The Hertz–Knudsen equation shows that the rate of displacement of the interphase boundary, $U = I/n_L$ (n_L is the number of atoms of liquid per unit volume), for cesium near the spinodal line and p = 1 atm is about 10 m/sec. At this velocity the interphase boundary shifts by 10^{-3} mm in 0.1 μsec and this means that vaporization of metal from the free surface of the liquid can be neglected when $\gamma \ge 10$ deg/sec.

Equations (2.8) and (2.10) show that for metals containing impurities which are adsorbed on the surface, explosive boiling can be realized at lower values of γ than for pure metals; this is explained by the effect of those impurities on the reduction of the vaporization coefficient α. (Knudsen[14] has observed a reduction in α from 1 to 10^{-3} for mercury contaminated by surface impurities.)

3. NATURE OF ELECTRICAL EXPLOSION

The entire process of heating a wire with a current pulse lasting 10^{-6}–10^{-4} sec is often called an electrical explosion, but experimental facts indicate that the true explosion begins at a time at which the voltage on the specimen increases abruptly, and the current falls under conditions which exclude surface discharge and mechanical breakdown of the specimen. At this point a sharp increase is observed in the velocity of the shock wave created in the surrounding medium;[15] this is then taken to be the initial point of the electrical explosion.

In the description of the electrical explosion of a wire it is important to know the pressure acting on the surface of the wire during the heating pulse; only when this pressure is below the critical value are superheating and explosive boiling of the liquid phase possible (see Fig. 1). We now estimate this pressure for a wire heated in air.

In this case the equilibrium pressure of saturated vapor cannot be established above the surface of the wire because the heating time is short and the vapor can expand into the surrounding air. However, the vapor flux leaving the surface of the metal will produce a reactive pressure given by

$$p_J=\frac{\alpha p}{2\pi}. \tag{3.1}$$

as follows from Eq. (2.6) when $p_0 = 0$.

In a liquid conductor of radius r_0 carrying a current i, the magnetic pressure at a distance r from the axis is

$$p_m=\frac{\mu\mu_0 i^2}{4\pi^2 r_0^2}\left(1-\frac{r^2}{r_0^2}\right) \tag{3.2}$$

(μ is the magnetic permeability of the conductor material, $\mu_0 = 4\cdot10^{-7}$ H/m). When $r \to r_0$, $p_m \to 0$, i.e., the magnetic pressure is close to zero in the surface layer of the metal. The pressure p_{in} produced by the inertia of the surrounding air in thermal radial expansion of the wire by an amount Δr is $p_{in} = \rho_a v \Delta r$ in accordance with the acoustic equation (ρ_a is the air density and v is the velocity of sound in air); this quantity is small and can be neglected. Thus, only the reactive pressure p_p and atmospheric pressure p_{at} act on the surface of the wire. The reactive pressure is a maximum for pure conductors ($\alpha = 1$); for "dirty" conductors, $\alpha \leq 1$ and p_p is insignificant. In any case, $p_p < p$ and therefore the process of pulsed heating of the surface of a conductor in air, contrary to the ideas of David,[16] does not go along the binodal line, but crosses it and penetrates into the region of metastable liquids (see Fig. 1). Heating of the surface of a "dirty" conductor is roughly isobaric for $p_0 = p_{at}$.

To explain the nature of an electrical explosion from the viewpoint of the kinetics of the liquid–vapor phase transition, we start with the following simplifying assumptions: 1) MHD instabilities, magnetic pressure, and skin effect are unimportant; 2) the heating rate satisfies the condition (2.10) but is not so large as to break down the stationarity of homogeneous nucleation [see Eq. (2.5)]. We now show that under these assumptions the explosion point must lie in the neighborhood of the spinodal line.

As was shown above, pulsed heating must be accompanied by crossing of the binodal line and penetration into the region of metastable states. The heating of the metastable phase proceeds for a comparatively long time when only heterogeneous vapor nuclei are present; these have an insignificant effect on vaporization and boiling when the condition (2.10) is satisfied. Considerable superheating is required before the first homogeneous nuclei are created in the metal; thereafter the number of such nuclei increases in avalanche fashion. This state in the metastable phase can be achieved by nearly maximum superheating (see Fig. 1), in which the activation energy for the formation of a homogeneous critical nucleus (2.3) is reduced so much because of superheating that it becomes comparable with the fluctuation energy (1.2); therefore the dominant boiling effect is the fluctuation mechanism for the formation of vapor nuclei. A sharp rise in the number of homogeneous nuclei produces a rapid increase in the volume of the specimen, leading to the creation of a shock wave in the surrounding medium. At the same time, there is a pronounced increase in the electrical resistance of the conductor which also leads to a current discontinuity under suitable conditions (for example, an explosion in a dense atmosphere of inert gas). At the beginning of the discontinuity the specimen is in the form of a dense metallic vapor containing drops of superheated liquid; vaporization of these drops continues because of superheat energy. When the metal vapor expands to the extent that ionization becomes possible, a second current pulse occurs.

If an explosion occurs in a liquid dielectric and is accompanied by current cutoff at the point of explosion, an aerosol consisting of fine metal particles 0.01-0.06 μ in size remains in the dielectric.[17] The later in the explosion the current is cut off, the finer the aerosol particles, since the greater number of homogeneous nuclei leads to a finer subdivision of the metal.

For the conditions assumed above, therefore, the initial point of an electrical explosion must be in the immediate vicinity of a point on the spinodal line; this gives the point a completely definite thermodynamic meaning and is in agreement with the existence of an "energy threshold" for an electrical explosion.[19] An electrical explosion is, in fact, a thermodynamic explosion which consists of the transition of a metastable superheated liquid into a two-phase state. If the external pressure varies, the curve produced by the electrical explosion points lies close to the spinodal line. The spinodal line calculated above for cesium satisfies the rule for thermodynamic similarity when compared with the spinodal line found experimentally for a number of organic liquids.[5] If the existence of thermodynamic similarity for metals is assumed by analogy the electrical explosion of a metal should occur at temperatures satisfying Eq. (1.6).

A measure of the metastability of a liquid heated from the boiling point T_0 to T at a constant pressure p_0 is the quantity g_L, which is the difference between the free energy of the liquid and that of its saturated vapor at the temperature T calculated per unit mass. By analogy with Eq. (2.3)

$$g_L = \lambda_0 \beta. \tag{3.3}$$

For maximum superheating of cesium at p_0 = 1 atm, $g_L = 0.89\,\lambda_0$.

A measure of energy deposition during the transition of a metastable liquid into the two-phase state is the excess enthalpy of the superheated liquid $H(T) - H(T_0)$ which leads to vaporization of the liquid. In a rapid transition to the state defined by the point p_0 the fraction of vaporized liquid $x = [H(T) - H(T_0)]/\lambda_0$. For Cs, $x \approx 0.4$ at p = 1 atm. Thus in the electrical explosion of a wire in air the energy released can be roughly 40% of the heat of vaporization. With conversion to unit initial volume this amounts to ~ 4500 cal/cm^3 for Cu and ~ 8000 cal/cm^3 for W, which exceeds the energy release in the explosion of TNT (1460 cal/cm^3). If one recalls that the electrical explosion occurs in a time less than 1 μsec and that the duration of a chemical explosion is greater,[18] it follows that the power in an electrical explosion is greater than the power of conventional chemical explosives.

As follows from Fig. 1 and Eq. (3.3), the energy β_L released in an electrical explosion is reduced by the reduction in λ_0 and β_c when the external pressure is increased. When $p \geq p_k$ then $\beta_L = 0$, i.e., critical and supercritical transition of a liquid metal into the gaseous state[21] is not accompanied by superheating of the liquid phase and by the release of energy during pulsed heating; therefore it should not be called an explosion.

The possibilities of superheating of the liquid metal and explosive boiling in an electrical explosion have been discussed qualitatively by Chace;[22] however, Chace does not discuss kinematics of the liquid metal–vapor transition. Subsequently, Chace rejected this idea[23] and adopted the David viewpoint of the nature of an electrical explosion,[16] which does not agree with the present paper.

The picture of an electrical explosion given above is somewhat idealized since various factors are not taken into account. We first consider the effect of magnetic pressure on the process. As follows from Eqs. (3.1) and (3.2), in pulsed heating of a wire by a current only a thin layer of metal near the surface of the wire is at a pressure equal to $p_{at} + p_p$; the pressure increases toward the axis. Consequently, the explosive boiling of superheated liquid metal first occurs in this layer, after which the boiling front is rapdily displaced toward the axis of the wire. The time at which the boiling front reaches the axis also corresponds of the boiling front, which is determined by the rate of homogeneous nucleation (2.4), must be somewhat greater, in the neighborhood of a spinodal point, than the rate of displacement of the interface boundary during vaporization, $u = J/n_L$, which is determined by the Hertz–Knudsen equation (2.6). It is obvious that the displacement of the boiling front we have discussed is significantly different from the so-called "ablation"[23] which is observed with pronounced skin effect.

A stratification structure has been observed in x-ray shadowgraphs of exploding wires after the initiation of explosion. These pictures indicate that the explosion of a wire does not occur simultaneously along its length, but rather in separate cross sections with an alternation of exploding sections, and sections in which the metal remains liquid. From the standpoint of the theory developed here, the creation of a stratified structure can be explained as follows. In pulsed heating of a liquid conductor a sausage MHD instability can be excited for a short time (0.1-0.2 μsec). At the constrictions the specific rate of heat deposition and the temperature are greater; therefore maximum superheating will be achieved earlier at those points, and these become local centers for electrical explosion.

Explosive boiling of a metal is obviously not restricted to the surface of a conductor but can also occur in deeper layers. The latter is possible in the case where current cutoff in the circuit occurs as the surface layer approaches the spinodal. This leads to a disappearance of the magnetic compression at the internal layers and to a displacement of material from the axis in a radial direction. As a result of this displacement and the effects of inertial forces, the initial compression of material on the axis is replaced by rarefaction,[24] leading to earlier intense homogeneous nucleation in that region. The magnetic pressure itself may also be a cause for the "internal" explosion; the internal, more compressed layer has a higher electrical conductivity and consequently can be superheated more than layers near the surface.

What has been said here indicates the effect of magnetic pressure on an electrical explosion may appear in various forms. However, one can show on the basis of Eq. (1.6) that in any case, electrical explosion of any layer of the metal under positive pressure should occur in the comparatively narrow temperature range from $0.9T_k$ to T_k.

In conclusion, we point out once more that the scheme proposed here for an electrical explosion is realistic only when the heating rate satisfies the conditions specified above. For rates smaller than the value given by Eq. (2.10) the liquid conductor breaks down at insignificant superheating because of the growth of heterogeneous vapor nuclei. Breakdown can also occur at an earlier stage because of the screw instability.[19] In this case the abrupt increase in voltage may not have any thermodynamic meaning.

If the heating rate is so great that the stationarity (2.5) for homogeneous nucleation breaks down, it is impossible to apply any results from equilibrium thermodynamics to the system. In that case, the initial point for the abrupt rise in electrical resistance will be located in the region of unstable states to the right of the spinodal line. These states can be realized with current pulse lengths below 10^{-7} sec.

Approximate similarity relations in the electrical explosions of underwater conductors

E. V. Krivitskii and V. K. Sholom

Design and Construction Bureau of Electrohydraulics,
Academy of Sciences of the Ukrainian SSR, Nikolaev

(Submitted November 9, 1973; resubmitted August 13, 1973)
Zh. Tekh. Fiz., 44, 1271-1276 (June 1974)

An attempt is made to generalize the available experimental data to obtain similarity conditions for the electrical characteristics for the explosion of conductors for the case in which the conductors do not explode and for the case in which there is no current pause. The explosion of a conductor can be arbitrarily divided into three basic stages on the basis of the behavior of the current. Three similarity criteria are obtained for these stages through an analysis of the differential equation of the discharge circuit and the energy balance during the destruction of the conductor. Analysis of the experimental data reveals that at corresponding times (determined by normalizing the time axis on the basis of the length of the half-period of the short-circuit current) the dimensionless discharge-current curves indicate approximate similarity relations. Experiments involving the explosion of copper and aluminum conductors have been carried out for broad ranges of the parameters.

Despite the many papers which have appeared on the explosion of conductors, relatively little is known about the mechanism for such explosions, and certain details of the process have not been explained.

The destruction of a conductor caused by the passage of a high-density current can be attributed qualitatively to the development of MHD instabilities, which change the shape of the conductor and ultimately cause fractures in it.[1]

If a current which produces a nearly critical pressure at the surface flows in the conductor during the growth of the instability, the conductor could undergo homogeneous vaporization.[2]

We restrict the discussion below to these two characteristic cases, although the actual explosion is more complicated.

From the standpoint of the electrical characteristics, the explosion of a conductor, which disrupts the metallic conductivity in part of the discharge circuit, is accompanied by a rapid decay of the discharge current and the appearance of an inductive overvoltage.[3]

In some cases the current decay ends with a complete current cutoff, which causes a "current pause" or "dark pause." The current increase which follows the pause or a partial current decay begins as a result of the breakdown of the explosion products of the conductor, and displays the behavior characteristic of a gas discharge.

During the explosion of a conductor the electrical characteristics [the discharge current i(t), the voltage across the discharge gap U(t), etc.] are governed by the voltage associated with the charge on the capacitor bank, U_0; the capacitance of this bank, C; the inductance of the discharge circuit, L; the length of the conductor, l; the conductor diameter d; the conductor material; and the properties of the medium in which the explosion occurs.

Many experiments on the electrical characteristics of conductor explosions[3–6] have shown that identical oscillograms (with identical decay phases, decay depths, and magnitudes of the secondary discharge-current pulse) can be obtained with various combinations of the discharge-circuit and conductor parameters.

We report here an attempt to obtain approximate similarity criteria for the electrical characteristics of the underwater explosion of conductors in the high-voltage discharge of a capacitor bank.

Since many parameters govern the several successive stages of the conversion of the conductor and the corresponding processes in the discharge circuit, we seek the similarity criteria through analysis and control experiments.

The equation of a discharge circuit consisting of a series connection of a charged capacitor bank, the inductance of the leads, and a nonlinear resistance can be written in general as

$$L\frac{di}{dt}+iR+\frac{1}{C}\int i dt=0, \tag{1}$$

where R is the sum of the resistance of the elements of the discharge circuit, R_d, and that of the conductor, R_n.

Using the similarity or scaling factors $m_i = U_0\sqrt{C/L}$ for the current and $m_i = \pi\sqrt{LC}$ for the time, we can rewrite Eq. (1) in dimensionless form with the single similarity criterion $S_1 = R\sqrt{C/L}$.

The resistance of the discharge-circuit elements is governed primarily by the resistance which is equivalent to the dielectric loss in the capacitor.[7] Its value is usually 0.1 of the characteristic impedance of the discharge circuit, $\sqrt{L/C}$.

For conductors which are not too thin, the value of R_c is comparable to that of R_d.

Since the temperature coefficients of the resistances of various metals (mercury is an exception) are almost the same, we can use the following approximate similarity criterion for the initial stage of the explosion (for the first current pulse):

$$S_1=(R_d+R_0)\sqrt{\frac{C}{L}}, \tag{2}$$

where R_0 is the initial resistance of the conductor.

Dimensionless combinations governing the phase of the rapid decay of the discharge current can be obtained from the energy-balance equation for the explosion which, according to ref. 4, can be written

$$\frac{d(w)}{g(w)}=\frac{R_0 i^2}{m}dt. \tag{3}$$

Here, w is the energy per unit mass of the conductor,

$g(w) = R_n/R_0$, $g(w_0) = 1$, and m is the mass of the conductor.

Integration of the left side of Eq. (3) from w_0 to w_1, which is set by the instant of explosion, gives a Stieltjes integral which is a function of the properties of the material alone, and is therefore constant.

Normalizing both parts of the equation to the specific energy required to heat, melt, and evaporate the conductor (w_c), we find (in dimensionless form)

$$\text{const} - \frac{R_0}{mw_e}\int_0^{t_e} i^2 dt = 0. \quad (4)$$

If we neglect the energy loss due to the heating of the conductor and the increase in its volume before destruction, define $I = i/m_i$ and $\tau = t/m_t$ and write the initial resistance in terms of the electrical conductivity σ and the mass, m, in terms of the geometric dimensions and the density ρ, then

$$\text{const} - \frac{1}{d^4\rho\sigma(\lambda + r)}\frac{U_0^2 C^{3/2}}{L^{1/2}} f(\tau_e) = 0. \quad (5)$$

Here, λ and r are the specific heats of fusion and vaporization, respectively, and

$$f(\tau_e) = \int_0^{\tau_e} I^2 d$$

is the dimensionless phase function of the explosion.

This dimensionless expression, which is a combination of dimensional quantities characterizing the circuit and the conductor, thus determines the explosion phase unambiguously and can serve as a second similarity criterion during the explosion:

$$S_2 = \frac{1}{d^4\rho\sigma(\lambda + r)}\frac{C^{3/2}U_0^2}{L^{1/2}}. \quad (6)$$

When the conductor is destroyed as a result of MHD instabilities, evaporation occurs locally, and only a negligible part of the conductor material manages to evaporate before the destruction. The energy-balance equation must be normalized, taking account only of the energy required for the heating and the melting. The function $f(\tau_e)$, a dimensionless function of the time, becomes a function of the time required for the growth of the instability.[1]

Experiments showing that the properties of an underwater spark discharge are similar to those of a discharge in the explosion products of a conductor in the stage following the explosion[8,9]

$$S_3 = \frac{Al^2}{U_0^2 \pi \sqrt{LC}} \quad (7)$$

is a third criterion. Here A, the spark constant, which is not a function of the conductor material, is $10^4\ V^2 \cdot sec/m^2$.

From (2), (6), and (7), we see that for similarity of the electrical characteristics as the diameter of the conductor is increased by a factor of n the bank capacitance C, the discharge voltage U_0, and the conductor length l, must be increased by a factor of n, while the inductance L and the resistance of the discharge-circuit elements must be reduced by a factor of n.

In these experiments the conductors are exploded by current pulses from the discharge of a capacitor bank charged to 8-40 kV. To determine the influence of the rate at which the energy is supplied to the conductor, we vary the inductance of the discharge circuit and the bank capacitance in such a way that the short-circuit length of the current half-period varies by a factor of about 10 (from ~ 8 to ~ 70.0 μsec).

Copper and aluminum conductors are used in most of the experiments; the discharge current is displayed on an oscilloscope by means of a coaxial shunt, while the voltage drop across the electrodes of the test sample is taken from a capacitive voltage divider.

The inductive component of the voltage drop is balanced out.

The system used to measure the current (the shunt and oscilloscope) is calibrated on the basis of a calculation of the peak short-circuit discharge current from the parameters of the discharge circuit for a specified bank voltage. The resistance is assumed to be constant. In this way we avoid errors in the determination of the conversion coefficients which incorporate the sensitivity of the oscilloscope, and of the properties of the shunt resistance.

The measurement system (the voltage divider and oscilloscope) is calibrated on the basis of the deflection of the oscilloscope trace during the discharge of the capacitor bank into a resistance chosen to provide a time constant of the RC circuit much longer than the length of the short-circuit current half-period. The similarity coefficients m_i and m_t are used to convert the oscillograms to dimensionless form.

The accuracy with which the electrical characteristics are determined is monitored on the basis of the energy balance in the discharge circuit, through the use of

$$\int_0^\infty P_R dt = \frac{CU_0^2}{2},$$

where P_R is the total power evolved in the resistance of the discharge circuit and the conductor. The deviation from an energy balance usually does not exceed 5%-7%.

The phase change of the rapid current decay accompanying the explosion of the conductor as S_2 is varied (with S_3 = idem), by means of a change in the conductor diame-

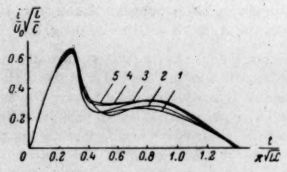

Fig. 3. Similarity of the current curve for the discharges being compared (Table 1) with S_2 = idem and S_3 = idem.

ter, is illustrated by the dimensionless oscillograms in Fig. 1. From the very slight deviation of the initial stage of the current increases from the short-circuit curve, we conclude that criterion S_1 has only a slight effect on the similarity of the discharge.

The differences in the second discharge pulse (despite the condition S_3 = idem) can be easily explained by noting that the initial conditions for this stage, which are governed by the depth of the discharge-current decay and by the relative energy expenditures in the first pulse, are different.

Figure 2 shows a family of discharge-current curves obtained in the explosion of copper conductors of the same diameter (d = 0.5 mm) but different length. Here, the condition S_2 = idem is satisfied.

Turning to the phase of the explosion, we see from these curves that it is essentially independent of the length of the conductor, which in this case governs the value of S_3. The discrepancies in the peak values of the first discharge current pulse (ranging up to 14%) can be attributed to the circumstance that with conductors 100 mm and longer the initial impedance of the conductor reaches 5%–10% of the characteristic impedance of the discharge circuit.

Heating the conductor to the melting point or above strongly affects the value of R_n (refs. 10, 11) and thus S_1.

Nevertheless, in this analysis of approximate similarity we use S_2 and S_3 as the basic criteria.

Figure 3 illustrates the situation with the dimensionless discharge-current curves for the case S_2 = idem and S_3 = idem as essentially all the dimensional properties of both the discharge circuit and the sample itself are varied.

Table 1 shows the basic electrical parameters and the properties of the conductor, along with the relative inductive peak of the overvoltage U_n/U_0 for the corresponding oscillograms in Fig. 3. In calculating S_2 and S_3 we express all the dimensional quantities in International Units.

From the satisfactory coincidence of the normalized discharge-current curves and overvoltage peaks we conclude that our similarity criteria can be used to model discharges in the underwater explosion of conductors.

It should be noted, however, that the similarity which we observe here is characteristic of the two metals which we have studied, for which the voltage curve does not display the continuities observed in the explosion of steel or iron conductors during current flow before the disruption of metallic conductivity.

These anomalies are apparently due to certain features of the conductor material itself which lead to an abrupt change in the conductivity at the transition from the solid phase to the liquid phase during melting.

Furthermore, these results refer primarily to discharges not accompanied by a pause after the first current pulse.

The presence of such a pause during the explosion of comparatively thin conductors, in which case the energy expended in the first current pulse can be neglected, does not play a special role, and the similarity of the discharges initiated by such conductors is discussed in ref. 12.

A current pause can be observed for large-diameter conductors (curve 6 in Fig. 2) if the length of the first pulse becomes comparable to the length of the half-period of the short-circuit current. In this case the energy evolved in the conductor during the first current pulse can be so large that expansion of the vapor–gas cavity toward the end of the current pause and toward the beginning of the second breakdown (the arc stage of the discharge) cannot be neglected. In this case the use of the criterion S_3, derived for the case in which the channel radius is a = 0 toward the beginning of the discharge, requires a further experimental check.

In conclusion, the authors thank B. P. Peregud for discussion.

Breakdown caused by electron bombardment of the surface of an alloy electrode

N. V. Belan, G. I. Kostyuk, and V. A. Pimkin

(Submitted September 17, 1973)
Zh. Tekh. Fiz., 44, 1277-1279 (June 1974)

An experimental study has been made of the conditions governing the development of a vacuum discharge when an electron beam is incident on the surface of the ternary alloy 50% Bi + 25% Sn + 25% Pb or on the surface of the quaternary alloy 50.1% Bi + 14.2% Sn + 24.9% Pb + 10.8% Cd. Study of the discharge delay time and the mass composition of the ions produced in the discharge reveals selective evaporation of the alloy components which leads to a change in the discharge delay time with the number of breakdown events.

An understanding of the developments of a discharge in the case of an alloy electrode is important in connection with the use of breaker contacts of alloys, the use of alloys as working media in accelerators, and the electric-spark processing of alloys.

Conditions governing the development of a discharge which occurs when an electron beam is incident on the surface of a pure metal are derived in refs. 2 and 3 on the basis of the assumption that the anode breakdown mechanism[1] operates when an electron beam affects the surface of an anode. It is shown[2,3] that the breakdown conditions are satisfied when the evaporated material at the electode surface reaches a pressure of $2 \cdot 10^{-3}$ torr. These conditions correspond to a redistribution of the heat flux over the surface as a result of ion (gas) focusing, which leads to heat fluxes for which the vapor pressure at the surface reaches the value required for the ignition of a discharge in the vapor of the anode.

We have studied the development of a discharge as an electron beam is incident on the surface of an alloy in a prototype pulsed coaxial plasma accelerator with electron-beam ignition of the discharge.[4] Figure 1 shows the experimental apparatus, which consists of a dish 1 which holds the alloy 3; accelerator electrodes 2 and 10, separated by dielectric 9; the anode of the electron source 4; a thermionic cathode 5; a focusing electrode 6; the heater of the electron emitter, 7; the power supply for the electron source, 8; and a time-of-flight mass spectrometer.

The experiments are carried out in a vacuum chamber at a residual gas pressure $5 \cdot 10\text{-}10^{-5}$ torr. We study the alloys 50% Bi + 25% Sn + 25% Pb (Rose metal) and 50.1% Bi + 14.2% Sn + 24.9% Pb + 10.8% Cd (Wood's alloy) and the pure metals Bi, Sn, Pb, and Cd.

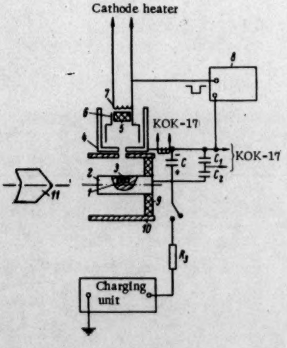

Fig. 1

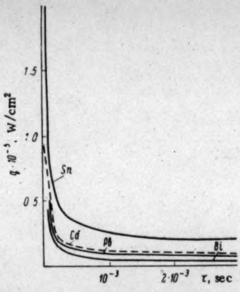

Fig. 2

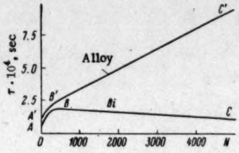

Fig. 3. $q = 1.5 \cdot 10^4$ W/cm².

The beginning of breakdown is determined from the display of the current and voltage on the screen of an OK-17M oscilloscope, which is triggered when the voltage is supplied to the electrodes of the electron source.

The mass-spectrometry experiments are carried out with a time-of-flight mass spectrometer; the measurement circuit is similar to that of ref. 5.

Study of the delay time for the discharge development when an electron beam is incident on the surface of a pure metal has shown that the discharge delay time τ is related to q, the heat flux produced by the electron beam by[2]

$$q = A \frac{1}{\sqrt{\tau}},$$

where A is a constant governed by the thermophysical properties of the bombarded material and by its initial temperature. For lead, tin, bismuth, and cadmium this functional dependence is shown in Fig. 2. A satisfactory agreement is found between the experimental and calculated results. As the number of breakdowns is increased, the discharge delay time falls off slightly, due to an in-

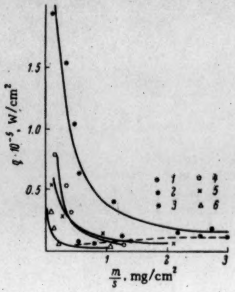

Fig. 4

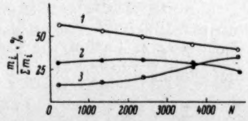

Fig. 5

crease in the initial temperature of the metal before breakdown; this increase reduces the time required for the vapor pressure above the metal surface to reach $2 \cdot 10^{-3}$ torr (Fig. 3). Figure 3 shows the discharge delay time as a function of the number of breakdowns for bismuth (the surface is not outgassed).

In region AB of the curve the metal surface is outgassed, i.e., from point A to point B a progressively smaller relative number of gaseous inclusions contributes to reaching breakdown conditions. In region BC there is some decrease in the discharge delay time because the alloy temperature increases.

As the electron beam affects the surface of the Rose alloy the functional dependence of the discharge delay time on the number of breakdowns changes (Fig. 3); there are two characteristic regions, A'B' corresponding to the outgassing of the surface (here the curve is of the same nature as that in region AB), and B'C', in which the behavior of the curve is different from that in region BC. It would be natural to assume that this feature is a reflection of the nature of the alloy evaporation during pulsed heating.

To clarify this situation we carry out experiments in which we determine the generation characteristics (the mass removed from a unit surface area as a function of the heat flux) for one filling of the dish with the alloy. To compare the experimental results for the alloys and the pure metals, we study the alloy components (Bi, Pb, Sn, and Cd) (Fig. 4).

In the first experiment the expenditure characteristics of the Rose metal and the Wood's alloy are similar to those for bismuth; in the second experiment, they are similar to those for lead or cadmium; and in the subsequent experiments they are similar to those for tin. This functional dependence $m/s = f(\tau)$ for the alloys implies that, after only a few breakdowns, bismuth, the most easily evaporated component, has been removed from the surface layer of the alloy, and the breakdown conditions correspond primarily to the vapor of this metal over the time required to reach the saturation vapor pressure above a bismuth surface. After more breakdowns the surface layer is depleted of bismuth, so that the role of lead and cadmium vapor in governing the breakdown conditions becomes more important; however, since this increased importance can result from an increase in the surface temperature, the time required to reach breakdown conditions is increased. Thereafter, the discharge delay time increases because of an increase in the relative amount of tin vapor. All these results point to the selective nature of the escape of the alloy components.

To check the selectivity of this evolution from the Rose metal, we subject the ion fluxes after various numbers of breakdowns to a mass-spectrometry study. For this purpose we use a time-of-flight mass spectrometer with time and natural modulation of the ion beam, so that the energy and velocity distributions of ions of various masses can be obtained. In this manner we are able to determine the nature of the ion and the relative number of ions of each species. Figure 5 shows the relative number of ions of each species as a function of the number of operations of the ignition system. The relative number of bismuth ions falls off as the number of breakdowns increases, while the relative number of lead ions at first increases and then decays. The relative number of tin ions increases as the number of breakdowns increases. The mass-spectrometry results verify the selective escape of the components during electron-beam ignition of the discharge. Study of the discharge development as an electron beam is incident on the surfaces of ternary and quaternary alloys showed that (1) the discharge delay time increases with an increase in the number of breakdowns and (2) selective evaporation of the components is observed. This selective evaporation explains the changes in the discharge delay time.

Emission characteristics of an explosive gallium cathode*

G. N. Fursei and V. M. Zhukov

A. A. Zhdanov Leningrad State University

(Submitted July 9, 1973; resubmitted November 30, 1973)
Zh. Tekh. Fiz., 44, 1280-1286 (June 1974)

The temporal characteristics and emission properties of the initial stages of vacuum breakdown are studied. An attempt is made to distinguish processes related to the parameters of the external circuit from those due directly to the emission properties of the cathode. The delay times and switching times are measured during the development of vacuum breakdown on the surfaces of liquid and solid gallium with a limited emitting surface and on extended electrodes. The explosive-emission current displays saturation due to the limited cathode emissivity.

In the initial stages of vacuum breakdown explosive emission of electrons occurs as a result of the explosion of microscopic inhomogeneities on the cathode of the evacuated gap by the field-emission current.[1-2]

Until now it has been assumed[2-4] that the increase of the current as a function of the time and the voltage-current characteristics of explosive-emission diodes are governed primarily by the conditions under which the plasma bridges the evacuated gap. On the other hand, experiments with separate field emitters and studies of the microrelief of the cathode surface after breakdown[5] are consistent with the assumption that an equally important role is played by the growth of the emitting surface of the cathode as a function of the time[1]; this growth is a result of the propagation of plasma along this surface. An important role is also played by the strength of the explosion process, which is governed by the electric field and, correspondingly, by the density of the field-emission current. We report here on an attempt to distinguish these fundamental processes more clearly and to show why these processes are masked in most experiments with macroscopic surfaces.

1. EXPERIMENTAL PROCEDURE

Figure 1 shows a block diagram of the experimental apparatus. The experiments are carried out in sealed vessels at a residual pressure of 10^{-7}-10^{-6} torr. The vessels are pumped by titanium electric-discharge pumps. The anode-cathode separation can be adjusted continuously over a range of 20 mm. The cathodes are made of "Ga-00" gallium. Gallium is selected because it can be used to study both solid and liquid cathodes in ultrahigh vacuum.[6]

Since the explosive-emission current density can reach values up to 10^6-10^8 A/cm^2 at microscopic points (ref. 5), the total current for macroscopic cathode surfaces of the usual size (0.1 cm^2 and larger) is not limited by emission, but by the parameters of the external circuit and the space charge in the evacuated diode. To isolate the emission characteristics it is necessary to restrict the current increase resulting from the increase in the emitting surface area[1] during the explosive emission. A particular case with this limitation is the explosive emission of single microscopic points.[5] For this reason, in the present study we use Ga cathodes with a small, specially limited surface area [$S \sim 7 \cdot (10^{-4}$-10^{-3} cm^2)]. The results are compared with those for cathodes with extended surfaces (with S up to 1 cm^2). In most of the experiments the length of the rectangular voltage pulses (τ_p) is 130 nsec, the rise time (τ_r) is 5 nsec, and the peak value is 12-50 kV. In the experiments with extended cathodes we use voltage pulses of 60-120 kV, (τ_p) ≈ 100 nsec, and (τ_r) = 1 nsec.

EXPERIMENTAL RESULTS

Temporal characteristics. a) Explosive emission is customarily characterized by two times:[3-4] the delay time for the appearance of the explosive-emission current with respect to the leading edge of the voltage pulse, t_d, and the time required for the current to grow to values limited by the parameters of the external circuit, which has been called the "switching time" t_s (Fig. 2a).

In our experiments we also attempt to provide a cathode with a small emitting surface, so that the explosive-emission current will be governed not only by the parameters of the external circuit and the effect of the electron space charge, but also (and primarily) by the cathode emissivity. We find that the current oscillogram does in fact display a saturation region (Fig. 2b). In this case it is convenient to introduce the time required for the current to grow to its quasisteady-state value, t_g.

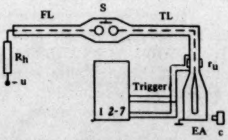

Fig. 1. Block diagram of the measurement apparatus. R_h) Charging resistance; FL) forming line; S) switch; TL) transmitting line; r_u) measuring resistance; EA) experimental apparatus; I2-7) time-interval meter; C) camera.

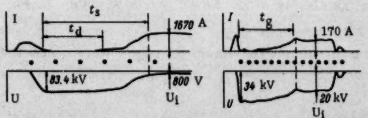

Fig. 2. Oscillograms of the explosive-emission current and voltage for cathodes with extended (a) and limited (b) emitting surfaces. U_{gap}) Discharge voltage. The time markers indicate intervals of 10 nsec.

Below we clearly distinguish between t_s and t_g, since their physical meanings are significantly different.

b) The value of t_d for a liquid cathode varies from hundreds of nanoseconds to several nanoseconds (Fig. 3a) over the ranges of the voltage U, the gap d, and thus the electric field F which we have studied. This result agrees well with the results obtained previously with solid metals[4,7] (Table 1). The scatter in the values of t_d for a cathode with an extended liquid surface is much smaller than that for solid electrodes. For liquid Ga the scatter does not exceed 5-10% (Fig. 3c), while for solid metallic cathodes under approximately the same conditions[4-7] the values of t_d can vary by a factor of 2-3.

The general behavior of t during the first few switchings on solid Ga is the same (Fig. 3b, I). A characteristic effect is the formation of the surface: After a few dozen switching events, t_d contracts rapidly to values shorter than 1 nsec (Fig. 3b, II). The formation effect can be related unambiguously to the formation of a large number of microscopic points on the solid gallium cathode under the influence of the preceding breakdowns. The formation of microscopic points on the surface of solid Ga under the influence of single breakdowns has been studied previously.[8] Conversion of the formed cathode to the liquid state and its subsequent "freezing" make it possible to restore the original functional dependence of t_d on U (Fig. 3b, I).

The time t_d is not a function of the magnitude of the voltage, being governed by F alone (Fig. 3a).

The absolute values of t_d on a gallium cathode are considerably shorter than for more refractory materials under similar conditions (Table 1). This difference can be naturally attributed to the low melting point of Ga and the change in the cathode geometry which occurs as the microscopic protuberances are drawn from the liquid phase.[6]

c) Figure 4 shows the functional dependence of t_s on the applied voltage U. A result not found earlier with solid cathodes[3,4,7] is the strong functional dependence of t_s on U (region I in Fib. 4) and, thus, on F. We believe that this functional dependence was not observed in the earlier experiments because most of these experiments were carried out at stronger fields. In our experiments we also observe a region in which t_s is actually independent of U (region II in Fig. 4).

Accordingly, in the functional dependence of t_s on U we can distinguish two branches, characterized by a decrease in t_s with increasing U (region I) and constancy of t_s with a further increase in U (region II). We attribute the decrease in t_s with increasing U to an increase in the number of explosive-emission centers accompanying an increase in F. This functional dependence is manifested only at comparatively small values of F, at which the switching process is a function of the growth of the effective emitting surface as well as of the conditions governing the bridging of the evacuated gap by the plasma. This effect should obviously be displayed most clearly at large electrode separations d, when one or several microscopic points explode. It is precisely this favorable situation which arises in experiments with a liquid gallium cathode.

TABLE 1

Material	t_d, nsec	t_s, nsec	d, mm	Reference

Ga solid	~1	20	0.55	

Note: The voltage is U = 40 kV in all the experiments.

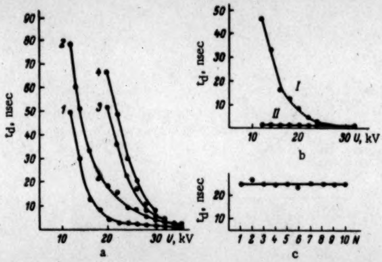

Fig. 3. Delay time as a function of the voltage on the liquid cathode (a, b) and reproducibility of the delay time for a cathode with an extended emitting surface (c). a: 1) d = 0.55 mm; 2) 0.70; 3) 1.35; 4) 3.2. b: d = 0.55 mm. c: U = 83.4 kV.

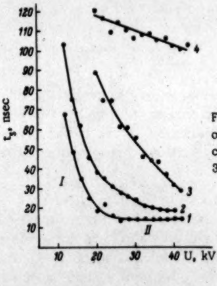

Fig. 4. Switching time as a function of the applied voltage on a liquid cathode. d, mm: 1) 0.55; 2) 0.70; 3) 1.35; 4) 3.2.

At small values of d and at large overvoltages, from the very beginning the number of centers is sufficient for the current increase in the gap to be governed entirely by space charge.

The data obtained for Ga agree well with the data from other works (Table 1).

Mesyats el at.[3] attempted to calculate t_s, taking account of the space-charge effect, in a model with an evacuated gap which contracts with the plasma expansion. The calculated results agree with the experimental data in region II of the $t_s = f(U)$ curve (Fig. 4).

We note that the decrease in t_s with increasing U can also be observed with a solid cathode. The cathode must be smooth and cannot have a large number of microscopic protuberances. Such conditions can be arranged by

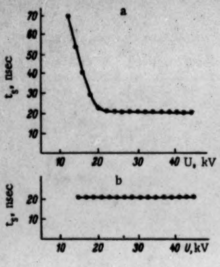

Fig. 5. Switching time as a function of the applied voltage during (a) and after (b) the forming of the solid cathode. d = 0.55 mm.

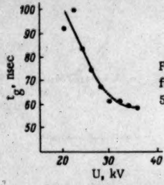

Fig. 6. Current-growth time t_g as a function of the applied voltage. d = 5.5 mm, S = $0.7 \cdot 10^{-3}$ cm^2.

solidifying liquid Ga (Fig. 5a). After several successive breakdowns we find the formation effect described above, which results from the formation of a large number of microscopic protuberances. In this case we observe the independence of t_s from U, which has been noted in several works (Fig. 5b). A formation process of this type apparently occurred in most of the experiments reported previously, in which the electrodes were almost always conditioned beforehand by breakdowns.

On a liquid-gallium cathode and on a smooth solid gallium cathode, as we see from Fig. 4, I, and in the region which is the transition to region II the linear functional dependence of t_s on U which is usually observed[3,4] is not found.

d) Comparison shows that t_g is much smaller than t_s for each voltage (Figs. 4 and 6). We see from these figures that this feature holds even when t_s is determined at a slightly smaller anode−cathode separation d. On the basis of this observed difference between t_s and t_g we can conclude that when the avalanche current increase at the cathode is artificially cut off (for the specified parameters of the external circuit) by a limitation on S, there is an important reduction of the formation time for the explosive-emission pulse.

Voltage−current characteristics. a) The use of an extended cathode to obtain electron beams by means of explosive emission suffers from the disadvantage that the voltage across the gap (U_{gap}) decays rapidly as a function of the time (Fig. 2a). This decay results from the rapid growth of the emitting surface area and from the high density of the explosive emission, which leads to a very rapid increase in the conductivity of the gap. Accordingly, a high-energy electron beam can be obtained only in a comparatively brief time interval during the initial stage of the discharge. Limitation of S permits us to overcome this difficulty and obtain an essentially rectangular pulse of a high-energy electron current (Fig. 2b).

b) Figure 7 shows the voltage−current characteristics of the discharge for various values of S and d. For large S these characteristics are the typical decaying characteristics of a self-maintained discharge[9] (Fig. 7a), limited by the resistance of the discharge circuit (in our case, $\rho = 75\ \Omega$). This typical voltage−current characteristic of the discharge shows that here we are apparently dealing with a cathode spot which has already formed; the elementary mechanism for the operation of such a spot is the explosion of a microscopic inhomogeneity under the influence of the field-emission current which is flowing. Emission at a cathode spot is the essence of explosive emission. The quantity U_{gap} is in fact the arcing voltage for the given circuit resistance.

When the cathode surface area is limited we find increasing voltage−current characteristics (Fig. 7b).

All the characteristics are plotted according to the current values measured in the quasisteady-state part of the functional dependence of the current on the time (Fig. 2).

Emission properties of a liquid cathode. a) The emission current density j obtained from a cathode with a limited surface area is $\sim (1\text{-}5) \cdot 10^5$ A/cm^2. The magnitude of the current is determined from oscillograms, and the emitting surface area is assumed to be the total surface area of the cathode. The average values of j are approximately equal to those obtained recently from the cathode spot of a self-maintained discharge.[9,10] We note that this is the average current density. The local value of j can be much larger in the region in which the microscopic explosion occurs.[5] The emission current density is a function of the average electric field1) F (Fig. 8). This functional dependence can be attributed to the different growth of explosive emission.[5]

b) The glow of a discharge on a cathode with a limited surface area is localized near the axis of the cathode. The expansion rate of the plasma, determined from the measured values of t_s and d by the procedure of ref. 3, is $(2\text{-}4) \cdot 10^6$ cm/sec for a liquid cathode.

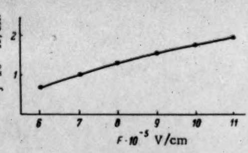

Fig. 8. Emission current density as a function of the average electric field.

CONCLUSION

1. The switching time has been found to decrease with increasing electric field F. This decrease has been shown to be the result of the growth of the effective emitting surface area and the increase in the number of cathode bursts with increasing F.

2. It has been shown that by limiting the emitting surface area of the cathode one can obtain high-energy electron beams with a specified impedance and with short rise times.

3. The voltage–current characteristics of the initial stages of vacuum discharge have been found to display two branches with decaying and increasing voltages. The behavior of the characteristics as a function of the parameters of the external circuit shows that we are dealing with the formation of a cathode spot from essentially the first few nanoseconds. The mechanism for the emission at a cathode spot is explosive emission of electrons.

4. Successive breakdowns lead to the formation, on a solid gallium cathode, of a large number of microscopic points, which are drawn from the molten metal during breakdown by the ponderomotive forces associated with the electric field. As a result the switching and delay times are shortened, and the switching time becomes independent of the applied voltage.

5. The measured average current densities on a liquid gallium cathode with a limited surface area are $(1\text{–}5) \cdot 10^5$ A/cm^2, in good agreement with recent data on the average current density at a cathode spot.[10]

6. The results agree with the model proposed in ref. 1 for the formation of a cathode spot.

Atomic recombination on a solid surface

V. P. Pinchuk, A. N. Gorban', and V. G. Kornich

(Submitted July 2, 1973)
Zh. Tekh. Fiz., 44, 1287-1291 (June 1974)

A study of the effect of atomic hydrogen on the surfaces of several materials has shown that the recombination of hydrogen atoms leads to effects such as the sputtering of certain metals and semiconducting compounds (without any important change in the stoichiometric composition); the appearance of characteristic microscopic swelling on the surface of certain metals; and electron emission. The temperature dependence of the emission current has been determined.

A comparatively large amount of energy is evolved (up to 10 eV per recombination event[1] in the recombination of free radicals at the surface of a solid). This energy is transferred either to the lattice or to individual atoms and electrons. In the first case the solid surface is heated, in certain cases by tens or even hundreds of degrees.[2] Under certain conditions we have observed the heating of platinum, nickel, and copper, which are active catalysts for the recombination of atomic hydrogen, to 650–700°C.

Transfer of the recombination energy to individual atoms of a semiconductor, resulting in the ionization of the atoms and the appearance of free charge carriers, leads to such effects as a change in the electrical conductivity, radical-recombination luminescence,[6] etc. It can be assumed that the recombination of radicals on a surface can also stimulate electron emission and the conversion of atoms of a solid into the gas phase. This conversion could of course also be related to the formation of highly volatile chemical compounds. (We note the familiar Panet mirror method, which can be used to determine the concentration of free radicals from the rate at which films of certain materials disappear).

We have studied the interaction of atomic hydrogen (recombination energy of 4.48 eV) with the surface of several materials – metals, elemental semiconductors, and semiconducting compounds.

The atomic hydrogen is produced by an rf electrodeless discharge. The hydrogen atoms defuse from the discharge region into the working chamber over a distance longer than 20 cm. The working chamber is a cup 1500 cm^3 in volume mounted on a plate. The hydrogen-atom density in the working volume is 10^{14} cm^{-3}.

Visual observations show that the exposure of a solid surface to atomic hydrogen usually leads to a change in the surface state. The nature of this change is governed by several surface processes. Previously oxidized metal surfaces (copper and molybdenum) are reduced even at room temperature. Increasing the temperature to 250°C raises the reduction rate. Magnesium oxide and zinc sulfide films as thick as 1.5 μ are evaporated essentially without change of the stoichiometric composition for 1-2 h. Since no change occurs in the stoichiometric composition in this case, as can be seen from the rate and nature of the radical-recombination luminescence, we conclude that the disappearance of the films results from sublimation of the material, rather than from a chemical interaction.

The exposure of pure molybdenum, copper, and platinum to atomic hydrogen leads to the appearance of characteristic formations on the surfaces. Photomicrographs (Fig. 1) show previously polished surfaces of these metals after exposure to atomic hydrogen. The atomic hydrogen leads to the appearance of areas of microscopic swelling on the metal surfaces. The rate at which these formations grow is largest for molybdenum and smallest for platinum.

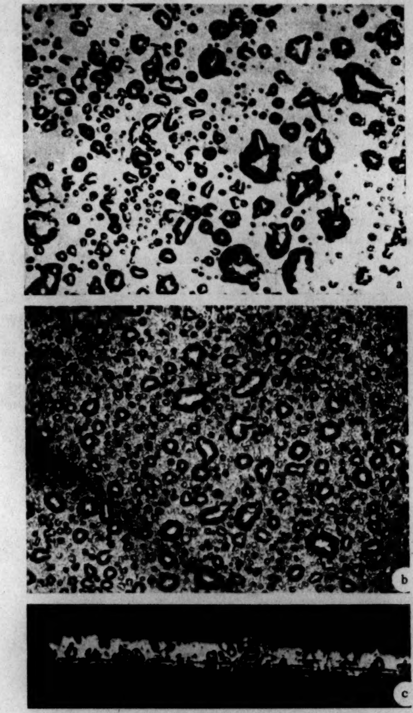

Fig. 1. Photomicrographs of the metal surfaces after exposure to atomic hydrogen. a) Molybenum (× 100); b) copper (× 100); c) platinum wire (× 200).

It is interesting to note that the appearance of similar bubbles on an iron surface during electrolysis has been described in ref. 7, in which the bubbles are attributed to the adsorption on the iron surface of atomic hydrogen evolved during electrolysis. By analogy with the explanation in ref. 7, it could be suggested that the appearance of the microscopic swelling shown in Fig. 1 results from the diffusion of hydrogen atoms adsorbed on the surface into the interior of the sample and the subsequent concentration of these atoms near volume defects (microscopic pores and inclusions). As it recombines into molecules, the hydrogen rapidly loses its mobility and produces a high pressure near the defects which in turn leads to the appearance of the characteristic swelling. The circumstance that the bubble-nucleation rate is highest in molybdenum can be attributed to the layered structure of the samples, which were prepared from rolled molybdenum and which therefore have a large number of microscopic pores.

Special experiments show that the effect of atomic hydrogen on many materials is to cause electron emission. Figure 2 shows a block diagram of the apparatus used to study this emission. In the emission experiment we apply a negative potential to the sample; the potential is chosen to lie in the saturation region of the voltage–current characteristic of the emission current. The heat-transfer conditions are such that the sample is warmed only slightly if the heater is turned off. The samples are 34 mm in diameter and not more than 0.5 mm thick.

The sample temperature can be held constant or varied according to a specified program by means of a heater and regulator. The emission current is measured by a V2-5 millivoltmeter–electrometer, which provides a current sensitivity of 10^{-15} A. Since the atomic hydrogen is produced in an rf discharge, particular care is taken to shield the generator, the rf feeder, and the measuring part of the apparatus. The density of atomic hydrogen is monitored with a platinum–Chromel–Copel thermocouple, which permits absolute measurements of the atomic density at some standard pressure (the system for monitoring the atomic density is not shown in the diagram).

Electron emission is observed in the recombination of hydrogen atoms on the surfaces of molybdenum, nickel, silver, copper, tantalum, magnesium, aluminum, germanium, the oxides of molybdenum and copper, and zinc sulfide. We have not been able to detect electron emission from a silicon surface. The steady-state emission current in the case of the metallic samples falls off slowly with increasing temperature (the emission current decreases 30%-40% upon heating to 250°C) and near 100°C is 0.37 pA for Mo, 0.145 pA for Ni, 0.125 pA for Ag, 0.090 pA for Cu, 0.075 pA for Ta, 0.064 pA for Mg and 0.061 pA for Al.

The change in the magnitude of the emission current as a function of the temperature in the recombination of atomic hydrogen on the surface of zinc sulfide and on the surface of molybdenum oxidized in air for 5 min at 260°C is shown in Fig. 3. The temperature dependence of the emission current from the surface of a zinc sulfide film 1.5 μ thick is easily reproducible upon cooling and repeated heating. For the oxidized molybdenum samples, on the other hand, the peak on the temperature dependence of the emission current is not observed after a cooling and repeated heating. This peak vanishes because the surface is reduced during the interaction with atomic hydrogen. After complete reduction of the surface a steady-state emission current is established; this current falls off slightly with increasing temperature, in the manner typical of pure metals. In those cases in which the oxide layer on the surface is thick (after oxidation for 5 min at 800°C in air), so that the sample is not reduced in a single heating cycle, the temperature peaks are observed for several cycles. The peak emission intensity falls off with each cycle.

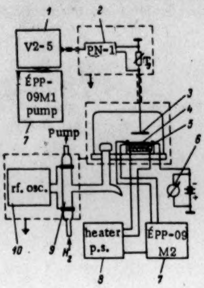

Fig. 2. Block diagram of the apparatus for measuring the electron emission stimulated by the recombination of hydrogen atoms. 1) V2-5 millivoltmeter–electrometer; 2) capacitance voltage transformer; 3) aluminum electron collector; 4) sample; 5) heater; 6) meter for measuring the voltage applied to the sample; 7) ÉPP-09M2 recording potentiometer; 8) power supply for heater; 9) discharge tube; 10) rf oscillator.

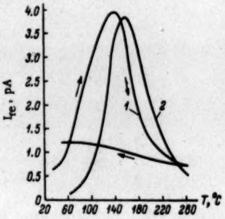

Fig. 3. Temperature dependence of the electron emission stimulated by recombination of hydrogen atoms with a molybdenum surface oxidized for 5 min at 260°C in air (1) and on the surface of a zinc sulfide film (2).

According to preliminary data the magnitude of the emission current varies from sample to sample and with a change in the temperature according to the rate at which atomic hydrogen recombines, i.e., according to how effectively the materials catalyze the recombination of hydrogen atoms into molecules.

CONCLUSIONS

Recombination of hydrogen atoms on the surfaces of metals and semiconductors can have several consequences, among which the following must be included:

a) sublimation of the atoms of the material (in the cases of zinc sulfide and magnesium oxide the evaporation occurs without any change in the stoichiometric composition);

b) the microscopic swelling of the surfaces of certain metals, which occurs because hydrogen atoms diffuse toward volume defects and lead toward the accumulation of molecular hydrogen there;

c) electron emission from the surface, governed by the surface state.

Adsorption of bismuth on tungsten.
I. Steady-state processes

M. A. Mittsev

(Submitted July 23, 1973)
Zh. Tekh. Fiz. 44, 1292-1297 (June 1974)

The flux of particles desorbed from a heated tungsten ribbon on which a steady-state bismuth beam impinges is investigated by means of a mass spectrometer. Only Bi atoms are desorbed from the surface of the ribbon if its temperature is higher than 850°K. In addition to the desorption of Bi atoms, desorption of Bi_2 and Bi_4 occurs in the range 490-850°K. Analysis of the temperature dependences of atomic and molecular fluxes shows that, in contrast to tungsten–alkali-halide salt systems, the condition of equilibrium at the surface, where the evaporation rate is much lower than the molecular dissociation rate, is not satisfied for the W–Bi system.

INTRODUCTION

Investigations of the dissociation of NaCl and NaI molecules on a tungsten surface in ref. 1 have shown that quasiequilibrium processes occur in the adsorbed layer under the experimental conditions. The molecular dissociation energy MX of the salts used in the above work is considerably higher than the sublimation heat, so that surface molecular dissociation under equilibrium conditions occurs at a temperature above the temperature at which the crystalline phase obtains at the surface. The results given in ref. 1 support this conclusion.

We report here on the composition of desorption products from a tungsten surface exposed to a steady-state bismuth beam as a function of the tungsten temperature. In contrast to the alkali halide salts bismuth is characterized by the fact that the dissociation energy D of the Bi_2 molecule is approximately equal to the sublimation heats l of the monomer and the dimer[2,3] [$D_0(Bi_2)$ = 47 kcal/mole; $l_0(Bi)$ = 50 kcal/mole; $l_0(Bi_2)$ = 53 kcal/mole]. Therefore, in the case of equilibrium for bismuth, the dissociation temperature range for the Bi_2 molecule either coincides with the temperature range in which the condensed phase forms on the surface or is close to it. It is interesting to determine the characteristics of the dissociation and formation of molecules at the surface in this case.

DESCRIPTION OF THE DEVICE

The experiments are performed by means of a 90° mass spectrometer with an ion source similar to that used in ref. 1 (Fig. 1). A molecular beam of bismuth from the tantalum-foil evaporator 1 impinges on the tungsten ribbon 2. Atoms or molecules desorbed from the ribbon enter the region of electron-impact ionization 3 through a number of collimating slits. Usually, the ionizing electron energy is 2-4 V higher than the threshold energy for each component of the beam desorbed from the ribbon. The dissociative ion currents are negligible at these energies.

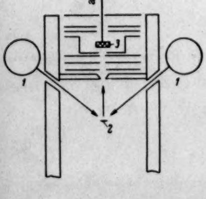

Fig. 1. Ion source of the mass spectrometer. 1) Evaporators; 2) tungsten ribbon; 3) cross section of the ionizing electron beam.

The ion current at the output of the mass spectrometer is recorded by means of a VÉU-1A electron multiplier, to which a U1-6 electrometric amplifier is connected.

The ribbon temperature T is determined by means of an optical pyrometer in the 1100-2500°K range or from the T = f(i) calibration curve, where i is the heating current, in the range below 1100°K. This curve is obtained in a separate experiment by measuring the temperature of a control ribbon by means of a Pt–Pt+10% Rh thermocouple. The control ribbon has the same dimensions as the operating ribbons (60 × 1 × 0.10 mm). The operating ribbons are chosen so that their temperature in the pyrometer range coincides with the temperature of the control ribbon. The accuracy of temperature measurements is also checked by determining the sublimation heats of magnesium and bismuth, which are evaporated from thick layers deposited on the ribbon.[4] The discrepancies between our sublimation heat values and those given by other authors are smaller than ± 2 kcal/mole.

The residual gas pressure in the vacuum system of the mass spectrometer is less than $(4\text{-}8)\cdot 10^{-9}$ torr.

DISCUSSION OF THE MEASUREMENT RESULTS

The mass spectrum of the ions produced by electron ionization of the neutrals desorbed from ribbon 1 as a steady bismuth beam strikes its surface shows peaks due to Bi^+, Bi_2^+, Bi_3^+, and Bi_4^+.

For a Maxwellian velocity distribution in the flux ν desorbed from the ribbon, the ion current I^+ is related to ν by[5,1]

$$\nu = kI^+T^{1/2}, \tag{1}$$

where k is a proportionality factor, which depends on the instrumental geometry, the electron ionization cross sec-

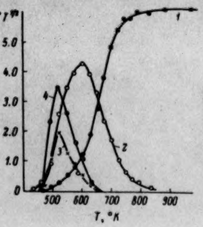

Fig. 2. Atomic and molecular fluxes (relative units) desorbed from a tungsten ribbon as functions of temperature for a steady flux arriving at the ribbon from the evaporator. 1) Bi; 2) Bi$_2$; 3) Bi$_3$; 4) Bi$_4$.

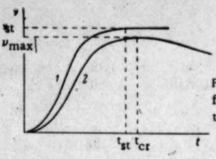

Fig. 3. Atomic and molecular fluxes from a tungsten ribbon as functions of time. 1) T > 520°K; 2) T < 520°K.

tion, and other factors, but is independent of T. We have been able to measure only the values of $I^+T^{1/2}$, proportional to the fluxes, since the coefficients k have not been determined in these experiments.

Figure 2 shows the value of $I^+T^{1/2}$ in relative units as a function of T for Bi^+, Bi_2^+, Bi_3^+, and Bi_4^+. These functions are measured in the following manner. Adsorbed gases are removed from the ribbon by pulsed heating at T = 2400°K, and the ribbon heating current is then changed abruptly to correspond to the ribbon temperature at which the ion current I^+ is to be measured.

The functions in Fig. 2 pertain to the molecular flux incident on the ribbon $\nu_0 \sim 10^{14}$ atoms/cm^2. The value of ν_0 is estimated with respect to the evaporator temperature, which is measured by means of a thermocouple, the bismuth vapor pressure, and the geometry of the ion source.

It is evident from Fig. 2 that only Bi atoms are desorbed at temperatures higher than 850°K. The atomic flux diminishes for T < 850°K, which is connected with an increase first in the flux of Bi$_2$ molecules and then in the flux of Bi$_4$ molecules. The Bi_3^+ ions in the mass spectrum evidently are of dissociative origin, since the ratio $I^+(Bi_3^+)\cdot T^{1/2}/I^+(Bi_4^+)\cdot T^{1/2}$ is independent of the ribbon temperature within the limits of experimental error, while the maxima of the curves $I^+(Bi_3^+)\cdot T^{1/2} = f(T)$ and $I^+(Bi_4{}^+)\cdot T^{1/2} = f(T)$ correspond to the same values of T.

Curve 1 of Fig. 3 illustrates schematically for T > 520°K the dependence of the flux of any beam component desorbed from the strip on the time t after the ribbon temperature reaches a steady-state value. After a time t_{st}, which depends on T and ν_0, the flux assumes the steady-state value ν_{st}. For T < 520°K, the dependence of ν on t is illustrated by curve 2 in Fig. 3. The flux ν decreases after it has reached its maximum value at the time t_{cr}. The variation rate is higher for low values of T. The value of ν decreases for $t > t_{cr}$ because the crystalline phase forms on the ribbon surface at these temperatures. From this point of view, desorption of Bi$_2$ and Bi$_4$ from the ribbon surface at T > 520°K is caused by the development of crystalline phase nuclei of subcritical size on the surface.

In Fig. 2, the steady-state flux values are given for T > 520°K, and the flux values $\nu = f(T)$ corresponding to the time t = 2 min > t_{cr} after the ribbon temperature has become steady are given for T < 520°K.

Investigations[1] of molecular dissociation MX of alkali halide salts on tungsten show that the dependence of the experimental values of $\nu(M)\nu(X)/\nu(MX)$ on T can be written in the following form:

$$\ln\frac{\nu M\,()\,\nu\,(x)}{\nu\,(Mx)} = \ln A - \frac{E}{RT}, \tag{2}$$

where A is a quantity which depends weakly on T, R is the gas constant, and E is equal to the molecular dissociation energy MX within the limits of experimental error. Figure 4 shows similar dependences for bismuth on tungsten: curve 1 for the reaction $Bi_2 \rightleftharpoons 2Bi$ and curve 2 for the reaction $Bi_4 \rightleftharpoons 2Bi_2$. It is evident that the experimental points lie on straight lines. The function $\log[\nu^2(Bi)/\nu(Bi_2)] = f(1/T)$ is observed only for low values of T. However, the values of E calculated from the slopes of these straight lines are much smaller than the bond breaking energies in the corresponding molecules. Thus, the mean of a number of E values calculated from the slope of curves similar to curve 1 is equal to E = 34 ± 3 kcal/mole, while the dissociation energy of Bi$_2$ molecules, calculated with respect to the evaporation heats[2] of Bi and Bi$_2$ and determined by mass spectrometry,[3] is equal to $D_0(Bi_2) = 47$ kcal/mole.

There is an even larger difference between the Bi$_2$–Bi$_2$ bond-breaking energy[3] $D_0(Bi_2 - Bi_2) = 47$ kcal/mole and the value E = 17 kcal/mole, calculated from the slope of the curve $\log \nu^2(Bi_2)/\nu(Bi_4)] = f(1/T)$.

To explain the above discrepancies let us consider the kinetics of surface phenomena under steady-state conditions, as in refs. 6 and 7. Such an analysis is rather complicated in the temperature range where simultaneous desorption of all three types of particles, i.e., Bi, Bi$_2$, and Bi$_4$, occurs. Therefore, we consider values of T for which the formation and dissociation of Bi$_2$ molecules are the only significant processes.

Assume that a beam consisting of Bi atoms and Bi$_2$ molecules strikes the surface, which is at a temperature

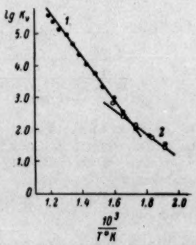

Fig. 4. Curves of log $K_\nu = f(1/T)$. 1) $K_\nu = \nu^2(Bi)/\nu(Bi_2)$ for the reaction $Bi_2 \rightleftharpoons 2Bi$; 2) $K_\nu = \nu^2(Bi_2)/\nu(Bi_4)$ for the reaction $Bi_4 \rightleftharpoons 2Bi_2$.

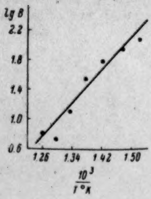

Fig. 5. Graph of log B = f(1/T).

T. We denote the atomic flux on the surface by ν_{01}, the atomic flux from the surface by ν_1, and the Bi_2 molecular flux from the surface by ν_2. Then, under steady-state conditions, we have the following equation for the atomic density N_1 at the surface:

$$\frac{dN_1}{dt} = \nu_{01} + 2kN_2 - \frac{1}{2}k'N_1^2 - \nu_1 = 0, \tag{3}$$

where k is the dissociation rate of diatomic molecules, k' is the atomic association rate, and N_2 is the surface density of Bi_2 molecules. Passing from densities to fluxes by using the relationships $C_iN_i = \nu_i$, we obtain the following after simple transformations:

$$\frac{\nu_1^2}{\nu_2} = 4\frac{k}{k'}\frac{C_1^2}{C_2}\left(1 - \frac{\nu_1 - \nu_{01}}{2\nu_2}\frac{C_2}{k}\right). \tag{4}$$

Under equilibrium conditions, we have

$$\frac{\nu_1^2}{\nu_2} = 4\frac{k}{k'}\frac{C_1^2}{C_2} \equiv K_{\nu p}, \tag{5}$$

which is readily shown by putting $\nu_1 = \nu_{01}$ according to the detailed balancing principle. Then, (4) assumes the following form:

$$K_\nu = \frac{\nu_1^2}{\nu_2} = K_{\nu p}\left(1 - \frac{\nu_1 - \nu_{01}}{2\nu_2}\frac{C_2}{k}\right). \tag{6}$$

In the case of alkali halide salts on tungsten, the slope of $\log K_\nu = f(1/T)$ is identical to the slope of a similar dependence under thermodynamic equilibrium conditions. According to (6), this is possible if $K_\nu \simeq K_{\nu p}$. We note in passing that for $K_\nu = K_{\nu p}$ the value of E from (2) is $E = D_T - 1/2\ RT$, where D_T is the molecular dissociation energy MX at temperature T. As mentioned earlier, the temperature dependence of K_ν is substantially different from the dependence $K_{\nu p} = f(1/T)$.

By using (6) we can determine C_2/k as a function of T if we know the temperature dependence of all the other quantities figuring in (6). For a certain $T = T_0$, $\nu_1 = \nu_{01}$ and

$$K_\nu = K_{\nu p}. \tag{7}$$

By subtracting (7) from (6), we obtain

$$\left(\frac{K_\nu}{K_{\nu p}}\right)_T - \left(\frac{K_\nu}{K_{\nu p}}\right)_{T_0} = -\frac{\nu_1 - \nu_{01}}{2\nu_2}\frac{C_2}{k}$$

and

$$\ln B \equiv \ln\left\{\frac{2\nu_2}{\nu_1 - \nu_{01}}\left[\left(\frac{K_\nu}{K_{\nu p}}\right)_{T_0} - \left(\frac{K_\nu}{K_{\nu p}}\right)_T\right]\right\} = \ln\frac{C_2^0}{k^0} - \frac{E_C - E_k}{RT}, \tag{8}$$

where C_2^0 and k^0 multiply the exponential factors, while E_C and E_k are the desorption activation energy and the dissociation activation energy of diatomic molecules, respectively.

To process experimental results by means of (8) it is necessary to know the percentage of atoms in the beam incident on the ribbon surface, i.e., the ratio ν_{01}/ν_0. This value is determined in a special experiment. An evaporator is substituted for ribbon 2 (Fig. 1), and the composition of the beam from the evaporator is determined for low ionizing electron energies. The ratio of efficiencies in mass-spectrometric detection of Bi atomic and Bi_2 molecular fluxes is determined by means of the steady-state temperature dependences of ν_1 and ν_2, similar to those given in Fig. 2 and the stationarity equation

$$\nu_0 = \nu_{01} + 2\nu_{02}. \tag{9}$$

For the evaporator temperatures at which the basic measurements are performed, the ratio ν_{01}/ν_0 is equal to 0.78.

The dependence of $K_{\nu p}$ on T is approximated by the function

$$K_{\nu p} = A\exp\left(-\frac{D_T}{RT}\right), \tag{10}$$

where A is assumed to be independent of T, while D_T = 48 kcal/mole, where T ~~= 720°C~~ is the mean value of the range of T used in calculations: 650-790°K.

Figure 5 shows the results of calculations based on (8) for one measurement of $\log K_\nu = (1/T)$. The mean of the six values of $E_k - E_C$ calculated from the slopes of graphs similar to that in Fig. 5 is equal to $E_k - E_C = 26 \pm 4$ kcal/mole.

It follows from these results that the dissociation activation energy of Bi_2 molecules at the surface is much higher than the desorption activation energy for these molecules. By using the obtained value of $E_k - E_C$ we estimate the order of magnitude of C_2^0/k^0.

By approximating K_ν and $K_{\nu p}$ by a function of the type (10) and using (6) and (7), we obtain

$$\frac{K_{\nu T}}{K_{\nu T_0}} = \frac{K_{\nu p T}}{K_{\nu p T_0}}\left(1 - \frac{\nu_1 - \nu_{01}}{2\nu_2}\frac{C_2}{k}\right)$$

and

$$\frac{C_2^0}{k^0} = \frac{2\nu_2}{\nu_1 - \nu_{01}}\exp\left(\frac{E_C - E_k}{RT}\right)\left\{1 - \exp\left[\frac{D_T - E}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)\right]\right\}. \tag{11}$$

For different measurement series, estimates of $C_2^0 \cdot (k^0)^{-1}$ based on (11) yield values in the range 10^{-7}-10^{-9}. For comparison it should be noted that Re–LiCl has been obtained in ref. 7 for the system $C_2^0/k^0 \approx 2 \cdot 10^{-2}$ on the basis of absolute reaction rate theory. The assumptions made in ref. 7 in estimating C_2^0/k^0 apparently also hold for bismuth on tungsten, so that $C_2^0/k^0 \sim 10^{-2}$ for this system.

The available experimental data on the system W–Bi are inadequate for an explanation of the large difference between C_2^0 and k^0 and the fact that the calculated value of C_2^0/k^0 exceeds the experimental value by a factor of 10^5-10^7.

The author is grateful to N. I. Ionov for discussion.

Effects of cleaning on adsorption by germanium single crystals

Yu. I. Belyakov, M. P. Volkov, and T. N. Kompaniets

A. A. Zhdanov Leningrad University
(Submitted July 6, 1973)
Zh. Tekh. Fiz., 44, 1298-1301 (June 1974)

Shock desorption has been used in a time-of-flight mass spectrometer to examine the adsorption of hydrogen and oxygen by germanium single crystals whose surfaces have been purified by reduction in atomic hydrogen or by bombardment with argon ions and subsequent brief or prolonged annealing. It is found that argon bombardment of a surface produced by reduction in hydrogen increases the rate of adsorption for molecular oxygen by a factor 5-6, while the rates of adsorption of atomic hydrogen and oxygen are only affected slightly. After prolonged annealing the adsorption behavior of surfaces after bombardment is the same as for surfaces obtained by reduction in atomic hydrogen.

We have examined the adsorption of hydrogen and oxygen on single crystals of germanium whose surfaces have been cleaned by various methods. The purity of the adsorbed gases and the cleanliness of the surfaces are recorded with a pulsed time-of-flight mass spectrometer, which records the desorption products. The amounts of adsorbed gas are determined by shock desorption.[1] See ref. 2 for details of the experimental methods.

The specimens are plates fabricated from single crystals 25 × 5 × 0.2 mm with (111) or (100) surfaces. The criterion for surface cleanliness in all cases is evaporation of the pure substance in the absence of desorption of any other products.

METHODS OF SURFACE CLEANING

Before installation in the mass spectrometer, the specimens are polished, etched in SR-4 solution, and washed with distilled water. During baking of the vacuum system the temperature of the specimen is kept above that of the walls. When the vacuum has attained $2\text{-}3 \cdot 10^{-9}$ torr, the surfaces are processed in three different ways.

a. Reduction in atomic hydrogen. It has been shown[3,4] that adsorption of atomic hydrogen on oxidized germanium makes it possible to remove oxygen as H_2O molecules at temperatures well below the desorption temperature for germanium monoxide. This result indicates that atomic hydrogen can clean germanium, removing nonvolatile films which usually remain after etching in SR-4.

The initial stages of cleaning with atomic hydrogen give rise to thermal desorption of water molecules, while desorption of atoms or molecules of hydrogen is not observed. The atomic hydrogen is produced by dissociation of H_2 molecules at a heated tungsten filament.[2-4] With the passage of time, the numbers of desorbed H_2O molecules falls and molecular hydrogen begins to dissolve. At the same time, thermal desorption of the germanium monoxide follows adsorption of the oxygen. After reduction in atomic hydrogen at $p\ (H_2) \sim 10^{-7}$ torr, there follows annealing under a very high vacuum, which reveals that no more H_2O molecules are desorbed. Then the specimens are annealed additionally for several hours at very low pressures with constant mass spectrometer monitoring of the evaporation products. The cleaning is terminated when the mass spectra only show peaks corresponding to germanium isotopes.

b. Bombardment with argon ions. A surface cleaned by reduction in hydrogen is bombarded with ions with energies of about 500 eV, the argon pressure in the system being about 10^{-3} torr. After bombardment for 10 min at 50-60 $\mu A/cm^2$, the specimen is given a 30 min annealing. The argon trapped by the specimen during bombardment is released during the first few minutes of annealing, and no subsequent desorption of argon is observed. This cycle is repeated several times, and is followed by annealing for 1-2 h at about 1000°K.

c. Annealing. The surface purified by bombardment is subjected to prolonged annealing in a very high vacuum at about 1000°K for several days.

The surface of each specimen thus undergoes all three stages of processing, after each of which we measure the amounts of adsorbed hydrogen and oxygen under standard conditions (constant gas pressure and temperature in the dissociation apparatus).

RESULTS

Surfaces cleaned by reduction in hydrogen give sticking coefficients[3] for O_2 of about 10^{-5}, with a substantial increase when the adsorption is performed in the presence of a hot tungsten filament. The amount of adsorbed oxygen is deduced from the number of GeO molecules released, and this depends substantially on the geometry of the specimen in relation to the tungsten filament as well as the temperature of the latter. This effect is not due to exposure of the surface to electrons, to the action of the light, to heating, to a deposition of tungsten or tungsten oxide on the surface, or to the generation of CO, CO_2, or H_2O at the hot tungsten. We conclude that the longer sticking coefficient is due to atomization of the O_2 at the hot tungsten and the easier adsorption of oxygen atoms; this result agrees with the results of ref. 5, where molecular beam methods are used to show that the rate of adsorption of oxygen atoms on germanium is larger by an order of magnitude than that for molecules.

Figure 1 shows the amount of desorbed GeO as a function of oxygen adsorption time for the adsorption of molecules (case 1) and common adsorption of atoms and molecules (case 2), the surface having been cleaned in hydrogen. The molecules make only a small contribution to the adsorption when atoms and molecules are present together, so in what follows we only consider adsorption of atomic oxygen.

When the surfaces have also been cleaned by bombardment, the O_2 is adsorbed much more rapidly (Fig. 2), while

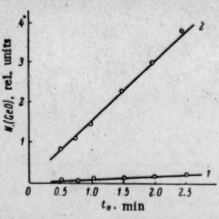

Fig. 1. Number of desorbed GeO molecules as a function of oxygen adsorption time for a germanium surface reduced in atomic hydrogen for adsorption of: 1) molecular oxygen; 2) atomic and molecular oxygen, P(O_2) ≈ $2 \cdot 10^{-6}$ torr.

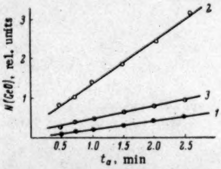

Fig. 2. Number of desorbed GeO molecules as a function of molecular oxygen adsorption time after: 1) reduction in atomic hydrogen; 2) additional bombardment by argon ions; 3) annealing (~ 30 h).

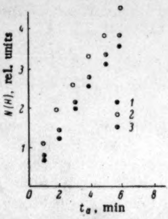

Fig. 3. Number of adsorbed hydrogen atoms as a function of time after: 1) reduction in atomic hydrogen; 2) additional bombardment by argon ions; 3) annealing (~ 30 h).

the amount of adsorbed oxygen is increased by less than 30-40%, the differences being within the limits of experimental error. The amount of adsorbed O_2 falls as the annealing time increases (Fig. 2), and after annealing for 50 h the value is approximately the same as for a surface cleaned by reduction in hydrogen.

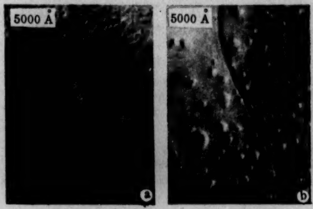

Fig. 4. Germanium surfaces made by: a) reduction in atomic hydrogen; b) bombardment with argon ions.

No adsorption of molecular hydrogen is found in any case. Figure 3 shows the amount of adsorbed hydrogen atoms as a function of adsorption time for surfaces cleaned in various ways. There is some increase in the amount of hydrogen adsorbed on the surface cleaned by bombardment because of the change in the surface relief, as is clear from photographs obtained by means of carbon replicas and an ÉM-5 electron microscope (Fig. 4).

Ion-bombarded surfaces show uptakes of O_2 molecules increased by factors of 5-6, which appear not to be related to additional purification of the germanium since we do not find a similar increase in the number of desorbed GeO molecules after adsorption of atomic oxygen. We assume that the more rapid adsorption of O_2 molecules on surfaces cleaned by bombardment is due either to increased microdefect concentrations, which heal only on prolonged annealing,[6] or to a change in the structure of the bonds at the surface during the bombardment—annealing cycle.[7]

We are indebted to N. I. Ionov for discussion and to M.I. Rudenko for the electron microscopy.

Monte Carlo analysis of ion scattering in a mass spectrometer

M. L. Aleksandrov, L. N. Gall', and N. S. Pliss

(Submitted April 26, 1973)
Zh. Tekh. Fiz., 44, 1302-1305 (June 1974)

A Monte Carlo method is proposed for calculating the ion scattering by the residual gas and thus, the isotopic sensitivity of a mass spectrometer. Use of this method on a computer shows that the results are simple to interpret. It can be applied to various spectrometers and particular geometric features can be incorporated in the method. It can be used to optimize ion-optics systems. A calculation of the ion-scattering background in a static magnetic mass analyzer on a Minsk-22 computer and an experimental check of the results are reported.

In nuclear physics, semiconductor physics, and in chemical kinetics it is frequently necessary to analyze microscopic amounts of a material, this material frequently appearing as a microscopic impurity in some other material. When mass-spectrometric methods are used for this analysis, the most crucial aspect of the spectrometer is its isotopic sensitivity, i.e., its ability to measure microscopic amounts of material at high intensity ratios of peaks corresponding to adjacent masses. This sensitivity can be defined as the ratio of the background current at a point M±1 in the mass spectrum to the current of unscattered ions with mass M (ref. 1). If the analyzer is capable of completely resolving ion beams with masses M and M±1, the background current at the mass positions adjacent to the main peak results from two effects: scattering of ions of the main beam by residual-gas molecules and the reflection of these ions from the walls of the analyzer chamber.

Efforts to reduce the scattering effect and to increase the isotopic sensitivity have been based on several methods, primarily those involving improvement of the vacuum, tandem analyzers, and retarding-potential electrostatic systems.[2-4] As a rule, the choice of a method depends on the materials being studied and on the intuition of the person designing the apparatus, since no methods have been available for calculating ion scattering. Theoretical papers[5,6] which appeared in the 1960s did not find practical applications because of serious calculation difficulties and several important limitations; in particular, the theories neglected the aberrations of the beam focusing, the energy lost by an ion in a collision, and the geometric structure of the interior of the analyzer chamber. We have now worked out a versatile method for calculating the background due to ion scattering by the residual gas in a mass spectrometer.

METHOD FOR CALCULATING ION SCATTERING

In working out this method we have been guided by the following considerations:

1. The method must be versatile, i.e., applicable to both static and dynamic instruments; it must be easily adaptable for computer calculations; and the results must be easy to interpret.

2. In the choice of the optimum ion-optics systems for mass spectrometers[7] with high isotopic sensitivity it is clearly necessary to put the same emphasis on the ion scattering as on the focusing properties of the analyzer. The method must therefore be flexible enough to incorporate easily the geometric structure of the particular analyzer.

3. The scattering of ions in an analyzer is a random process, in that the initial conditions under which the ion enters the analyzer chamber are random, the point at which an ion meets a residual-gas molecule is random, and the number of possible encounters, i.e., the angle through which the ion is deflected as a result of the first collision, is random. The method must therefore be based on statistical probabilities.

With these considerations in mind, we choose the Monte Carlo method, whose use on a computer requires analytic expressions for the ion trajectories in the analyzer for specified initial conditions and for specified distributions of the several random quantities. Then the computer can be used to simulate "histories" of the motion and scattering of individual ions, to determine the coordinates of the points at which the ions are incident on the plane of the detector slit, and thus to construct the appropriate histogram, which can then be analyzed to study the effect in question.

We can briefly review the basic steps and features of the simulation of ion scattering by the residual gas; the corresponding simulation for scattering of ions by the chamber walls is not fundamentally different, but does have certain unique features.

Simulation of the injection of ions into the vacuum chamber of the analyzer. Here we need to know the combined distributions of certain random quantities: the angles describing the direction of the ion velocity at the entrance into the chamber, the ion energy at the entrance, and the coordinates of the entrance point. This information can be extracted from a statistical analysis of the processes occurring in the ion source. The purpose of this step is to simulate the initial conditions under which the ion enters the chamber, i.e., to construct the random vector $\mathfrak{A}_0$, whose components are the random quantities listed above.

Determination of the coordinates of the point at which the next scattering event occurs. Here we need the distribution of the random quantity l, the mean free path of the ion between successive collisions. After constructing this distribution and plotting it along the ion trajectory, we can easily find the coordinates of the scattering point.

The distribution of the quantity l can be assumed to be exponential:

$$F(l)=\begin{cases} 1-\exp(-\lambda l), & l\geqslant 0, \\ 0 & l<0, \end{cases} \qquad (1)$$

where $\lambda = \sqrt{2}n\sigma_{tot}$, n is the number of residual-gas molecules per unit volume, and σ_{tot} is the total scattering cross section.

It is important to note that at the vacuum levels used in modern mass spectrometry, the mean free path of an ion is much longer than its path in the apparatus. Therefore, only a small number of the histories generated on the basis of distribution (1) will contribute useful information; the overwhelming majority of the ions reach the collector without having undergone any collisions. To avoid the unproductive expenditure of computer time which would result from this direct simulation of the mean free path, we simulate a nominal mean free path which is defined for our purposes.

We denote by $S(\tilde{\alpha}_0)$ the length of the trajectory of an unscattered ion which enters the analyzer chamber under initial conditions $\tilde{\alpha}_0$; then the distribution of the nominal mean free path between collisions can be specified as

$$G(l)=\frac{F(l)}{F[S(\alpha_0)]},$$

with $F(l)$ given by (1).

Analysis of this second step of the calculation reveals another important advantage of this method: The ion-scattering background can be evaluated by varying the pressure at various parts of the apparatus. For example, in the case of an exponential distribution of the mean free path, we can do this by introducing scaling factors for various parts of the apparatus as functions of the pressure.

Simulation of the initial conditions of the ion motion after a scattering event. Here we need to know the distributions of the angles specifying the direction in which the ion moves after a collision; these angles are measured with respect to the direction in which the ion was moving initially. Here it is convenient to analyze the scattering event itself, in the spherical coordinate system fixed in the center of mass. If we adopt as the polar axis the vector of the relative velocity of the ion and the target molecule before the scattering, we can assume the azimuthal angle of the new relative velocity to be distributed homogeneously over the interval $[0, 2\pi]$ by virtue of the axial symmetry of the scattering.

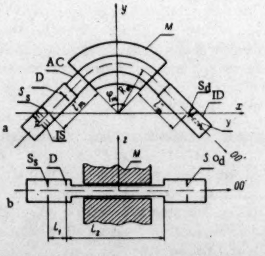

Fig. 1. Arrangement and basic structural parameters of a magnetic analyzer. a) Diagram of the analyzer in the xy plane; here φ_m = 90° and $R_m = l'_m = l''_m$ = 500 mm. b) Diagram of the analyzer in the $x\dot{z}$ plane along the axis of the central trajectory; here L_1 = 300 mm and L_2 = 1040 mm. IS) Ion source; S_s) exit slit of the ion source (0.1 × 4 mm); D) diaphragm which limits the beam to a height h_D = 7 mm; AC) analyzer chamber (70 × 11 mm); S_d) slit of ion detector (0.4 × 7.6 mm); ID) ion detector with movable collector; M) multiplier.

The polar angle θ, on the other hand, is a function $\theta(b)$ of the impact parameter b. For the scattering of a spatially homogeneous ion beam by a single scattering center, the impact parameter has the distribution

$$f(b)=\begin{cases} cb, & b\in[b_1, b_2], \\ 0, & b\notin[b_1, b_2], \end{cases} \tag{2}$$

where c is a normalization factor, and b_1 and b_2 are determined from the equations $\theta(b_1) = \theta_{max}$ and $\theta(b_2) = \theta_{min}$. The angle θ_{max} is governed by the total length of the interval over which the histogram is constructed, while θ_{min} is governed by the length of the partitioning interval. As the quantity σ_{tot} in (1) we adopt $\sigma_{tot} = \pi b_2^2$. The random quantity b with distribution (2) can be simulated easily, while the function $\theta(b)$ is governed by the nature of the ion, the nature of the molecule, and the ion energy, and thus requires a special study.

After calculating θ and transforming the velocity vector to the laboratory system, we can easily determine the trajectory along which the ion subsequently moves.

Plotting of the scattered-ion histograms. We consider the xz plane of the detector; we draw axis Ox through the midpoint along the long dimension of the detector slit, and we draw axis Oz, perpendicular to it. If the detector slit has a length h, we consider the band in this plane defined by $(-h/2) \leq z \leq (h/2)$; it is in this band that we record the coordinates of all the incident ions. As a result we find a sample $x_1, x_2, \ldots, x_N$, where N is the number of "histories"; according to the rules of statistics, we use this sample to construct the histogram for evaluating the scattered-ion background.

Example. As an example we calculate and compare by experiment the scattered-ion background in a static magnetic mass analyzer (Fig. 1).

Figure 2 shows the "tail" of the K^{39} peak for scatter-

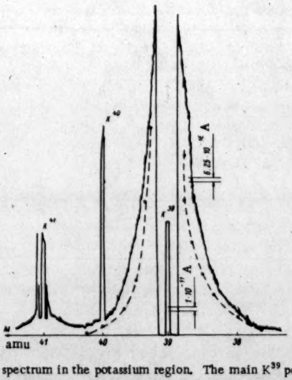

Fig. 2. Mass spectrum in the potassium region. The main K^{39} peak and the scattered-ion peak are plotted with different scales (the scale divisions are $1 \cdot 10^{-11}$ and $6.25 \cdot 10^{-16}$ A, respectively). The dashed curve is plotted by smoothing the scattered-ion histogram calculated by the method of the present paper.

ing by residual air, measured in an apparatus having U_{acc} = 3 keV and an analyzer-chamber pressure of $p = 3 \cdot 10^{-7}$ torr. The dashed curve in this figure is the calculated background found by the simulation of 4000 histories in 40 min on a Minsk-22 computer.

We see that the results agree well. The apparent reason that the calculated curve lies below the experimental curve is that our calculation takes into account only the elastic scattering of ions by residual-gas molecules, while there are other effects which influence the background.

CONCLUSIONS

1. An effective and versatile Monte Carlo method has been worked out for calculating the ion scattering by the residual gas and walls of an analyzer chamber of a mass spectrometer. No such method has been reported previously.

2. Since the method can incorporate any geometric structure of the analyzer chamber and the features of the ion-beam focusing, it can be used to select and optimize ion-optics systems for mass-spectrometer.

Behavior of molten salts in strong electric fields

A. Z. Éfendiev, O. M. Shabanov, S. M. Gadzhiev, and S. M. Tagirov

V. I. Lenin Dagestan State University

(Submitted April 10, 1973)
Zh. Tekh. Fiz., 44, 1306-1311 (June 1974)

In an effort to fill a gap in the literature on the behavior of molten electrolytes (salts) in strong electric fields, a study is made of the electrical conductivity of molten lithium chloride at 630, 660, 735, and 800°C, of sodium chloride at 830 and 885°C, and of potassium chloride at 800, 840, and 885°C. Various field intensities are used. At fields above 40 kV/cm the discharge is accompanied by a glow of the salt, not due to breakdown. The electrical conductivity increases with increasing field, approaching a limiting value at a certain field which is a function of the temperature and the nature of the salt. The high-voltage conductivities agree with the Nernst–Einstein equation, so that the self-diffusion coefficients of the ions in the various salts can be calculated. The activation energy for the conductivity is higher in strong fields than in weak fields.

The few works which have been reported on the high-voltage behavior of conducting liquids can be classified into two groups; in the first group[1–3] it has been established that the electrical conductivity of molten electrolytes increases with increasing electric field, reaching saturation in fields of the order of 10^5 V/cm. These results constitute experimental confirmation of the existence of ion environments, in accordance with the Debye–Hückel–Onsager theory. In the second group, comparatively recent work,[4–6] a first attempt has been made to establish the physical nature of a high-voltage discharge in a conducting liquid. It was concluded that the discharge can be of the nature of an exponential decay, an oscillatory discharge, or a voltage cutoff (breakdown), depending on the high-voltage conductivity and the intensity of the electric field. The high-voltage behavior is found to be a function of the low-voltage conductivity, but not the nature of the electrolyte.

Our search of the literature has revealed no work on the behavior of molten electrolytes in strong electric fields, even though ionic liquids, of which molten salts are typical, are the most interesting, (from the theoretical standpoint) class of liquids displaying a long-range structural-particle potential. Furthermore, such liquids are widely used in atomic power and metallurgy. Study of the high-voltage behavior of molten salts can yield valuable information about the structures and transport properties of these liquids; in particular, as pointed out in ref. 7, a knowledge of the limiting conductivity of an electrolyte can shed light on the discrepancy in the Nernst–Einstein equation and can make it possible to use this equation to determine the self-diffusion coefficients of ions in melts. This latter result would greatly facilitate study of the kinetics of electrode processes.

We have therefore begun a study of molten salts in strong electric fields.

EXPERIMENTAL PROCEDURE

The apparatus used to measure the electrical conductivity of the molten salts as a function of the electric field is similar to that described in ref. 6, but the current is measured by a Rogowski loop instead of a current shunt. A generator with a controllable switch produces pulses, whose amplitude is adjustable up to 30 kV. The oscilloscope sweep is synchronized with the generator switch by means of a special single-pulse unit with delay adjustable from 0.3 to 50 μsec. The voltage drop across the sample and the current through it are recorded by means of an OK-21 dual-beam high-speed oscilloscope. The oscillograms are taken with a Zenit S camera using high-speed film. Mel'nikov et al.[6] did not state whether the electrolyte impedance was monitored in the course of their experiments. In the present experiments the low-voltage impedance of the sample is measured with an ac bridge after each pulse. The succeeding pulse is supplied only after the low-voltage impedance returns to its original value.

The maximum voltage drop across the melts is about 15 kV, and the currents do not exceed 6000 A. The electrodes are molybdenum conductors 1-2 mm in diameter, enclosed in long porcelain tubes. The ends of the electrodes are bent at a 90° angle and held tightly in a short (2 cm) porcelain tube to keep the polished bare surfaces strictly parallel. This short tube is ground off near the ends of the electrodes to allow free access of the melt to the interelectrode volume. The procelain tubes are reinforced with platinum wire at several points to keep the electrodes from being driven apart by the shock wave which arises in the discharge. The samples are prepared from "chemically pure" stock, recrystallized, and dried for 10-15 h. The salt is held in a porcelain or alundum crucible, which is lowered into position on the bottom of the quartz tube. The tube is filled with argon. The temperature of the melt is measured by a platinum/platinum–rhodium thermocouple. The entire system is placed in a muffle furnace.

RESULTS AND DISCUSSION

We have studied the electrical conductivity of the salts as a function of the electric field at several temperatures: 630, 660, 735, and 800°C for lithium chloride, 830 and 876°C for sodium chloride, and 800, 840, and 885°C for potassium chloride.

Because of the high conductivity of molten salts the impedance of the discharge gap can be lower than the critical impedance of the discharge circuit, in which case the

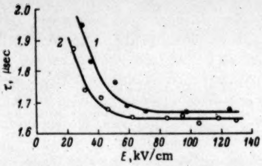

Fig. 2. Voltage-discharge time as a function of the electric field in LiCl at various temperatures. t, °C: 1) 735; 2) 800.

discharge becomes oscillatory. We therefore connect a 3.58 Ω noninductive resistor in series with the discharge gap; this resistor also limits the discharge current. Figure 1 shows typical oscillograms. The time constant of the discharge circuit is a function of the capacitance of the capacitor, the 3.58 Ω resistor in series with the salt, and the impedance of the salt itself. In the present experiments, this time decreases with increasing voltage. Figure 2 shows the discharge time of the first half-period of the aperiodic voltage oscillations for LiCl at 735 and 800°C as a function of the electric field. Other conditions being equal, a decrease in this time should be the result of a decrease in the resistance of the molten salts accompanying an increase in the electric field. The discharge time becomes constant at a certain value of E, which is a function of the temperature and the nature of the salt.

At fields above 40 kV/cm the salts glow; the oscillograms reveal no corresponding rapid voltage drop or current discontinuity. The glow becomes more intense as the field is strengthened (we did not take photographs of the glow). The oscillograms show that over the field and temperature ranges in question the glow is not due to a breakdown; it might be electroluminescence. Over a time of the order of 10^{-6} sec the Joule heat and the discharge products do not change the temperature or composition perceptibly.

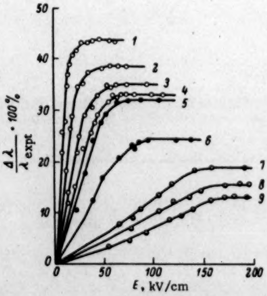

Fig. 3. The quantity $(\Delta\lambda/\lambda_{expt}) \cdot 100\%$ as function of the electric field. t, °C: 1-4) LiCl; 1) 800; 2) 735; 3) 660; 4) 630; 5, 6) NaCl; 5) 876; 6) 830; 7-9) KCl; 7) 885; 8) 840; 9) 800.

The electrical conductivities of LiCl, NaCl, and KCl at the stated temperatures, calculated from the oscillograms, increase with increasing field, tending toward a limiting value at a field value governed by the temperature and the nature of the salt. Figure 3 shows the relative change in the equivalent conductivity of these salts as a function of the electric field; at a certain field (E_{lim}) this conductivity becomes constant (the equivalent conductivity reaches its limiting value). Table 1 shows the limiting conductivities λ_{lim} along with the fields at which they are reached (E_{lim}), the relative change in the equivalent conductivity $(\Delta\lambda/\lambda_{expt}) \cdot 100\%$, the ordinary low-voltage conductivity λ_{expt}, and the ratio $\lambda_{lim}/\lambda_{expt}$.

The data in Fig. 3 and Table 1 show that for a given salt the quantities λ_{lim} and $(\Delta\lambda/\lambda_{expt}) \cdot 100\%$ increase while the quantities $\lambda_{expt}/\lambda_{lim}$ and E_{lim} decrease with increasing temperature. The relative change at a given temperature decreases from LiCl to KCl, while E_{lim} and $\lambda_{expt}/\lambda_{lim}$ increase (the latter quantity is adopted as the degree of dissociation of the electrolyte in the case of electrolytic solutions; then λ_{lim} is the equivalent conductivity at infinite dilution).

We believe there are two reasons for the increase in the conductivity of the molten salts with increasing electric field. The structure of the molten chloride of an alkali metal can be described by[9, 10]

$$\mathrm{MeCl}_n^{(n-1)-} + (n-1)\,\mathrm{Me}^+ \quad (\mathrm{Me}^+ = \mathrm{Li}^+,\ \mathrm{Na}^+,\ \mathrm{K}^+). \tag{1}$$

The conductivity is governed principally by the free cations in the second coordination sphere, which, like the complex $\mathrm{MeCl}_n^{(n-1)-}$ ions, have ion environments. In certain molten salts the motion of an ion in the electric field is prevented by the relaxational damping which results from a Coulomb interaction between the moving ion and the environment, whose symmetry is disrupted.[11] As the field is strengthened the drift velocity increases and can reach a value such that the ion environment does not manage to form along the path of the ion, i.e., the relaxational damping is removed. This case corresponds to the condition

$$l \leqslant \tau v, \tag{2}$$

TABLE 2

Salt	t, °C	λ_p	λ_{lim}	$D_+ \cdot 10^4$, cm²/sec		$D_- \cdot 10^4$, cm²/sec	
				[12]	from λ_{lim}	[12]	from λ_{lim}

	885	—	148.4	—	0.96	—	0.59

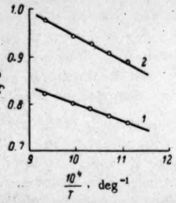

Fig. 4. log σ as a function of 1/T.

where l is the thickness of the ion environments (the Debye shielding length), τ is the relaxation time, and v is the ion velocity.

On the other hand, the ion energy in the field can be equal to or larger than the energy with which the ions are bound in the complex, so that the complex ions can decay, increasing the concentration of current carriers. Thus an increase in the field can increase both the mobility and the concentration of the carriers. These increases can continue until a field E_{lim} is reached, above which the mobility and concentration remain constant and Ohm's law holds.

Comparison shows that the values of E_{lim} for molten salts are low in comparison with those for electrolytic solutions,[1,3] apparently because solvation and electrophoretic damping do not occur in the molten salts. The functional dependence of E_{lim} on the temperature for a given melt can be described by the empirical equation

$$\ln E_{\text{lim}} = A - BT, \tag{3}$$

where E_{lim} is in volts per centimeter, T is in deg K, and A and B are constants for a given salt. For LiCl, e.g., the constants are A = 15.15 and B = $4.6 \cdot 10^{-3}$.

We can find an explanation for this functional dependence of the relative conductivity change on the temperature by considering the way in which the structure of the molten salt varies with temperature. As the temperature is raised the first coordination number, n, in Eq. (1) must decrease; then the relative number of free ions in the second coordination sphere decreases, and the relative number of ions bound in the complex increases. These changes explain the increase in $\Delta\lambda \cdot 100\%/\lambda_{\text{expt}}$ with increasing temperature: At high fields the relaxational damping is weakened and the complexes decay. The observed change in $\lambda_{\text{expt}}/\lambda_{\text{lim}}$ for a given salt as a function of the temperature can also be explained in this manner. The relative change in the conductivity decreases from LiCl to KCl at a given temperature because the relative stability of the complexes and the extent of binding in complexes decrease from LiCl to KCl, as follows from an analysis of the radial-distribution curves.

In weak fields the logarithm of the conductivity is a linear function of 1/T for alkali chlorides.[8] To check this functional dependence for strong fields we have plotted the corresponding data from the present experiments in Fig. 4, where the weak-field data from ref. 8 are shown for comparison. We see that ln σ is again a linear function of 1/T in strong fields, but that the activation energy is higher than in weak fields. This increase in the activation energy corresponds to an increase in the height of the potential barrier, which hinders ion migration.

According to the Nernst–Einstein equation,

$$\lambda_D = \frac{F^2}{RT}(D_+ + D_-), \tag{4}$$

the self-diffusion coefficients of the ion of a salt are unambiguously related to the equivalent conductivity; however, in the case of molten salts the conductivity calculated from the experimental self-diffusion coefficients is 40% higher than the (directly measured) weak-field conductivity. Nevertheless, the strong-field values of λ_{lim} agree with the values calculated from the self-diffusion coefficients by means of Eq. (4). The values of λ_{lim} can thus be used to calculate the self-diffusion coefficients of the various ions, if t and λ_{lim}, and the transition number are known. Table 2 shows the coefficients calculated from

$$D_i = t_i \sum D_i = t_i \frac{RT}{F^2} \lambda_{\text{lim}} \tag{5}$$

along with the experimental coefficients for LiCl, NaCl, and KCl. The literature reveals no data on self-diffusion for the cases of LiCl and KCl, but the agreement between the coefficients measured directly and calculated from λ_{lim} for NaCl is quite satisfactory, so that we can hope that experiment will confirm the values calculated for LiCl and KCl.

In calculating the self-diffusion coefficients we use the transition numbers for NaCl, calculated from

$$t_\pm = \frac{D_\pm}{D_+ + D_-}.$$

The values of D_+ and D_- are taken from ref. 12. In the calculations for LiCl and KCl the transition numbers are taken from ref. 13.

SUMMARY

1. The electrical conductivity of molten salts (alkali chlorides) has been measured as a function of the electric field for the first time. The conductivity has been shown to increase with increasing field, reaching a limiting value.

2. Breakdown is not observed in the molten salts. The discharge is accompanied by a glow.

3. The limiting conductivities, used in the Nernst–Einstein equation, give values for the self-diffusion coefficients of the ions which agree well with the values measured directly.

4. The activation energy for the conductivity increases with increasing field.

A theoretical and experimental study has been made of the effect of the shape of a superconducting shield on its shielding properties. Axisymmetric shields (cylindrical shield with a bottom or spherical shield with a circular aperture) are shown to be effective. The calculated shielding coefficients agree with the experimental data.

In modern physics experiments it is frequently necessary to produce a homogeneous magnetic field which is highly stable in time or to reduce the magnetic field to zero in some volume. Both problems can be handled successfully by means of superconducting shields. The Meissner effect induces superconducting currents at the surface of such a shield and these currents prevent the magnetic flux from penetrating into the region enclosed by the shield. The shielding properties are governed by several factors: the shape of the shield, the configuration of the external magnetic field, and the physical and chemical properties of the shield material (the purity of the metal, the surface state, strain, etc.). We report below a theoretical and experimental study of the effect of shape on the shielding properties of a superconducting shield.

A rigorous approach to this problem would involve the solution of Maxwell's equations outside and inside the superconductor and matching the solutions at the interface, but this approach is complicated by the need to know the distribution of the currents induced on the surface of the superconductor. Alternatively, in shielding problems it is possible to use the model of an ideal Meissner effect, letting the London penetration depth of the magnetic field, δ_L, approach zero. Then the analytic problem becomes a boundary-value problem with a vanishing normal derivative of the magnetostatic potential.[1)]

If the results of this analysis are to be correct, the value of δ_L must be much smaller than all characteristic dimensions of the problem (e.g., the radius of curvature ρ of the convex parts of the shell); otherwise, as follows from potential theory, divergences can occur at certain points. It is convenient to exploit the strong analogy between the current distribution over the surface of a superconductor and the distribution of electrostatic charge in a conductor. The magnetic field produced by the surface current has equipotentials which are coupled to surface charges. When there are convex areas on the surface of the superconductor, the magnetic lines of force become dense near them, as if the surface current were increased locally. On the other hand, there is an important distinction between our problem and the electrostatic problem: This increase in the magnetic field cannot continue without limit. Each superconductor is characterized by a definite value of the critical field H_k so that we can work from the requirement that the field near convex regions cannot exceed the critical field to find a rough estimate of the applicability range of this calculation method:

$$H < H_k \frac{\rho}{a}, \tag{1}$$

where H is the external field, and a is the characteristic width of the aperture in the shield. We conclude from this estimate that an effort should be made in the design of a shield to smooth out any corners.

In this work we consider superconducting shields of simple shape: plane shields and axisymmetric shields.[4,5] Evaluation of the shielding coefficients shows that the axisymmetric shields are more effective, so that only such shields are studied in the experiments: cylindrical shields (with closed bottoms) and spherical shells with apertures. We describe the experimental apparatus and report on the results of measurements for lead shields.

CALCULATION OF SHIELDING PROPERTIES

Superconducting plane with an aperture. We assume that a homogeneous magnetic field is produced far from a superconducting plane with an aperture and that the field is parallel to the plane of the shield, in the x direction. The field in the volume occupied by the superconductor is described by the Maxwell equations

$$\left.\begin{aligned}\operatorname{curl}\mathbf{H}=0,\\ \operatorname{div}\mathbf{H}=0.\end{aligned}\right\} \tag{2}$$

Introducing the potential φ and exploiting the symmetry of the problem, we reduce system (2) to the Laplace equation

$$\frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial y^2}=0,\ \mathbf{H}=-\operatorname{grad}\varphi. \tag{3}$$

This equation is solved with the boundary condition that the normal derivative of the potential $\partial\varphi/\partial n$ must vanish at the boundary of the superconductor. It is convenient to use the conformal-mapping method of ref. 6, which does not alter the Laplace equation but simply transforms the boundary condition (see, e.g., ref. 7):

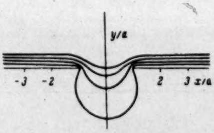

Fig. 1. Distribution of magnetic lines of force for a plane shield with an aperture.

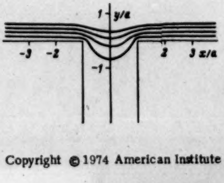

Fig. 2. Distribution of magnetic lines of force for a superconducting half-space with a groove.

$$\left.\frac{\partial\varphi_1}{\partial n_1}\right|_{S_1}=\left.\frac{\partial\varphi}{\partial n}\right|_S|z'(z_1)|=0, \tag{4}$$

where the complex quantity is $z = x + iy$, and the subscript "S" indicates that the derivative is to be evaluated at the boundary of the superconductor. Solving Eq. (4), we use the Cauchy–Riemann conditions to construct the complex potential $W_1 = \varphi_1 + i\psi_1 = A_1 z_1 + B_1$. To find the potential $W(z) = W_1[z_1(z)]$ in the z plane it is sufficient to know the function $z_1 = z_1(z)$. Using a Schwarz–Christoffel transformation,[6] we find

$$z_1=\frac{C}{a}\left(z+\sqrt{z^2-a^2}\right), \tag{5}$$

where $2a$ is the width of the aperture and C is a constant. The sign in front of the radical is chosen so that the transformation maps all points z into the upper half-plane of z_1. In this way we find the complex potential W(z). Then we use Eqs. (3) to calculate the components of the magnetic field around the shield:2)

$$H_x=-\frac{\partial\,\mathrm{Re}\,W}{\partial x},\quad H_y=-\frac{\partial\,\mathrm{Re}\,W}{\partial y}. \tag{6}$$

After lengthy but simple calculations we find

$$\begin{aligned}H_x=\frac{1}{2}\Bigg\{1+\Bigg[&\frac{x\,\mathrm{sign}\,(xy)\,(x^2+y^2-a^2)}{[(x^2-y^2-a^2)^2+4x^2y^2]^{3/4}}\\ &\times\frac{1}{\sqrt{2}}\sqrt{1+\frac{x^2-y^2-a^2}{\sqrt{(x^2-y^2-a^2)^2+4x^2y^2}}}\\ &+\frac{y\,(x^2+y^2+a^2)}{[(x^2-y^2-a^2)^2+4x^2y^2]^{3/4}}\frac{1}{\sqrt{2}}\sqrt{1-\frac{x^2-y^2-a^2}{\sqrt{(x^2-y^2-a^2)^2+4x^2y^2}}}\Bigg]\Bigg\};\\ H_y=\frac{H}{2}\Bigg\{&\frac{y\,\mathrm{sign}\,(xy)\,(x^2+y^2+a^2)}{[(x^2-y^2-a^2)^2+4x^2y^2]^{3/4}}\frac{1}{\sqrt{2}}\sqrt{1+\frac{x^2-y^2-a^2}{\sqrt{(x^2-y^2-a^2)^2+4x^2y^2}}}\\ &-\frac{x\,(x^2+y^2-a^2)}{[(x^2-y^2-a^2)^2+4x^2y^2]^{3/4}}\frac{1}{\sqrt{2}}\sqrt{1-\frac{x^2-y^2-a^2}{\sqrt{(x^2-y^2-a^2)^2+4x^2y^2}}}\Bigg\}.\end{aligned} \tag{7}$$

Let us consider the behavior of the field components along the x and y symmetry axes; according to (7), for example, we have $H_y = 0$ at the y axis, while H_x is described by

$$H_x=\frac{H}{2}\left(1+\frac{y}{\sqrt{y^2+a^2}}\right). \tag{8}$$

The shielding properties are customarily expressed in terms of a shielding coefficient K_S, which is the factor by which the magnetic field in the shielded volume is reduced at a distance equal to the width of the aperture in the shield.3) For a shield which is a superconducting plane with an aperture $2a$ wide we find $K_S \simeq 20$. As we move along the x axis we find

$$\left.\begin{aligned}&H_x=\frac{H}{2},\quad H_y=\frac{H}{2}\frac{x}{\sqrt{a^2-x^2}},\quad |x|<a,\\ &H_x=\frac{H}{2}\left\{1+\mathrm{sign}\,(y\to\pm 0)\frac{x\,[\theta(x-a)-\theta(-x-a)]}{\sqrt{x^2-a^2}}\right\},\\ &H_y=0,\quad |x|>a,\end{aligned}\right\} \tag{9}$$

where

$$\theta(x)=\begin{cases}1, & x>0,\\ 0, & x<0.\end{cases}$$

The reason for the divergences is noted above; The shield under consideration here is a plane with an aperture, near whose edge the condition $\delta_L \ll \rho$ does not hold. Figure 1 shows the distribution of the magnetic lines of force for this case. The principal drawback of such a shield is that if the field to be shielded against is not strictly parallel to the plane of the superconductor (if the component H_y does not vanish strictly) this field "falls into" the gap.4)

Superconducting half-space with a groove. Another possible version of the plane shield is a superconducting half-space with a groove; here we consider only the case of an infinitely deep groove. Again writing Maxwell equations (2), we conformally map the z plane into the upper half-plane of z_1. The Schwarz–Christoffel equation yields the relation

$$z=\frac{2a}{\pi}\left[\sqrt{z_1^2-1}+\arcsin\frac{1}{z_1}\right]. \tag{10}$$

Separating the real and imaginary parts in (10), we find a system of equations from which we can determine $x_1(x, y)$ and $y_1(x, y)$; these are used to construct the potential W(z):

$$\left.\begin{aligned}&x=\frac{2a}{\pi}\left[\sqrt{\rho}\,\frac{\theta}{2}+\mathrm{arc\,tg}\,\frac{x_1+\sqrt{\rho}\left(x_1\sin\frac{\theta}{2}-y_1\cos\frac{\theta}{2}\right)}{y_1+\sqrt{\rho}\left(x_1\cos\frac{\theta}{2}+y_1\sin\frac{\theta}{2}\right)}\right],\\ &y=\frac{2a}{\pi}\left[\sqrt{\rho}\,\sin\frac{\theta}{2}-\ln\sqrt{\frac{\rho+2\sqrt{\rho}\,\sin\frac{\theta}{2}+1}{x_1^2+y_1^2}}\right],\end{aligned}\right\} \tag{11}$$

where

$$\rho=\sqrt{(x_1^2-y_1^2-1)^2+4x_1^2y_1^2},\quad \theta=\theta_1+\theta_2,$$

$$\theta_1=\begin{cases}\mathrm{arc\,tg}\,\dfrac{y_1}{x_1-1}, & x_1>1,\\ \pi+\mathrm{arc\,tg}\,\dfrac{y_1}{x_1-1}, & x_1<1,\end{cases}$$

$$\theta_2=\begin{cases}\mathrm{arc\,tg}\,\dfrac{y_1}{x_1+1}, & x_1>-1\\ \pi+\mathrm{arc\,tg}\,\dfrac{y_1}{x_1+1}, & x_1<-1.\end{cases}$$

According to (11), at $x_1 = 0$ we have

$$x=0,\quad y=\frac{2a}{\pi}\left[\sqrt{y_1^2+1}+\ln\frac{y_1}{1+\sqrt{1+y_1^2}}\right]. \tag{12}$$

Noting that the left side of Eq. (12) vanishes at $y_1 \simeq 2/3$, we can find the analytic function $y_1 = y_1(0, y)$ within the shielded region by expanding (12) in powers of y_1. Retaining first-order terms and using (6), we find the behavior of the field components along the y axis:

$$H_x\cong\frac{2H}{e}e^{-\frac{\pi}{2a}|y|},\quad H_y=0, \tag{13}$$

from which we find $K_S \simeq 32$. Figure 2 shows the distribution of magnetic lines of force calculated from (11). Figure 3 shows the exact behavior of H_x along the y axis, plotted with the help of a computer.

Cylindrical superconducting shield. We turn now to axisymmetric shields, the simplest version of which is a superconducting cylinder. We assume the outer and inner radii of the cylinder to be a and b, respectively, and we assume the magnetic field to be directed along the z axis, the axis of the cylinder. We again begin the solution with the Laplace equation, which can be written as follows in the case of axial symmetry:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\varphi}{\partial r}\right)+\frac{\partial^2\varphi}{\partial z^2}=0. \tag{14}$$

We use the boundary conditions

$$\left.\frac{\partial\varphi}{\partial n}\right|_s=0,\quad -\left.\frac{\partial\varphi}{\partial z}\right|_{r=\infty}=H,\quad \left.\frac{\partial\varphi}{\partial z}\right|_{\substack{z=-\infty\\ r\leqslant a}}=0. \tag{15}$$

The last of these conditions reflects the circumstance that we are interested in a single connected shield: Experimentally, a superconducting shield is usually a long cylinder with a closed end. We divide the volume outside the superconductor into three volumes: (1) $0 \leq r \leq a$, $z \leq 0$; (2) the volume $r \geq 0$, $z \geq 0$; and (3) the volume $r \geq b$, $z \leq 0$.

We solve Eq. (14) by separation of variables. Using boundary conditions (15) we find the explicit form of the potential $\varphi(r, z)$ in these three volumes. We write the solution as a Fourier series (in the first volume) and as Fourier integrals (in the second and third volumes). The magnetic field components calculated from this solution ($H_r = -\partial\varphi/\partial r$, $H_z = -\partial\varphi/\partial z$) are, for the first two volumes,

$$\left.\begin{aligned} H_r^{(1)}&=H\sum_{m=1}^{\infty}A_m p'_m J_1\left(p'_m\frac{r}{a}\right)e^{\frac{p'_m}{a}z},\\ H_z^{(1)}&=-H\sum_{m=1}^{\infty}A_m p'_m J_0\left(p'_m\frac{r}{a}\right)e^{\frac{p'_m}{a}z}, \end{aligned}\right\} \tag{16}$$

$$\left.\begin{aligned} H_r^{(2)}&=H\int_0^{\infty}d\nu\,\nu F(\nu)\,J_1\left(\nu\frac{r}{a}\right)e^{-\frac{\nu}{a}z},\\ H_z^{(2)}&=H+H\int_0^{\infty}d\nu\,\nu F(\nu)\,J_0\left(\nu\frac{r}{a}\right)e^{-\frac{\nu}{a}z}. \end{aligned}\right\} \tag{17}$$

Here, J_n is the Bessel function of order n; p'_m are the zeros of J_1. Since we are only interested in the shielding properties of a cylindrical shell, we omit the field components in the third volume, which are functions of the unknown function $G(\nu)$. It turns out that both the coefficients A_m and the function $G(\nu)$ can be expressed in terms of $F(\nu)$; thus, the problem of calculating the field distribution reduces to that of finding $F(\nu)$. Using the continuity conditions on the potential at the boundaries of the volumes and using boundary conditions (15), we can use a Hankel transformation to find an integral Fredholm equation of the first kind for the function $F(\nu)$:

$$\int_0^{\infty}d\nu' F(\nu')\,K(\nu,\nu')=-\left(\frac{b}{a}\right)\frac{J_1\left(\nu\frac{b}{a}\right)}{\nu}. \tag{18}$$

The kernel of this equation is $K(\nu,\nu') = \xi(\nu,\nu') + \nu'\eta(\nu',\nu)$, where

$$\xi(\nu\nu')=2\sum_{m=1}^{\infty}p'_m\Gamma_m(\nu')\,\Gamma_m(\nu),$$

$$\eta(\nu,\nu')=\begin{cases}\dfrac{\left(\frac{b}{a}\right)\left[-\nu J_0\left(\nu'\frac{b}{a}\right)J_1\left(\nu\frac{b}{a}\right)+\nu' J_1\left(\nu'\frac{b}{a}\right)J_0\left(\nu\frac{b}{a}\right)\right]}{\nu'^2-\nu^2}, & \nu'\neq\nu,\\[2ex] \dfrac{1}{2}\left(\dfrac{b}{a}\right)^2\left\{J_0^2\left(\nu\dfrac{b}{a}\right)+J_1^2\left(\nu\dfrac{b}{a}\right)\right\}, & \nu'=\nu,\end{cases}$$

$$\Gamma_m(\nu)=\begin{cases}\dfrac{\nu J_1(\nu)}{\nu^2-p_m'^2}, & \nu\neq p'_m,\\[2ex] \dfrac{J_0(p'_m)}{2}, & \nu=p'_m.\end{cases}$$

This equation can be solved on a computer; the coefficients A_m are given by

$$A_m=\frac{2}{J_0(p'_m)}\int_0^{\infty}d\nu F(\nu)\,\Gamma_m(\nu). \tag{19}$$

In evaluating the shielding coefficient we need retain only the first term in the Fourier series, $H_z \sim He^{-7.6}$; the longitudinal field is then found to be $K_s \simeq 2000$ for this case.

In a transverse magnetic field (along the normal to the cylinder axis) the solution is written as a double Fourier series; an estimate shows that in this case the shielding coefficient is of the order of 40.

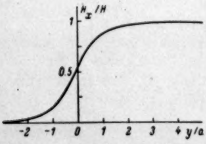

Fig. 3. The function $H_x = H_x(y)$ calculated on a computer for a shield which is a half-space with a groove.

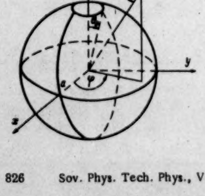

Fig. 4. Spherical shield with aperture.

Superconducting sphere with a circular aperture. We consider an infinitesimally thin superconducting sphere of radius a with a circular aperture $\theta = \theta_0$ in a homogeneous and fixed field $\mathbf{H}_0 \| 0z$ (Fig. 4). We seek a solution in the spherical coordinate system r, θ, φ, in which the potential of a homogeneous, azimuthally symmetric field is $U^{(0)} = -H_0 r P_1(\cos\theta)$, where $P_1(\cos\theta)$ is the Legendre polynomial of degree 1. We seek the total field potential in the form

$$U^{(e)}=U^{(0)}+V^{(0)},\quad U^{(i)}=V^{(i)}, \tag{20}$$

where the superscripts "e" and "i" refer to the exterior ($r > a$) and interior ($r < a$) of the sphere. We require that potential (20) satisfy the continuity conditions and the following boundary conditions:

$$\left.\begin{aligned} U^{(i)}|_{r=a-0}&=U^{(e)}|_{r=a+0},\quad 0\leqslant\theta\leqslant\theta_0,\\ \left.\frac{\partial U^{(i)}}{\partial r}\right|_{r=a-0}&=\left.\frac{\partial U^{(e)}}{\partial r}\right|_{r=a+0}=0,\quad \theta_0\leqslant\theta\leqslant\pi. \end{aligned}\right\} \tag{21}$$

The potentials themselves are sought in the form

$$U^{(e)}=-H_0 rP_1(\cos\theta)+H_0 a\sum_{n=0}^{\infty}A_n\left(\frac{a}{r}\right)^{n+1}P_n(\cos\theta), \tag{22}$$

TABLE 1

Diameter of aperture in sphere, mm	r, mm	Shielding coefficient		Sphere diameter mm
		longitudinal component	transverse component	
	40	$4.6 \cdot 10^4$	—	130
7	30	$8 \cdot 10^4$	—	—
14	30	$1.5 \cdot 10^4$	—	—
	25	$2.4 \cdot 10^4$	89	—
24	0	—	$4.5 \cdot 10^2$	—
49	0	$1.8 \cdot 10^3$	36	—
67	0	$4.5 \cdot 10^3$	18	—

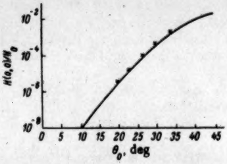

Fig. 5. Ratio of the field at the center of the sphere to the homogeneous external field H_0 as a function of the angle θ_0.

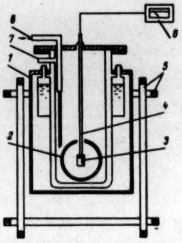

Fig. 6. The experimental apparatus. 1) Helium cryostat; 2) superconducting shield; 3) two-component pickup of the ferroprobe magnetometer; 4) calibrated rod; 5) Helmholtz coils; 6, 7) fittings for helium overflow and drainage; 8) ferroprobe magnetometer.

$$U^{(i)} = H_0 a \sum_{n=0}^{\infty} B_n \left(\frac{r}{a}\right)^n P_n(\cos\theta). \tag{23}$$

From the continuity condition we find a relation between expansion coefficients A_n and B_n:

$$-\delta_{1n} - (n+1) A_n = nB_n. \tag{24}$$

Conditions (21) with (24) lead to functional equations of the type

$$\left.\begin{aligned} &\sum_{n=0}^{\infty} B_n \frac{2n+1}{n+1} P_n(\cos\theta) = -\frac{3}{2} P_1(\cos\theta), \quad 0 \leqslant \theta \leqslant \theta_0, \\ &\sum_{n=1}^{\infty} B_n n P_n(\cos\theta) = 0, \quad \theta_0 \leqslant \theta \leqslant \pi. \end{aligned}\right\} \tag{25}$$

Using the integral Mehler–Dirichlet representation[8] for the Legendre polynomials, we can simplify Eqs. (25) (ref. 9):

$$\left.\begin{aligned} &\sum_{n=0}^{\infty} B_n \frac{2n+1}{n+1} \cos\left[\left(n+\frac{1}{2}\right)\theta\right] = -\frac{3}{2} \cos\frac{3\theta}{2}, \quad 0 \leqslant \theta \leqslant \theta_0, \\ &\sum_{n=1}^{\infty} B_n n \sin\left[\left(n+\frac{1}{2}\right)\theta\right] = 0, \quad \theta_0 \leqslant \theta \leqslant \pi. \end{aligned}\right\} \tag{26}$$

From (26) we find an infinite system of linear, homogeneous equations for the B_m:

$$\begin{aligned} mB_m = &-\frac{9}{8\pi}\left\{\frac{\sin[(m-1)\theta_0]}{m-1} - \frac{\sin[(m+2)\theta_0]}{m+2}\right\} \\ &-\frac{1}{4\pi}\sum_{n=0}^{\infty} B_n \left\{\frac{\sin[(n-m)\theta_0]}{n-m} - \frac{\sin[(n+m+1)\theta_0]}{n+m+1}\right\}\frac{1}{n+1}. \end{aligned} \tag{27}$$

Since we are interested only in the shielding coefficient and not the details of the magnetic field distribution around a superconducting sphere, we use (27) to find only the first expansion coefficient, B_1; this coefficient governs the magnetic field at the center of the sphere. The curve in Fig. 5 shows the ratio of the field at the center of the sphere to the external homogeneous field H_0 as a function of the angle θ_0.

EXPERIMENTAL STUDY OF SUPERCONDUCTING SHIELDS

Since this analysis shows axisymmetric shields to be more effective than planar shields, we have carried out an experimental study of the shielding properties of a spherical shield (with a circular aperture) and a cylindrical shield with a bottom.

The apparatus, shown in Fig. 6, consists of a helium cryostat 1 with superconducting shield 2 and a system of Helmholtz coils 5, 100 cm in diameter, used to produce the desired external field (with transverse and longitudinal components). The magnetic field is measured by ferroprobe magnetometer 8, which has a sensitivity of $3 \cdot 10^{-5}$ Oe at liquid-helium temperature. The shields are fabricated by cold compression from 99.995%-pure lead; the lead sphere is made from two hemispheres fabricated in this manner and then welded together. The sphere is 13 cm in diameter, with a wall 0.3 cm thick. The cylindrical shield, having a hemispherical bottom, is 11 cm in diameter and 22 cm long and has a wall 0.2 cm thick. In the measurements, a known external field is applied in two directions to the cylindrical shield: along the axis of the shield and along the normal to this axis. The changes in the magnetic field (for the two components) are measured along the axis within the shield. The shielding coefficient is evaluated from the results of the measurements.

In the case of the spherical shield with an aperture the external field is also imposed in two directions: perpendicular and parallel to the plane of the aperture. The penetrating field is measured along the radial direction through the center of the aperture. The maximum field imposed is 1.5-2 Oe.

Table 1 shows the data found on the shield of the longitudinal and transverse components by the superconducting sphere with an aperture, for various diameters of this aperture. The experimental points are also shown in Fig.

5, by the crosses. We see that the calculated data agree well with the experimental data.

The shielding properties of the cylindrical shield are studied for an untreated shield, i.e., one which is not annealed and whose surface is not etched, fabricated by mechanical compression. In this case the shielding coefficient for the transverse component is 30, while that for the longitudinal component is 1100. Etching the surface of the shield for 1 min in a solution of 20% hydrogen peroxide (30% concentration) and 80% glacial acetic acid causes no perceptible change in the shielding coefficients.

When the shield is annealed at + 170°C for 20 h, the shielding properties are affected: The shielding coefficient for the longitudinal field component increases to 1200, and that for the transverse component increases to 37. In the latter case there is a good order-of-magnitude agreement between theory and experiment. For the longitudinal component the discrepancy between the theoretical and experimental shielding coefficients is larger.

---

1) The distribution of the "frozen" magnetic flux and its homogeneity in doubly connected superconductors have been studied by several groups of investigators[1-3] working on the basis of the ideal Meissner effect, and the results have agreed satisfactorily with experiment.

2) The unknown constant is determined from the condition $\lim_{x \to \infty} H_x = H$.

3) Strictly speaking, this definition holds for an exponential decay of the field with distance into the shielded volume. We evaluate K_s for the configuration of this problem only for comparison with other shield configurations.

4) For consistency, a shield of finite dimensions should be treated.

Brief communications

Sign of the change in optical path length in a laser interferometer with feedback

I. M. Belousova and A. F. Zapryagaev

(Submitted April 24, 1973)
Zh. Tekh. Fiz., 44, 1321-1323 (June 1974)

An experimental investigation is made of the possibility of determining the sign of the change in optical path length in a passive (empty) resonator which is a part of a composite resonator of a He−Ne laser. A laser with coupled resonators has been considered as an interferometer by several authors. The experiments are carried out for different parameters of a composite resonator which is constructed from three or five mirrors. Under certain conditions the exit laser beam carries information about the sign of the change in optical path length in the resonator of a laser interferometer.

In a number of papers (in particular refs. 1-4) a laser with two coupled resonator cavities is considered as a system for interferometer measurements. A change in n, the refractive index of the medium between the mirrors in a passive (empty) resonator, or in L_p, the geometric length of this resonator, causes amplitude modulation of the laser output. By detecting and recording the laser output information is obtained about the time dependence of the magnitude of n or L_p.

In ref. 5 special conditions are determined under which the output laser beam from two coupled resonators carries information on ΔL_p, the sign of the change in optical path length of the passive resonator. This paper presents several experimental results on the possibility of determining the sign of ΔL_p for various passive resonator parameters. The following parameters of the passive resonator are varied: the number of mirrors forming the resonator, the mirror geometry and resonator length, and the position of the optical axis of the external spherical mirror (Z_3) with respect to the optical axis of the active resonator (containing the active medium).

In a He−Ne laser several longitudinal modes are excited. Higher transverse modes are suppressed by an iris. The wavelength of the laser emission is $\lambda = 0.63\ \mu$.

We consider the results of experiments with a three-mirror system $Z_1-Z_2-Z_3$, in which the lengths of the active, Z_1-Z_2, and the passive, Z_2-Z_3, resonators are the same ($L_{12} = L_{23} = 1$ m). The central mirror of the system is a plane. The laser beam, upon passing mirror Z_1, enters a photomultiplier tube, whose output signal is fed to an oscilloscope. The mirror Z_3 is translated along the system axis over a distance of 2 mm.

In the first group of experiments the degree of mismatch between the curvature of mirror Z_3 and of the incident TEM_{00} wave front from the active resonator is changed. The values of the radius of curvature r_3 of the exchangeable mirror Z_3 are given here (m):

r_3, m	1	2	3.4	10	20	34	∞

The coefficient of (energy) reflection of Z_3 is approximately 0.99. For $r_3 = 2$ m, the geometric parameters[6] of the characteristic TEM_{00} waves of the two coupled cavities are matched.

The sign of ΔL_p, the change in optical path length of the passive resonator of this system, can be measured if the function describing the periodic amplitude modulation of the laser emission is not symmetric. We have established experimentally that this is the case if systems are used in which the coupled coaxial resonators with spherical mirror Z_3 are mismatched, or the optical axes of coupled mismatched resonators are displaced by a distance on the order of 10^{-1} mm, or coupled resonators with a plane mirror Z_3 are mismatched.

We show that if L_p the length of the passive resonator

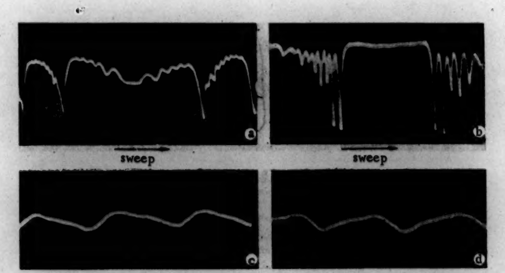

Fig. 1. Oscilloscope traces of photomultiplier current illustrating the possibility of determining the sign of ΔL_p. (a) Mismatched coupled coaxial resonators; (b) optical axes of mismatched resonators shifted approximately 10^{-1} mm; (c) and (d) a screen placed in the passive resonator of a matched system.

Z_2-Z_3 is changed in one direction with velocity V and then returned to its earlier value L_p at the same velocity, then each of the two traces of the time dependence of the photomultiplier current will be a mirror image of the other (see the oscilloscope traces of PM current in Fig. 1, a and b). In both traces 1a and 1b one can see two symmetrically located groups of signal. The first (after start of sweep) group corresponds to a reduction in length of the Z_2-Z_3 resonator; the second, to an increase. The forms of amplitude modulation of the laser output illustrated in Figs. 1a and 1b correspond, respectively, to the following cases: 1) mismatched coaxial resonators with spherical mirrors; 2) optical axes of mismatched resonators shifted on the order of 10^{-1} mm.

It is impossible to determine the sign of ΔL_p for matched optical parameters of the characteristic TEM_{00} modes of two coupled resonators. However, if the laser field is partially screened at the outer mirror of the passive resonator while the geometry of the coupled resonators is not changed, then, due to diffraction of light at the edge of the screen, information about the sign of ΔL_p may be obtained (see Fig. 1, c and d).

For the above described geometry of matched coupled resonators a shift of the optical axes of the resonators by a few millimeters, with all other conditions remaining fixed, causes an increase in the amplitude modulation frequency of the laser by a factor of 4. This effect arises because the light beam completes four double passes between the mirrors of the passive resonator before it falls into the exit point of the active resonator. In this case it is also necessary to partly screen the field of the external mirror of the passive resonator to determine the sign of ΔL_p. The result of inserting a screen in the passive resonator is shown in the oscilloscope traces of Fig. 1, c and d.

In addition to the experiments with a three-mirror system, we have conducted experiments with a five-mirror system, $Z_1-Z_2-Z_3-Z_4-Z_5$, which is of practical interest. For a given five-mirror geometry, periodic focusing of the light beam in the passive resonator Z_2-Z_3 occurs in the case where it is excited off-axis. For off-axis excitation of the passive resonator the axes of light beams falling on the external mirror of the given resonator and reflected from it do not coincide.

We point out two basic results of our experiments involving five-mirror laser resonators of differing geometries. In Fig. 2a an oscilloscope trace of photomultiplier current is shown which illustrates the unique form of the periodic amplitude modulation of the laser emission. This periodic amplitude modulation (of period T) is described by a nonsymmetric function. In this case it is possible to determine the sign of ΔL_p if $\Delta L_p \geq \lambda/14$. One cycle of amplitude modulation with period T (Fig. 2a) is completed as a result of a change in passive resonator lenght by $\Delta L_p = \lambda/2$. During the period T, seven modulation cycles with period $T' = T/7$ are completed. For another five-mirror geometry, with which we have experimented, 40 modulation cycles with period $T'' = T/40$ are completed during a change in passive resonator length $\Delta L_p = \lambda/2$. An oscilloscope trace of photomultiplier current for this experiment is shown in Fig. 2b. It is necessary to point out that during the experiment the speed at which the external mirror of the passive resonator moved is not strictly constant.

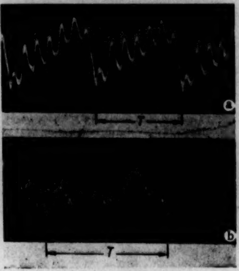

Fig. 2. Oscilloscope traces of photomultiplier current illustrating the form of periodic (period T) amplitude modulations of emission from a laser with a five-mirror resonator. The sign of ΔL_p may be determined (a) if $\Delta L_p \geq \lambda/14$; (b) if $\Delta L_p \geq \lambda/5$.

Using the system from which data are recorded in Fig. 2b, it is possible to measure an absolute value of $\Delta L_p \geq \lambda/80$. However, the sign of ΔL_p can be measured with confidence only for $\Delta L_p \geq \lambda/5$.

Spontaneous mode locking in a laser with a multifaceted element

E. I. Kamenskii and V. V. Kozlov

M. V. Lomonosov Moscow State University

(Submitted July 20, 1973)
Zh. Tekh. Fiz., 44, 1323-1326 (June 1974)

A laser with a multifaceted element operating in the mode-locked regime is investigated experimentally. A stable train of equally spaced pulses is obtained with an individual pulsewidth of ~ 2 nsec, a pulse separation of 13 nsec, and a peak power of ~ 15 MW. The reproducibility of the time trace and modulation character of the giant pulses is 95%. The investigated laser has the advantages of small physical size (~ 18 cm) combined with large optical length for the cavity (~ 200 cm).

A method widely used to enhance the output power of present-day lasers is mode locking by means of a bleachable filter in the cavity.[1,2] The time trace of the laser output in this case is a periodic train of pulses with repetition frequency equal to the frequency difference c/2L between adjacent modes, where L is the optical length of the cavity and c is the speed of light.

In certain cases it is necessary to have a single pulse rather than a pulse train. The isolation of an ultrashort pulse can be greatly facilitated by using a low duty-cycle factor for the pulse train. Since the time interval between consecutive pulses is 2L/c, increasing the pulse separation means an increase in the optical length of the cavity.

We have observed spontaneous mode locking in a PGLS-1 laser with a multifaceted neodymium-glass element.[3] The virtue of this laser is the fact that the physical length of the system on the optical bench is less than 18 cm, while the optical length of the cavity L = 200 cm (nl = 188 cm, where l is the length of the active element and n is the refractive index of the laser material).

A solution of No. 3955 polymethine dye in nitrobenzene is used for Q switching. The initial transmissivity T_f of the filter per unit wavelength $\lambda = 1.06\ \mu$ is varied from 0.55 to 0.9. The thickness of the cell containing the dye solution is 3 mm. A time trace of the output is made with an FÉK-09 detector and an I2-7 oscilloscope with a resolution of 1.5 nsec or better. The width of the pump at the half-power points is about 450 μsec.

The cell with the bleachable dye is set up at an angle of 30' to 40' with respect to the cavity axis. The active element is tilted 20' to 25' with respect to the cavity axis to eliminate the discriminating action of the end of the active element on the Q of closely spaced modes.

A train of short pulses is observed when the cell is placed near the exit mirror ($s \approx 4$ cm, where s is the distance between the cell and the mirror). For initial filter transmissivities T_f = 0.8 to 0.9 the intensity of 40% of the giant pulses is modulated at the frequency c/2L, the percentage modulation m_0 reaching 50%. The nature of the modulation is invariant from one burst to the next, remaining sinusoidal (Fig. 1a). The other pulses exhibit 100% modulation (Fig. 1b). For the time resolution of the instrumentation, ~ 1.5 nsec, an isolated light pulse is observed in one axial period. The width of the pulse is 2 or 3 nsec, and the repetition period t_r = 13 nsec ≈ 2L/c. The peak power attains 2 or 3 MW in this case. The total giant-pulse envelope width τ is 750 to 800 nsec for T_f = 0.8.

Stable time traces (from burst to burst) with a percentage modulation of about 100% (Fig. 1b) are observed when the initial transmissivity is decreased to T_f = 0.6. In this case a pulse train with close to 95% reproducibility is generated near the threshold (pump energy no more than 15% above threshold, which is interpreted as the self-excitation threshold of the laser and filter cell). The peak power is increased to 10-12 MW because of a reduction in the number of pulses and an increase in the lasing energy.

It is well known that at higher pump energy a passive switch can be bleached several times in one pump pulse, i.e., the generation of several giant pulses with a decaying amplitude is observed (Fig. 2). The position in time and the number of giant pulses are recorded with an F-5 detector and an S1-29 oscilloscope with a resolution of ~ 3 μsec.

To study the time variation of each of the giant pulses we have conducted an experiment using an I2-7 oscilloscope in the periodic regime. Inasmuch as the minimum spacing (with ~ 98% probability) between adjacent pulses is about 50 μsec, the instrumentation is capable of recording the time variation of all the pulses.

In the generation of two giant pulses the time variation of the first has the usual smooth shape, whereas the intensity of the second pulse is modulated with m_0 = 60 to 70% (Fig. 3a). The second pulse has $m_0 \approx 100\%$ in 40% of the cases (Fig. 3b). For T_f = 0.65 the total width τ of the giant pulse is 400 to 450 nsec.

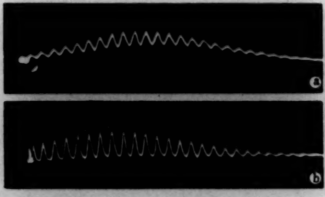

Fig. 1. Oscillograms of the giant-pulse output of a laser with a multifaceted neodymium-glass element. L = 200 cm; s = 4 cm.

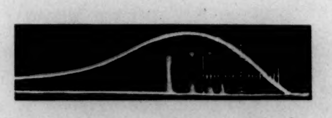

Fig. 2. Time trace of the pump intensity (upper curve) and output intensity (lower curve) of a laser with a multifaceted element and a passive Q-switch. One large division = 100 μsec.

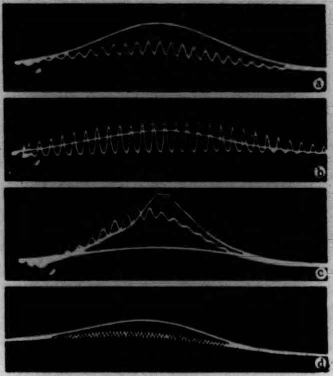

Fig. 3. Oscillograms of the giant-pulse output of a laser with a multifaceted element. The pump energy is more than 70% above threshold.

A further increase in the pump energy leads to the generation of three giant pulses (Fig. 3c). The time variation of each pulse is generally different. For certain bursts the first (and most powerful) pulse has a flattened pyramidal shape, obviously as the result of vibrational–rotational relaxation in the passive switch. A pulse train with $m_0 \approx 100\%$ is not observed in this case. The different time variations of two or more giant pulses is attributable to the fact that a very large part of the energy stored in the cavity is emitted during the first pulse; for the second pulse near-threshold conditions are established in the cavity, increasing the probability of excitation of a train of short pulses with a repetition rate c/2L. For $s \approx 50$ cm the pulse repetition rate is 3(c/2L), i.e., a displacement of the exit mirror for a constant position of the passive switch changes the pulse repetition rate. In this case, m_0 is not greater than 50% (Fig. 3d).

The width of the emission spectrum in the case of a tilted rod is investigated by means of a Fabry – Perot etalon with a resolution of $\sim 2 \cdot 10^{-3}$ cm^{-1}. Near threshold pump intensities, where mode locking of the laser is observed, the width of the spectrum is $\Delta\gamma_0 \approx 0.015$ cm^{-1}. The spectrum in this case consists of several components (five or six) separated by a distance ~ 1/2L. We have observed this effect in a free-running laser.[4]

According to refs. 5 and 6, the width of a single pulse at the 0.5 level in the case of N_j locked modes is

$$t_{0.5} = \frac{2.78 \cdot 2L}{\pi c N_j} \approx \frac{1}{c\Delta\lambda_0}.$$

For $\Delta\lambda_0 \approx 0.015$ cm^{-1} pulses of width $t_{0.5} \approx 2 \cdot 10^{-9}$ sec must be formed; this result is consistent with the experimental data.

The authors are grateful to R. V. Khokhlov for useful discussion.

Optical simulation of a radiator aperture with arbitrary amplitude – phase distribution

M. M. Butusov and Sh. V. Yurevichyus
M. I. Kalinin Leningrad Polytechnical Institute

(Submitted April 19, 1973; resubmitted August 13, 1973)
Zh. Tekh. Fiz., 44, 1326-1328 (June 1974)

A description is given of a method for producing transparencies for Fourier analyzers for arbitrary two-dimensional complex functions. The method is employed for simulation of an acoustic radiator with a complex amplitude–phase aperture distribution.

1. The wide-spread application of the fruitful idea[1,2] of coherent-optical simulation of the directivity patterns of radio and acoustic radiators has been hindered for a long time by the difficulties encountered in fabricating an input transparency which can simulate an arbitrary two-dimensional amplitude–phase distribution at the radiation aperture.

Simulation of amplitude distribution requires an exact evaluation of the nonlinear properties of the photographic film so that the amplitude transmittance of the transparency corresponds, on some scale, to the amplitude distribution of the field. However, linearization of the characteristic curve of the film is a complicated problem[3] even if a device is constructed in which the two-dimensional distribution of the light flux follows the required relation. In holography, preliminary exposure of film is often used to obtain the output for the quasilinear segment of the characteristic curve. This method is not applicable to Fourier analyzers since the output signal is the sum, with weighted coefficients, of the Fourier transform of the aperture, for which the input function is given and the desired output signal; unavoidable distortion is the result.

In simulation of two-dimensional arbitrary distributions it is inconvenient, and even impossible, to use the previously proposed methods (see refs. 4 and 5 for example) for inserting the appropriate phase plates or providing controlled bleaching of the transparency emulsion.

2. The present paper describes an experiment involving the idea proposed in refs. 6 and 7 for simulating amplitude distribution by a binary structure and phase distribution using a spatial carrier imprinted on a transparency by a holographic method. The advantages of using two-dimensional binary transparencies are described in ref. 8; the basic elements selected for the transparencies are circles located at the lattice points.

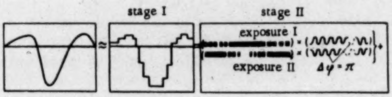

Fig. 1. Principle of transparency recording for a one-dimensional function. The initial function is on the left, next is a step approximation, and then binary masks for each of the inphase regions and the corresponding spatial carrier with a π phase shift.

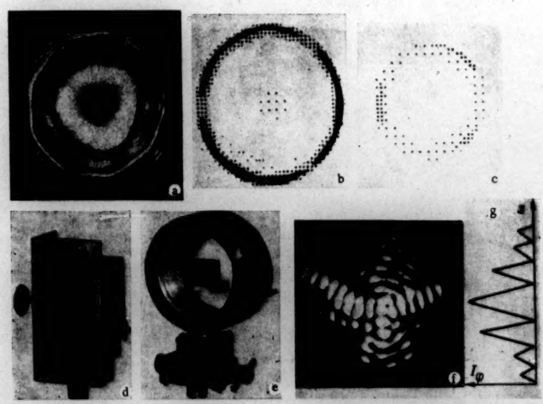

Fig. 2. Simulation of an acoustic radiator: interferogram of the surface (a), transparency masks for each of the two inphase regions (b, c), device for masking the holograph transparency in a system with a movable mirror (d), holograph transparency in the immersion cell (e), distribution of light near the central maxima of the pattern (g), and photometer cross section of this distribution (f).

We recall that the main advantage of using such elements is that the amplitude transmittance of the structure is proportional to the radius of the circles, which makes it easier to implement the transparency.

A holograph system is used to regulate the phase input from the spatial carrier. One of its mirrors is mounted on a piezoceramic column and the voltage across the column is used to vary linearly the phase of the diffraction grating recorded on the holograph transparency.

The basic idea of the method is shown in Fig. 1: Represented on the left is an arbitrary one-dimensional function whose phase assumes two values $(0, \pi)$ and whose amplitude varies arbitrarily. The amplitude is simulated in two stages, shown in Fig. 1 on the right: First, the function is broken down into several gradation regions whose number depends on the desired experimental accuracy. Then within each region a constant value of the function is simulated by the transmittance of the binary transparency. The spatial carrier (diffraction grating) is recorded on the binary transparency mask prepared in the above manner; only region I is exposed during the first exposure, and then the spatial carrier undergoes a phase shift and region II is exposed.

3. The results obtained from the method for simulation of the directivity pattern of an acoustic radiator are shown in Fig. 2. Shown on the left is an interferogram of the radiator surface obtained by a time-averaging holograph method. The interference bands represent lines of equal amplitude at each point on the surface. It can also be seen that the surface has two inphase regions: Central and peripheral regions oscillate in the same phase, and the average fringe region oscillates in the opposite phase. Further to the right there are two binary transparency masks corresponding to each of the two inphase regions. Then there is the device in which the diffraction grating in imprinted on the holographic transparency. The photograph on the extreme right shows the light intensity distribution at the output plane written in first-order diffraction on the spatial carrier of the holograph transparency and representing the directivity pattern of the radiator. The photometer cross section of this diagram is along the horizontal axis. The shape of this cross section agrees with the results of acoustic measurements.

Special attention should be given to two aspects of the experiment. First, the quality of the optics used to record the diffraction grating should not be worse than the quality of the Fourier objective. Otherwise, unavoidable aberrations appear and the transmission function of the Fourier transformer is distorted. Second, to increase the diffraction efficiency of the holograph carrier the transparency must be bleached and placed in an immersion cell. The very small decrease in diffraction efficiency after the transparency is submerged in the cell again convinces us that the primary reason for the diffraction of light in bleached holograms with a high frequency of the spatial carrier is the difference between the refractive coefficients of the gelatin and the silver salts arising after bleaching. The view that the decisive factor is the surface relief[9] is erroneous in this case.

Lasing properties of Yb^{3+} and Er^{3+} glass laser pumped by a laser

V. N. Kalinin, A. A. Mak, D. S. Prilezhaev, and V. A. Fromzel'

(Submitted September 14, 1973)
Zh. Tekh. Fiz., 44, 1328-1331 (June 1974)

Lasing at 1.54 μ is obtained in silicate and phosphate glasses activated by Yb^{3+} and Er^{3+} and pumped by a neodymium laser at 1.06 μ. Induced absorption of pump radiation resulting from the excitation of the $^4I_{13/2}$ level in Er^{3+} ions is investigated. When the Yb–Er glass specimens are placed in the pump cavity the pump spectrum shifts towards long wavelengths. These effects reduce the efficiency of the laser.

Lasing at λ = 1.54 μ by silicate and phosphate glasses activated by Yb^{3+} and Er^{3+} and pumped by flash lamps was first obtained by Snitzer.[1,2] However, the use of flash lamps to pump media activated by these ions is not very efficient since these do not produce the appropriate pumping spectrum of intense and broad absorption bands; therefore, such lasers have a comparatively low energy output and high pump thresholds.

We have investigated the possibility of lasing by Yb^{3+} and Er^{3+} glasses pumped by a neodymium laser to obtain efficient pump radiation (theoretically, the conversion factor can reach ~ 70%) and reduce thermal losses in the active medium.

Radiation of the neodymium laser is absorbed by the edge of the Yb^{3+} resonance absorption band (in the $^2F_{7/2}-{}^2F_{5/2}$ transition). Because of rapid radiationless transfer, excitation energy is transferred from Yb^{3+} ions to Er^{3+} ions (to the $^4I_{11/2}$ level), which relax in the metastable $^4I_{13/2}$ state. Three-level lasing occurs in the $^4I_{13/2}-{}^4I_{15/2}$ transition of Er^{3+}. Thus, direct excition of Er^{3+} does not occur with laser pumping.

Silicate and phosphate glasses with different $Yb^{3+}-Er^{3+}$ ratios are investigated in the present paper. Certain spectroscopic parameters of the glasses are shown in Table 1.

N_{Yb} and N_{Er} are the activator concentrations, τ_{Er} and τ_{Yb} are the the lifetimes of the $^4I_{13/2}$ level of Er^{3+} and the $^2F_{7/2}$ level of Yb^{3+}, k_λ are the absorption coefficients of the glasses at the appropriate wavelength (absorption of the glass base is shown for λ = 1.54 μ), σ is the cross section for the stimulated transition $^4I_{13/2}-{}^4I_{15/2}$, α is the energy transfer rate from Yb^{3+} to Er^{3+} ($\alpha = 1/\tau_{Yb} - 1/\tau^0_{Yb}$ where τ^0_{Yb} is the Yb^{3+} lifetime in a glass without Er^{3+}).

Lasing by Yb–Er glasses is investigated using the optical system shown in Fig. 1. The specimen is a parallelepiped placed in the cavity of the pumping laser. Since it is an efficient load for the neodymium laser, the pumping radiation is used with the greatest possible efficiency. The pump energy absorbed by the specimen is determined from the well-known absorption coefficient of the specimen at the pump wavelength and from the energy exiting from the pump cavity through one of the opaque mirrors.

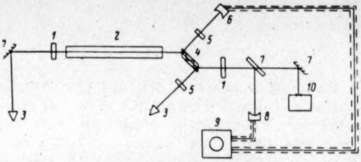

Fig. 1. Schematic diagram of the apparatus. 1) Cavity mirrors with transmission τ <0.5% for λ = 1.06 μ; 2) active medium of GLS-1 glass; 3) calorimeters; 4) Yb–Er glass samples; 5) cavity mirrors for radiation at λ ≈ 1.54 μ; 6) FD9E111 photodiode; 7) plane-parallel glass plate; 8) FÉU-22 photomultiplier; 9) S-1-17 oscilloscope; 10) spectrograph (9 Å/mm dispersion).

The cavity is formed by two planar dielectric mirrors for radiation at λ ≅ 1.54 μ, and the lasing radiation is propagated in the specimen at an angle of 45° to the direction of propagation of the pumping radiation.

Table 2 gives the measured values of the specific threshold pump energy W_{thr-V} and efficiency η for various glass specimens. The parentheses contain theoretical values corresponding to experiment, which are calculated according to the following relations:[1]

$$W_{thr-v} = \frac{h\nu_p}{2}(N_{Er}+\delta)\left[1+\frac{2N_{Er}}{\tau^0_{Yb}\alpha(N_{Er}-\delta)}\right] \times\left[1-\frac{(N_{Er}+\delta)N_{Er}}{\tau_{Er}N_{Yb}(N_{Er}-\delta)\alpha}\right],$$

$$\eta = \frac{\nu_l}{\nu_p}\frac{\ln\frac{1}{R}}{\ln 1/R+G}\left(1-\frac{1}{n_W}\right),$$

where

$$\delta = \frac{c\left(G + \ln\frac{1}{R}\right)}{2\varkappa h\nu_1 B_1 l}$$

is the threshold inversion, G are the nonactive and diffraction losses, R is the reflectance of the cavity mirrors, $\varkappa l$ is the optical length of the active medium, ν_p and ν_l are the pumping and lasing frequencies, respectively, and n_W is the excess of pumping energy over the threshold.

We note that the comparatively high G of the glasses investigated here, in particular the phosphate glasses, is due to the appreciable nonactive absorption at 1.54 μ caused by the presence of water traces in the glass matrix

It can seen from Table 2 that there are appreciable discrepancies between the calculated and experimental data. We have established that one of the reasons for these discrepancies is the additional (stimulated) absorption of pumping radiation by the specimens. To determine the magnitude and nature of this stimulated absorption we use probing pulses from a nonspiking laser with a narrow radiation spectrum which is tuned between 1.05–1.07 μ. The stimulated absorption occurring in the pumped specimen produces a substantial change in the shape of the probing pulse (Fig. 2). It is established that the magnitude of the stimulated absorption increases with the wavelength, and the duration of this absorption corresponds to τ_{Er}. From the above data and from an analysis of the Er^{3+} energy level diagram,[3] one can conclude that the stimulated absorption is related to the short wavelength edge of the $^4I_{13/2} - {}^4I_{9/2}$ absorption band, which is produced by excitation of the metastable $^4I_{13/2}$ level of Er^{3+}.

The measured values Δk_λ of the stimulated absorption are shown in Table 2 for different glasses activated by Yb^{3+} and Er^{3+}. The stimulated absorption is higher in the silicate glasses than in the phosphate glasses. This evidently is the main reason they have a low efficiency and a high pump threshold.

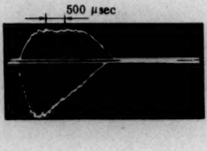

Fig. 2. Variation in the shape of the probing signal whose spectrum coincides with the pump spectrum when it passes through the pumped Yb–Er glass specimen as shown by the data of Tables 1 and 2.

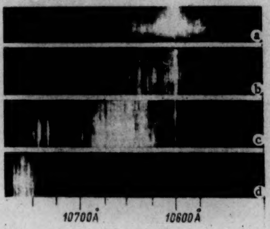

Fig. 3. Laser pumping spectrum with a GLS-1 glass active medium. a) Without Yb–Er glass in the cavity; b) with Yb–Er silicate glass; c and d) with Yb–Er phosphate glasses corresponding to the data of Table 1.

In our case, the discrepancy between the calculated and measured efficiencies and W_{thr-V} is also due to a certain degree to the properties of the intracavity pumping of the Yb–Er glasses by the neodymium laser. The neodymium lasing band coincides with the long-wavelength absorption edge of Yb^{3+}; therefore, the introduction of Yb–Er glass into the cavity is equivalent to the introduction of a spectral selector into the neodymium laser cavity. As a result, the pump radiation spectrum shifts towards long wavelengths (Fig. 3). In our case this shift leads to a number of undesirable effects: The pump laser efficiency is reduced by the reduction in the load efficiency, pumping efficiency falls so that Yb^{3+} absorption is reduced, and furthermore the losses increase due to the increase in stimulated absorption.

These considerations are evidently the cause of the anomalously strong dependence, for a three-level laser, of the laser pumping threshold on cavity Q.

The removal of the above-mentioned undesirable effects, which lower the lasing efficiency of Yb–Er glasses subjected to laser pumping, may be obtained by pumping at ≤ 1.05 μ.

In conclusion, the authors thank E. I. Galant, S. G. Lunter, and M. N. Tolstoi for preparing the Yb–Er glass specimens.

---

1) These relations are obtained from the balance equations. A more detailed account of the computational technique will be given in a separate paper.

Characteristics of diffraction gratings obtained by photoetching of semiconductor surfaces

L. V. Belyakov, D. N. Goryachev, M. N. Mizerov, and E. L. Portnoi

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted July 17, 1973)
Zh. Tekh. Fiz., 44, 1331-1333 (June 1974)

The present note reports on certain characteristics of diffraction gratings produced by selective photoetching of semiconductor surfaces. The method can be used to obtain relief-type diffraction gratings on the surface of semiconductors with a grating constant exceeding 2500 mm^{-1}. The diffraction efficiency of these gratings is high. The method can be employed to produce periodic inhomogeneities in various optical components.

Because of the recent rapid development of lasers, quantum electronics, and nonlinear optics, it is now frequently necessary to fabricate optical waveguides for the transmission between individual quantum-electronic components at optical frequencies. Simple to build and very convenient for optical solid-state devices is the plane, asymmetric waveguide in the form of a thin dielectric film deposited on a substrate. Optical waveguides with a transmission layer made of semiconducting material are of great importance for certain applications. Structures with heterogeneous junctions are very promising in this respect. The discontinuity in the refractive index at the boundary and the excellent optical properties of epitaxial layers mean that these structures can be used for optical thin-film waveguides. When special devices such as relief-type diffraction gratings on the surface of the waveguide are employed, it becomes possible to solve problems of coupling radiation in and out of the thin-film waveguides,[1] to achieve phase matching,[2] and to produce lasers with distributed feedback.[3] Selective photoetching without use of a photoresistive layer[4] is one of the possible techniques of producing such gratings on the surface of semiconductors. We have used this method to produce diffraction gratings on single crystals of both n- and p-gallium arsenide and on epitaxial AlGaAs layers. A two-beam interference pattern obtained from an LG-38 helium–neon laser is projected onto the semiconductor surface. The surface is etched at the same time with an aqueous solution of an oxidizing agent. When the oxidizing agent is selected, particular attention is paid to the transparency of the solution for the laser beam. Furthermore, no gas can be generated during the etching reaction with the semiconductor material. The optimum etching time depends both on the composition and concentration of the solution and amounts to several minutes. The etching conditions are selected with small spatial frequencies directly during the exposure process. The etching conditions are selected on the basis of the intensity of reflected first-order diffraction maxima. After the exposure, the sample surface is rinsed with distilled water.

Figure 1a shows the surface of a diffraction grating obtained with our method on n-type gallium arsenide; Fig. 1b is the profile of the grating. The cut runs along the crystallographic sample surface perpendicularly to the grating lines. The spatial frequency of the grating is 200 mm^{-1}.

Figure 2 shows a typical distribution of the intensity of diffraction maxima of various orders in normal incidence of a ray upon the grating (λ = 6328 Å).

Figure 3 shows the dependence of the relative intensity of the first-order maxima on the spatial frequency of the grating. The intensity of the beam which is reflected in mirror fashion from the polished crystal surface is taken as 100 %.

Our method makes it possible to obtain relief-type diffraction gratings on the surface of semiconductors; the gratings have a spatial frequency exceeding 2500 mm^{-1} and a rather high diffracting efficiency. The method is distinguished by simplicity and high reproducibility.

Ion emission into vacuum from a discharge in crossed electric and magnetic fields

V. A. Nikitinskii and A. S. Zakharov

Rubezhnoe Branch, V. I. Lenin Khar'kov Polytechnical Institute

(Submitted April 16, 1973)
Zh. Tekh. Fiz., 44, 1333-1334 (June 1974)

The ion emission has been studied in a low-pressure discharge constricted by a slit between coaxial ferromagnetic electrodes in a transverse magnetic field. Change of the discharge constriction approximately doubles the emission into vacuum, and the application of a transverse magnetic field increases this emission by a factor of tens.

The electrostatic double sheath which forms on the cathode side of the constriction in a constricted discharge produces oppositely directed electron and ion fluxes.[1,2] Dallenbach has suggested that the directional ion flux can be exploited to draw the ions off into vacuum from the cathode side of the constriction. However, a quantitative comparison on the basis of the extraction of ions from the cathode and anode sides of the constriction at accelerating voltages up to 10 kV has shown that for fixed constricting and emission apertures the efficiency of the ion extraction is roughly the same in both cases. The explanation lies in the fact that the electrostatic double sheath is convex toward the cathode and thus defocuses the ions, so that only a fraction of the ions accelerated by the sheath passes through the emission aperture into vacuum. The advantages of extracting ions from the cathode side of the constriction can be realized by shaping the sheath in an appropriate manner and by increasing the directed velocity of the ions.

In our experiments, the shape of the electrostatic double sheath is altered by inserting a cylindrical rod 2 along the axis of the aperture in intermediate electrode 1 (Fig. 1). The rod is maintained at the same potential as electrode 1. The directed velocity of the ions is increased by changing the discharge voltage by means of a transverse magnetic field. The magnetic field is produced in the annular gap (having an outside diameter of 8 mm and a width of 1 mm) between ferromagnetic electrodes 1 and 2 by means of coil 3 and magnetic guide 4. The electron emitter is a thermionic cathode 5, a tungsten-wire ring, and the anode is a hollow copper cylinder 6. The emission electrode 7, with an 8-mm exit aperture, is located 8 mm from intermediate electrode 1 and held at the potential of one of the cathode leads. It separates the discharge region from the high-vacuum volume, in which a pressure of $\sim 10^{-5}$ torr is maintained. The working gas, argon, is injected from the anode side of the slit. The current of ions which escape from the discharge into vacuum is measured by Faraday cup 8, connected electrically with electrode 7. When a discharge is initiated through the slit from the cathode side, an electrostatic double sheath in the form of an unterminated toroid is produced. This sheath shape permits an increase in the ion emission current because of a change in the ratio $k = S_e/S$ (where S is the total surface area of the double sheath and S_e is the part of the sheath surface from which ions reach the emission aperture). The quantity k is evaluated under the assumption that the toroid axis is the center line of the slit, while the center of the spherical double sheath produced in the same discharge system when the central rod 2 is removed lies at the center of the constricting aperture. Calculation shows that k is doubled, while experiments show that the ion emission current is increased by a factor of 1.8.

When the electromagnet coil is turned on, a radial magnetic field appears in the slit, increasing the discharge voltage. Under the influence of the crossed fields, the electrons drift in the constricting slit in the tangential direction. Unfolding the cylindrical surface over which an electron moves gives the electron trajectory in the form of a trochoid. Electrons can move in the axial direction toward the anode over a distance larger than the Larmor radius only as a result of collisions with gas atoms. By increasing the electron energy and the path which the electrons travel in the constricting slit, the magnetic field intensifies the gas ionization in the immediate vicinity of the exit aperture of the discharge chamber and leads to an order-of-magnitude increase in the current of ions which escape from the chamber into vacuum. Figure 2 shows the discharge voltage U_d and the ion current I_i as functions of the current in the electromagnet coil, I_c, for fixed values of the discharge current I (sic) and the gas flow rate (70 cm^3/h). The steepness of the functional dependence $U_d = f(I_c)$ increases due to a reduction of the gas density at the constriction, itself due to the removal of atoms in the form of ions by the electric field of the discharge. Increasing I_c beyond a certain critical value

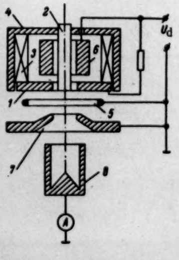

Fig. 1. The experimental apparatus.

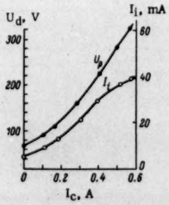

Fig. 2. Discharge voltage U_d and ion emission current I_i as functions of the current in the coil, I_c.

leads to oscillations and a cutoff of the discharge current. The gas flow rate must be increased to suppress these oscillations and to prevent the current cutoff. Bringing the emission electrode closer to the constricting slit results in a more efficient use of the directional ion flux; in particular, when the separation between the emission and intermediate electrodes is d = 3 mm, the current to the Faraday cup reaches 70 mA. When d is reduced further, it becomes difficult to initiate or maintain the discharge without increasing the gas flow rate.

A change in the potential of the emission electrode, with the potentials of the cathode and the Faraday cup held constant, does not appreciably affect the value of I_i.

Angular aberration corrector in a cylindrical mirror analyzer

V. V. Zashkavara and V. F. Tarasov

Nuclear Physics Institute,
Academy of Sciences of the Kazakhstan SSR, Alma-Ata

(Submitted June 18, 1973)
Zh. Tekh. Fiz., 44, 1134-1137 (June 1974)

A calculation is given for correction of third- and fourth-order angular aberrations in a cylindrical-mirror electrostatic analyzer. The correction is based on the refracting property of the potential of a double layer produced by two axially symmetric grid electrodes placed in the focal region of a charged particle beam on the axis of the cylindrical mirror.

The angular aberration in the direction of dispersion for a cylindrical mirror which focuses charged particles on the axis of symmetry can be of higher than second order.[1,2] The exact equations for plane trajectories in a cylindrical field can be used to show that for beam divergences up to 20° the spherical aberration can be closely approximated by the sum of third- and fourth-order angular aberrations; the cubic aberration makes the largest contribution and is of the order of 10-15% of the radius of the inner cylindrical electrode for an angular divergence of 20°. In cases where it is necessary to increase the aperture ratio of the cylindrical mirror by increasing the angular divergence of the beam without any serious loss of resolving power it becomes necessary to correct or at least partially compensate for these aberrations.

In this paper we give the design of a corrector for third- and fourth-order aberrations in a cylindrical mirror; the principle is based on the refracting property of the potential of a double layer produced by means of two axially symmetric grid electrodes of special shape, placed at the output of the analyzed beam from the cylindrical field. Figure 1 shows the focusing region of the charged particles, which have passed through the field of the cylindrical mirror. We discuss the arrangement of the electrodes at the end of the paper. Electrode 1 is at the same potential as the inner cylinder 3, while electrode 2 is connected to an accelerating potential U. Three rays are shown in Fig. 1: the central ray, which is at an angle α_0 to the axis of symmetry and for which the second-order angular focusing condition is satisfied, and two limiting rays in the beam. The central ray passes through the corrector normal to the surface; it does not suffer any refraction so it crosses the z axis of the mirror at the point 0, corresponding to the position of the second-order focus. If there is no corrector, or if U = 0, the limiting rays (denoted by the dashed lines) would cut the axis of symmetry at points separated from 0 by a distance l, as determined in our approximation by the amount of spherical aberration

$$l = r_1 \left[A_{III}\,(\alpha-\alpha_0)^3 + A_{IV}\,(\alpha-\alpha_0)^4\right], \tag{1}$$

where A_{III} and A_{IV} are the third- and fourth-order aberration coefficients of the cylindrical mirror.[3,4] In what follows we put $r_1 = 1$. The shape of the corrector electrodes in the approximation (1) must be calculated so that for a given double-layer potential U, all the particles in the analyzed beam are directed after refraction towards the point 0 with a kinetic energy W + qU, where q is the particle charge and W is the potential energy before passing through the corrector.

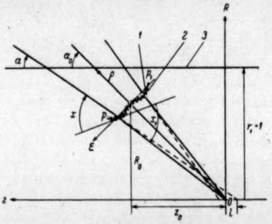

Fig. 1

We ignore the size of the interelectrode gap and consider the surface on which the charged-particle trajectories are refracted in accordance with Snell's law (Fig. 1):

$$\cos\chi_1 = \frac{\cos\chi}{\sqrt{1+u}}, \tag{2}$$

where u = qU/W. A line of refraction (pp' in Fig. 1) is formed on a section of the surface of the axial plane.

The differential equation of the refraction line in the R, z system of coordinates can be obtained from the law of refraction (2) and the condition that after refraction an arbitrary ray must pass through the focus 0:

$$(z + RR')\left[(1 - xR')^2 + u\,(1 + x^2)\,(1 + R'^2)\right]^{1/2} - (x + R')\,(R - zR') = 0, \tag{3}$$

where $R' = dR/dz$, $z = Rx - l(x)$, and $x = \cot\alpha$. The boundary condition is as follows: The central ray of the focused beam intersects the refraction line at the point R_0, z_0 at a right angle and at this point $R' = -\cot\alpha_0 = -x_0$, $z_0 = R_0x_0$. Equation (3) is a first-order nonlinear differential equation, which cannot be integrated in terms of elementary functions. The solution has been obtained by the power series method. The following equation has been found up to the seventh order in the small expansion parameter $x - x_0$ for the derivative which defines the slope of the tangent to the refraction line in the coordinate system ρ and ξ (Fig. 1):

$$\rho' = \frac{d\rho}{d\xi} = -\frac{x - x_0}{1 + xx_0} - \frac{\gamma}{\gamma - 1}\,\frac{(x - x_0)^3}{1 + x_0^2}\Bigg\{-\beta_3 + \left[\frac{x_0}{1 + x_0^2}\beta_3 - \beta_4\right](x - x_0)$$
$$+ \left[-\frac{x_0^2 + \frac{1}{2}}{(1 + x_0^2)^2}\beta_3 + \frac{x_0}{1 + x_0^2}\beta_4 - \beta_5\right](x - x_0)^2$$
$$+ \Bigg[\frac{x_0\left(x_0^2 + \frac{3}{2}\right)}{(1 + x_0^2)^3}\beta_3 - \frac{x_0^2 + \frac{1}{2}}{(1 + x_0^2)^2}\beta_4$$
$$+ \frac{x_0}{1 + x_0^2}\beta_5 - \beta_6\Bigg](x - x_0)^3$$

$$+\left[-\frac{x_0^4+3x_0^2-\frac{1}{8}}{(1+x_0^2)^4}\beta_3-\frac{1}{4}\frac{\beta_3^2}{(1+x_0^2)^2}+\frac{x_0\left(x_0^2+\frac{3}{2}\right)}{(1+x_0^2)^3}\beta_4\right.$$
$$\left.-\frac{x_0^2+\frac{1}{2}}{(1+x_0^2)^2}\beta_5+\frac{x_0}{1+x_0^2}\beta_6-\beta_7\right](x-x_0)^4\Bigg\},$$

where $\gamma = \sqrt{1+u}$ and the β_n are the expansion coefficients for the series in $x - x_0$ of the function (1), $l(x) = R_0 \sum_{n=3}^{\infty} \beta_n (x-x_0)^n$, and

$$\beta_3=-\frac{A_{III}}{R_0(1+x_0^2)^3},\quad \beta_4=\frac{3x_0A_{III}+A_{IV}}{R_0(1+x_0^2)^4},$$
$$\beta_5=-\frac{(6x_0^2-1)A_{III}+4x_0A_{IV}}{R_0(1+x_0^2)^5},$$
$$\beta_6=\frac{x_0(10x_0^2-5)A_{III}+\left(10x_0^2-\frac{4}{3}\right)A_{IV}}{R_0(1+x_0^2)^6},$$
$$\beta_7=-\frac{\left(15x_0^4-15x_0^2+\frac{14}{15}\right)A_{III}+x_0(20x_0^2-8)A_{IV}}{R_0(1+x_0^2)^7}\quad \text{etc.} \tag{6}$$

The first term in (4) is the tangent of the slope of the line which is orthogonal to the rays in the focused beam. We now use (4) to calculate and construct the refraction line. In the coordinate system ρ, ξ, the equation of any ray incident on the corrector can be written as

$$\rho=\frac{xx_0+1}{x-x_0}\xi-R_0\sqrt{1+x_0^2}\,\lambda(x),$$

where

$$\lambda(x)=1-\beta_3(x-x_0)^2-\beta_4(x-x_0)^3$$
$$-\beta_5(x-x_0)^4-\beta_6(x-x_0)^5-\beta_7(x-x_0)^6.$$

Assume that we have chosen the set of inclination angles α_i or $x_i = \cot\alpha_i$, which determines the bundle of rays in the beam incident on the corrector. If the bundle is sufficiently dense, a small section of the refraction line between the neighboring intersections with rays can be approximated by the straight-line section

$$\rho_{i+1}=\rho_i'(\xi_{i+1}-\xi_i)+\rho_i, \tag{7}$$

where ρ_i' is determined by (4) with $x = x_i$. At the point of intersection of the straight lines where $x = x_{i+1}$ we get from (6) and (7) that

$$\xi_{i+1}=\frac{\rho_i'\xi_i-\rho_i-R_0\sqrt{1+x_0^2}\,\lambda_{i+1}}{\rho_i'-\frac{x_{i+1}x_0+1}{x_{i+1}-x_0}}. \tag{8}$$

Equations (8) and (7), together with (4) for the initial data $\rho_0 = 0$, $\xi_0 = 0$ for $x = x_0$ (normal ray), enable the line of refraction to be calculated along the points corresponding to the set of α_i. The results of such a calculation for a cylindrical mirror which focuses a beam of charged particles in an ion-optical arrangement with a point source[1] is shown in Fig. 2. In this case $A_{III} = -15.5292$, $A_{IV} = 4.0532$, $\alpha_0 = 42°18'$, $x_0 = 1.0987$. The family of lines of refraction corresponding to values of u = 0.02, 0.06, 0.1, 0.2, 0.5, 0.7, 1.0, and 10.0 and the line orthogonal to the rays (the lower curve u = −1) are constructed in the ρ, ξ coordinate system with the origin on the central ray at the point $R_0 = 0.7$. Each line is calculated for the set of α_i in the interval 32-52° at 1° steps. Owing to the fourth-order aberration effect, the curves are all clearly asymmetric about the ρ axis. At the point $\rho = 0$, $\xi = 0$, the orthogonal line touches the family of refraction lines and the order of contact, from (4), is equal to 3. The error in ρ' due to the approximate nature of (4) increases with $x - x_0$ and for the limiting rays with α = 32 and 52° is a few percent in this particular case.

The corrector electrodes must be made of high-transparency metal grids parallel to the calculated surface of refraction and separated by a small gap. It is necessary to allow for the electron-optical action of the individual cells of the grid. In order to eliminate any focusing effect of the cells in the direction of the symmetric axis of the cylindrical mirror, each electrode must be made only of a set of wires placed uniformly in the axial planes at a small angular interval. Then, when the additional accelerating potential U is applied to the corrector, each cell of two pairs of wires will form an immersion cylindrical lens, which focuses an elementary beam only in the direction perpendicular to the symmetry axis of the mirror. A very approximate calculation made on the basis of the results in ref. 5 shows that the optical power when the interelectrode gap is twice the distance between the neighboring wires can be much less than $1/r_1$, if $u \leq 0.3$.

It should be noted that a grid-type electrostatic corrector for spherical aberration was earlier sucessfully used by Bergkvist in a $\pi\sqrt{2}$ type magnetic spectrometer[6] and increased the brightness of the instrument significantly. It is to be hoped that an electrostatic angular-aberration corrector for a cylindrical mirror will prove just as useful, in spite of the difficulties involved in its construction.

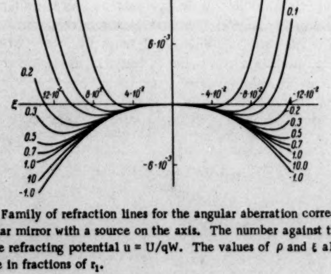

Fig. 2. Family of refraction lines for the angular aberration corrector in a circular mirror with a source on the axis. The number against the curves show the refracting potential u = U/qW. The values of ρ and ξ along the axes are in fractions of r_1.

Resonant amplification of an image potential by an electromagnetic wave

Yu. I. Balkarei É. M. Épshtein
Institute of Radio Engineering and Electronics,
Academy of Sciences of the USSR, Moscow
(Submitted June 18, 1973)
Zh. Tekh. Fiz., 44, 1337-1339 (June 1974)

The image potential is calculated for an electron above the surface of a conducting medium in the presence of an rf field parallel to the surface. The image potential can be amplified when the frequency of this field is close to a surface-plasmon frequency.

The image force which acts between the surface of a conductor and a nearby charge plays an important role in adsorption and desorption as particles move across various types of potential barriers at interfaces (in particular, in emission phenomena), etc. It was shown recently[1] that an electronic phase transition can be caused by image forces, so that it is extremely interesting to examine the possibility of influencing image forces. Below we show that it is in fact possible to influence the image force by imposing a sufficiently strong electromagnetic wave $\mathbf{E} = \mathbf{E}_0 \sin \Omega t$ on a charge (an electron).

The most convenient approach, developed in refs. 2-4, is that which the appearance of an image potential is treated as the result of an interaction between the charge and surface plasmons of the conductor. In particular, this approach makes it possible to incorporate dynamic corrections to the image potential.[4,5]

We begin from the Hamiltonian describing a system of surface plasmons which interact with a charge above the surface of the medium:[3]

$$H = \sum_{\mathbf{k}} \omega_{\mathbf{k}} \left(a_{\mathbf{k}}^{+} a_{\mathbf{k}} + \frac{1}{2} \right) + \Gamma_{\mathbf{k}}(\rho, z)\,(a_{\mathbf{k}} + a_{-\mathbf{k}}^{+}), \tag{1}$$

$$\Gamma_{\mathbf{k}}(\rho, z) = \left(\frac{\pi e^2 \omega_p^2}{2 A_0 k \omega_{\mathbf{k}}} \right)^{1/2} \exp(-kz + i\mathbf{k}\rho), \tag{2}$$

where $\omega_{\mathbf{k}}$ is the frequency of a surface plasmon having a (two-dimensional) wave vector $\mathbf{k}$, ω_p is the plasma frequency, $a_{\mathbf{k}}^{+}$ and $a_{\mathbf{k}}$ are the creation and annihilation operators for the surface plasmon, (ρ, z) are the cylindrical coordinates of the charge (the z axis is measured from the surface), A_0 is a normalization area, and we have set $\hbar = 1$.

The equation for the plasmon-annihilation operator,

$$\frac{da_{\mathbf{k}}}{dt} + i\omega_{\mathbf{k}} a_{\mathbf{k}} = -i\Gamma_{-\mathbf{k}}(\rho, z) \tag{3}$$

found from Hamiltonian (1), has the form of the equation of motion of an oscillator subject to an external force;[6] here the external force is the perturbing effect of the charge on the plasmon system. The image force is the reaction of the plasmon system to this perturbation, so that the image potential W must be equal in magnitude and opposite in sign to the work performed by the charge on the plasmon system:[6]

$$W = -\sum_{\mathbf{k}} \omega_{\mathbf{k}} \left| \int_{-\infty}^{t} \Gamma_{-\mathbf{k}}(\rho(\tau), z(\tau))\, e^{i\omega_{\mathbf{k}}\tau}\, d\tau \right|^2. \tag{4}$$

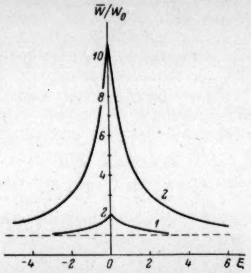

Fig. 1. Shape of the resonance line (the functional dependence of $\bar{W}/W_0$ on ξ). 1) A = 1; 2) A = 10.

We assume that a charge above the surface of a conductor is subject to the electric field of an electromagnetic wave propagating parallel to the surface, so that $\rho(t) = \rho_0 \sin \Omega t$, where $\rho_0 = (e\mathbf{E}_0)/(m\Omega^2)$ and m is the effective mass of the electron; we also assume that the charge moves parallel to the z axis at a constant velocity v. We are interested in the image potential average of a period of the wave $(T = 2\pi/\Omega)$, $\bar{W}$. Substituting $\rho(t)$ and $z(t)$ into (4) we find

$$\bar{W}(z) = -\frac{e^2\omega_s^2}{4\pi} \int_0^{2\pi} d\varphi \int_0^{\infty} dk\, e^{-2kz} \sum_{n=-\infty}^{\infty} \frac{J_n^2(k\rho_0 \cos\varphi)}{k^2 v^2 + (\omega_s - n\Omega)^2}, \tag{5}$$

where $J_n(x)$ is the Bessel function of real argument, $z = z(t) > 0$, and $\omega_s = \omega_p/\sqrt{2}$ is the frequency of a surface plasmon in the absence of dispersion; in deriving (5) we have assumed $z \gg R$, where R is the shielding length for the conductor.

It follows from (5) that with $v/z \ll \omega_s$ the functional dependence of the image potential on the wave frequency contains resonant peaks at $\Omega = \omega_s/n$; the widths of these peaks are governed by the velocity v. With $z \gg \rho_0$ and $z \gg v/\omega_s$, Eq. (5) becomes

$$\bar{W} = W_0[1 + AF(\xi)], \tag{6}$$

$$F(\xi) = 1 - \xi\,[\mathrm{ci}(\xi)\sin\xi - \mathrm{si}(\xi)\cos\xi], \tag{7}$$

where

$$A = \frac{1}{8}\left(\frac{\rho_0\omega_s}{v}\right)^2,\quad \xi = \frac{2z(\omega_s - \Omega)}{v},\quad W_0 = -\frac{e^2}{4z}$$

is the image potential in the absence of the wave field, and si(ξ) and ci(ξ) are the sine and cosine integrals. The amplitude of the first resonant peak ($\Omega = \omega_s$), A, can, in principle, become very large, since it is proportional to the product of the small expansion parameter $(\rho_0/z)^2$ and the large parameter $(z\omega_s/v)^2$. The height of each of the succeeding peaks ($n\Omega = \omega_s$, n = 2, 3, ...) is smaller than the height of the preceding peak by a factor $(\rho_0/z)^{-2}$. Figure 1 shows $\bar{W}/W_0$ as a function of ξ.

Result (6) can also be derived from the equations of electrodynamics. The field in the medium in which the charge is located consists of the field of the charge itself and the field which is the solution of the homogeneous system of Maxwell equations. The only field in the second medium is the solution of this homogeneous system. The matching of the fields at the interface ensures that the dynamic image potential is established as a result of the excitation of all types of surface waves.

For the case of an electron above the surface of a semiconductor ($\omega_s \sim 10^{14}$ sec^{-1}) and with $v \sim 10^7$ cm/sec, the value A = 1 is reached at $E_0 \sim 10^6$ V/cm (at $\Omega \sim 10^{14}$ sec^{-1}). If the electron is in another semiconductor (e.g., in the case of a heterojunction or tunnel contact), rather than in vacuum, the field required to reach A = 1 can be weaker by one or two orders of magnitude if the effective electron mass is small.

The height of the resonant peak is governed by factors such as the dispersion and damping of surface plasmons as well as by the motion of the charge normal to the surface; at typical parameter values these other factors make contributions on the same order as that of the charge motion, evaluated above.

An analogous resonant amplification of the image potential will occur if the charge is in a strong magnetic field normal to the surface; in this case the motion of the electron along its Larmor orbit plays a role analogous to that of the oscillations of the electron in the electric field of the electromagnetic wave.

Thermoacoustic waves in conducting gases and liquids

P. A. Andreev

Zh. Tekh. Fiz., 44, 1339-1342 (June 1974)

Instabilities occurring in the absorption of an acoustic wave which couples to temperature fluctuations in a medium are investigated.

It has been shown[1,2] that the transmission of sound through a conducting medium can generate waves and the nature of the resulting instabilities has been studied. Oscillations for which a variation of the temperature T does not occur were considered in this earlier work. In the present work we consider instabilities produced by an acoustic flux which couples to temperature deviations $\Theta \neq 0$. We call these instabilities thermo-acoustic instabilities.

As in the earlier work,[1,2] we write the expression for the acousto-electric field $\mathbf{E}^{ae}$:

$$\mathbf{E}^{ae} = \chi \mathbf{J} + \chi_1 [\mathbf{J},\ \mathbf{H}_0] + \chi_2 \mathbf{H}_0 (\mathbf{J},\ \mathbf{H}_0), \tag{1}$$

in which **J** is the acoustic energy flux ($J = J_x$) and H_0 is the external magnetic field.

The heat flux produced by absorption of the acoustic wave in the medium can be written

$$\mathbf{q} = \beta \mathbf{J} + \beta_1 [\mathbf{J},\ \mathbf{H}_0] + \beta_2 \mathbf{H}_0 (\mathbf{J},\ \mathbf{H}_0), \tag{2}$$

where the coefficients β, β_1, and β_2 are proportional to χ, χ_1, and χ_2, respectively, and are of order $\beta_i \sim \chi_i T/e$.

Assuming that the external magnetic field $H_0 = H_{0y}$, we write the following linearized system of equations for small deviations of the electric field $\mathbf{E}'$, magnetic field $\mathbf{H}'$, current $\mathbf{j}'$, and temperature Θ:

$$\left.\begin{aligned}
&\operatorname{curl} \mathbf{H}' = \frac{4\pi}{c}\mathbf{j}', \operatorname{curl} \mathbf{E}' = -\frac{1}{c}\frac{\partial \mathbf{H}'}{\partial t},\\
&\mathbf{E}' = \alpha \nabla\Theta + \alpha_1 [\nabla\Theta,\ \mathbf{H}_0] + \alpha_2 \mathbf{H}_0 (\nabla\Theta,\ \mathbf{H}_0)\\
&\quad + \rho \mathbf{j}' + \rho_1 [\mathbf{j}',\ \mathbf{H}_0] + \rho_2 \mathbf{H}_0 (\mathbf{j}',\ \mathbf{H}_0)\\
&+ \frac{\partial \chi}{\partial T}\Theta \mathbf{J} + \frac{2\chi}{H_0^2}(\mathbf{H}',\ \mathbf{H}_0)\mathbf{J} + \frac{\partial \chi_1}{\partial T}\Theta [\mathbf{J}, \mathbf{H}_0] + \chi_1 [\mathbf{J},\ \mathbf{H}'] + \chi_2 \mathbf{H}_0 (\mathbf{J},\ \mathbf{H}'),\\
&c_T \rho_0 \frac{\partial \Theta}{\partial t} = \operatorname{div}\Big\{\varkappa \nabla\Theta + \frac{\partial \beta}{\partial T}\Theta \mathbf{J} + \beta_1 [\mathbf{J},\ \mathbf{H}'] + \frac{\partial \beta_1}{\partial T}\Theta [\mathbf{J},\ \mathbf{H}_0]\\
&\quad + \beta_2 \mathbf{H}_0 (\mathbf{J},\ \mathbf{H}') + \frac{2\beta}{H_0^2}(\mathbf{H}',\ \mathbf{H}_0)\mathbf{J}\Big\},
\end{aligned}\right\} \tag{3}$$

where α, α_1, α_2 are the thermoelectric coefficients, ρ, ρ_1, ρ_2 are the normal, Hall, and focusing resistivities, c_T is the specific heat of the medium, ρ_0 is the density of the medium, and $\varkappa$ is the thermal conductivity of the medium.

Assuming that all the unknowns in (3) are proportional to $\exp i(\mathbf{kr} - \omega t)$, we obtain a dispersion relation, which (because of its intricacy we analyze only in special cases.

In the case $k = k_x$ the dispersion relation has the form

$$\omega^2 + \left[(\nu_m + a)ik + c\chi_1 J + \frac{\partial \beta}{\partial T}\frac{J}{c_T \rho_0}\right]k\omega$$
$$+ \left(aik + \frac{\partial \beta}{\partial T}\frac{J}{c_T \rho_0}\right)(\nu_m ik + c\chi_1 J)k^2 - \frac{2ck^2\beta J}{c_T \rho_0}\left(\frac{\partial \chi_1}{\partial T}J + i\alpha_1 k\right) = 0, \tag{4}$$

where $\nu_m = c^2\rho/4\pi$, $a = \varkappa/c_T\rho_0$.

For large acoustic fluxes $c\chi_1 J/k\nu_m \gg 1$ and for $c_T\rho_0 c\chi_1/(\partial\beta/\partial T) \gg 1$ we obtain the frequency of the resulting instability:

$$\omega = ck|\chi_1|J + ik^2\left(\frac{2c\beta\alpha_1}{c_T\rho_0|\chi_1|} - a\right). \tag{5}$$

Note that $\chi_1 < 0$ (see ref. 1). The ratio $\Lambda = (\Theta/T)/(H'/H_0)$, in which $H' = H'_y$, is of order unity for $\beta J/\varkappa k H_0 \gg 1$ and $\Lambda \ll 1$ for $\beta J/\varkappa k H_0 \ll 1$. An investigation[3] of the character of the instability (5) shows that this instability is of the convective type.

In the case $k = k_y$ the dispersion relation assumes the form

$$\omega^3 + (2\nu_m + a)ik^2\omega^2 + \left[\frac{J^2}{c_T\rho_0}\left(\beta_2 \frac{\partial \chi_1}{\partial T}H_0^2 + \beta_1 \frac{\partial \chi}{\partial T}\right) + k^2(\nu_m^2 + \nu_{m_1}^2 + 2a\nu_m)\right]k^2\omega$$
$$- ia(\nu_m^2 + \nu_{m_1}^2)k^6 + \frac{ik^4J^2}{c_T\rho_0}\left[\nu_{m_1}H_0\left(\beta_1\frac{\partial \chi_1}{\partial T} - \beta_2\frac{\partial \chi}{\partial T}\right)\right. \tag{6}$$
$$\left. + \nu_m\left(\beta_2 H_0^2 \frac{\partial \chi_1}{\partial T} + \beta_1 \frac{d\varkappa}{\partial T}\right)\right] = 0,$$

where $\nu_{m_1} = c^2\rho_1 H_0/4\pi$.

We assume that the acoustic flux is large, i.e., that the following relation holds:

$$\frac{J^2}{c_T\rho_0\nu_m k^2}\left(\beta_2 H_0^2 \frac{\partial \chi_1}{\partial T} + \beta_1 \frac{\partial \chi}{\partial T}\right) \gg 1. \tag{7}$$

The solution for Eq. (6), i.e., a solution with $\operatorname{Im}\omega > 0$, is given by the expression

$$\omega = -ik^2\left(\nu_m + \nu_{m_1}H_0 \frac{\beta_1 \frac{\partial \chi_1}{\partial T} - \beta_2 \frac{\partial \chi}{\partial T}}{\beta_2 \frac{\partial \chi_1}{\partial T}H_0^2 + \beta_1 \frac{\partial \chi}{\partial T}}\right). \tag{8}$$

Equation (8) describes a periodic structure if the following relation holds:

$$\frac{\rho_1 H_0^2}{\rho}\,\frac{\beta_1 \frac{\partial \chi_1}{\partial T} - \beta_2 \frac{\partial \chi}{\partial T}}{\beta_2 \frac{\partial \chi_1}{\partial T}H_0^2 + \beta_1 \frac{\partial \chi}{\partial T}} > 1. \tag{9}$$

In the case $k = k_z$ the dispersion relation has the form

$$\omega^2 + \left[(\nu_m + a)ik - 2_e\frac{\chi}{H_0}J + \frac{\partial \beta_1}{\partial T}\frac{JH_0}{c_T\rho_0}\right]k\omega$$
$$+ \left(aik + \frac{\partial \beta_1}{\partial T}\frac{JH_0}{c_T\rho_0}\right)\left(\nu_m ik - 2_e\frac{\chi}{H_0}J\right)k^2 + \frac{ck^2\beta_1 J}{c_T\rho_0}\left(\frac{\partial \chi}{\partial T}J - i\alpha_1 H_0 k\right) = 0.$$

For large acoustic fluxes

$$\frac{J}{kv_m}\left(\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}\right)\gg 1,\quad \frac{J}{k}\,\frac{\left(\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}\right)^2}{\frac{v_m H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}-\frac{\chi}{H_0}cv_m+\frac{ca_1\beta_1 H_0}{c_T\rho_0}}\gg 1 \qquad (11)$$

we find that a nonstationary distribution of the field and temperature is established in the medium:

$$\omega=\frac{2\chi}{H_0}ckJ+i\left(\frac{ca_1\beta_1 H_0}{c_T\rho_0}\,\frac{1}{\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}}-a\right)k^2 \qquad (12)$$

for

$$\left(\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}\right)^2\gg\frac{c}{c_T\rho_0}\beta_1\frac{\partial\chi}{\partial T},$$

and

$$\omega=J_k\left(\frac{\chi}{H_0}c-\frac{H_0}{2c_T\rho_0}\frac{\partial\beta_1}{\partial T}+i\sqrt{\frac{c}{c_T\rho_0}\beta_1\frac{\partial\chi}{\partial T}}\right) \qquad (13)$$

for

$$\left(\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}\right)^2\ll\frac{c}{c_T\rho_0}\beta_1\frac{\partial\chi}{\partial T}.$$

The instability described by (12) and (13) is of the convective type.

To find the conditions for the onset of instability in the conducting medium we use the system of magnetohydrodynamic equations,[4] which must be solved simultaneously with the system (3); in the latter it is necessary to replace **E'** by **E'** + (1/c)[**v**, H_0], where **v** is a small velocity perturbation in the medium. The resulting dispersion relation is analyzed in special cases.

Inasmuch as $v_A/u_0 \ll 1$ in real situations, where v_A is the Alfvén velocity and u_0 is the velocity of sound, the dispersion relation has the same form as (4) for $k = k_x$.

For the case $k = k_z$ the dispersion relation has the form

$$[\omega^2-(u_0^2-i\nu\omega)k^2]\left(\omega+iv_mk^2+\frac{2\chi}{H_0}ckJ\right)\left(\omega+iak^2+\frac{\partial\beta_1}{\partial T}k\frac{JH_0}{c_T\rho_0}\right)+ck^2\frac{\beta_1 J}{c_T\rho_0}$$
$$\times\left(J\frac{\partial\chi}{\partial T}-ia_1H_0k\right)[\omega^2-(u_0^2-i\nu\omega)k^2]$$
$$-\frac{H_0^2}{4\pi\rho_0}\omega k^2\left(\omega+iak^2+\frac{\partial\beta_1}{\partial T}k\frac{JH_0}{c_T\rho_0}\right)=0. \qquad (14)$$

If we assume that $\omega = \omega_0(1+\delta+i\delta_1)$, where $\omega_0 = \pm k\cdot\sqrt{u_0^2 + H_0^2/4\pi\rho_0}$, we can linearize (14) with respect to δ and δ_1 to obtain

$$\omega=\omega_0\left[1+\frac{J}{2}\left(\frac{k}{\omega_0}\right)^3\frac{H_0}{c_T\rho_0}\left(\frac{H_0^2}{4\pi\rho_0}\frac{\partial\beta_1}{\partial T}-\nu a_1c\right)+\frac{J\nu}{2}\left(\frac{k}{\omega_0}\right)^3\left(\frac{2\chi c}{H_0}a+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}v_m\right)k^2\right.$$
$$\left.-i\frac{\nu J}{2}\left(\frac{k}{\omega_0}\right)^2\left(\frac{2\chi}{H_0}c+\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}\right)k-i\frac{\nu J^2}{2}\left(\frac{k}{\omega_0}\right)^3\frac{c}{\beta_1}\frac{\partial}{\partial T}(\chi\beta_1^2)\,k\right]. \qquad (15)$$

Growth of the excited fluctuation requires that the following relation be satisfied:

$$J\gg\omega_0\frac{\frac{2|\chi|}{H_0}c-\frac{H_0}{c_T\rho_0}\frac{\partial\beta_1}{\partial T}}{k\frac{\partial}{\partial T}(\chi\beta_1^2)}. \qquad (16)$$

The following ratios are determined from the system of fundamental equations for the given case:

$$\frac{w}{u_0}\Big/\frac{H'_y}{H_0}=\frac{\omega}{u_0k},\quad \frac{\theta}{T}\Big/\frac{H'_y}{H_0}=\frac{\beta_1}{T}\Big/\frac{\partial\beta_1}{\partial T}, \qquad (17)$$

where w is the x component of the velocity. The ratios (17) are of order unity.

It is instructive to compare the critical acoustic fluxes J_{kR_1} and J_{kR_2} for the excitation of acoustomagnetic waves [see ref. 2, Eq. (4)] and thermo-acoustic waves [Eq. (9) above], respectively.

The ratio $J_{kR_1}/J_{kR_2} \approx k|\chi|/\gamma|\chi_1|H_0 = k\Omega\tau/\gamma$, where γ is the acoustic damping factor and k is the excited wave vector. Thus, thermo-acoustic waves are more readily excited in the short-wave range, and acoustomagnetic waves in the long-wave range.

I am grateful to I. V. Ioffe for discussion.

Hologram interferometry for vibration analysis (review)

V. S. Listovets and Yu. I. Ostrovskii

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted July 26, 1973)
Zh. Tekh. Fiz., 44, 1345-1372 (July 1974)

The application of hologram interferometry to vibration analysis is reviewed. The Powell–Stetson (time-averaging) method, the hologram strobe method, and the phase modulation of a reference beam are considered. The merits and limitations of these methods are discussed. Experimental results are provided on vibration analysis of industrial products by hologram methods.

INTRODUCTION

As early as 1932 the American scientist Osterberg[1] used time averaging of light waves, reflected by a vibrating surface, for interferometer vibration analysis of piezoelectric crystals. He showed that the luminosity distribution over the investigated surface, observed at the interferometer output, is given by the function

$$I=I_0\left[1+J_0\left(\frac{4\pi A}{\lambda}\right)\right],$$

where J_0 is the zeroth-order Bessel function, A is the vibration amplitude, and λ is the wavelength of the light.

Osterberg used a Michelson interferometer, replacing one of the mirrors by the investigated crystal with a polished surface. Osterberg's method is restricted by the fact that the investigated object must be a planar, mirror-finished surface.

In 1965, in one of the first papers on hologram interferometry,[2] Powell and Stetson suggested a more powerful method of vibration analysis, which is based on Osterberg's principle, but uses the hologram scheme of Leith and Upatnieks[3] for recording the light scattered by the vibrating object.

The hologram technique widened the possibilities of Osterberg's method, allowing interferometer analysis of opaque objects of any shape with any surface state. Polishing of the investigated surface or deposition of a mirror coating is not required.

In the same year, 1965, Stetson and Powell suggested a real-time variation of their own method,[4] in which the interference pattern formed by the waves, recovered from the hologram of the unperturbed object and scattered by the vibrating object (the hologram occurs at the same place or is recovered after occurrence at the previous place), is observed directly or photographed.

The idea of the time-averaging method is simple. If the object vibrates during an exposure time significantly longer than the period of vibration the waves scattered by this object in all states which it traverses will be recorded on the hologram.

The waves restored by the hologram form an interference pattern, which provides information on the motion of the various portions of the object.

The contributions of the various object positions to the total exposure is determined by the velocity with which the object passes through these positions. The higher the velocity, the shorter the time spent by the object at this position, and the smaller the contribution of this state to the exposure. Since the object stops at the extreme positions and its velocity is low close to these positions, the contribution of these two object states to the exposure is very large and we can assume that the hologram is due to the two corresponding positions of the object, i.e., a hologram obtained by two exposures. The recovered image of the object is the intersection of interfering fields of equal vibrational amplitudes. The nonmoving object portions (node lines) exhibit the maximum luminosity, since these object points are in the same position during the total exposures. The points for which the path difference between the waves scattered by the object consists of an odd number of half-wavelengths provide minimum intensity and correspond to dark bands.

The points for which this path difference is an even number of half-wavelengths form the maxima of the light bands. These maximum intensities, however, decrease for increasing vibrational amplitudes since then the time which the object spends around the extremum is reduced (Fig. 1).

A more rigorous analysis verifies these qualitative considerations.

Thus, due to the capability of recording the complex amplitude of light waves in the Powell–Stetson method, we do not deal with an intensity average (as in the Osterberg method), but with the actual complex amplitude.

EFFECT OF VARIOUS OBJECT MOTIONS ON IMAGE LUMINOSITY

We perform this analysis for general motion. The complex amplitude of the wave, scattered by some point of a fixed object, can be represented in the form

$$ae^{-i\psi_0},$$

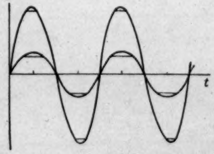

Fig. 1. With increasing vibrational amplitudes the time which the object spends near the extremum position is reduced.

where

$$\psi_0 = \frac{2\pi x \sin\theta}{\lambda}.$$

If this point moves in direction v (Fig. 2), the time dependence of the phase of the wave scattered into the same hologram point is

$$\psi = \psi_0 + \frac{2\pi}{\lambda}\int_0^t (\cos\varphi_1 + \cos\varphi_2)\,v\,dt. \tag{1}$$

The notation for the angles φ_1 and φ_2 is clear from Fig. 2.

The complex amplitude is

$$ae^{-i\left[\psi_0 + \frac{2\pi}{\lambda}\int_0^t (\cos\varphi_1 + \cos\varphi_2)\,v\,dt\right]}, \tag{2}$$

and its average over the exposure time T determines the luminosity of point 0 in the restored object image:[1)]

$$I \sim \left|\frac{a}{2}\int_0^T e^{-i\left[\psi_0 + \frac{2\pi}{\lambda}\int_0^t (\cos\varphi_1 + \cos\varphi_2)\,v\,dt\right]}\,dt\right|^2. \tag{3}$$

Equation (3) is very general and covers different motions of the point 0. For a nonmoving object (v = 0) we obtain the obvious equation $I \sim a^2$.

Constant velocity. In case of rectilinear uniform motion (v = const) we have

$$I \sim \left|\frac{a}{2}\int_0^T e^{-i\left[\psi_0 + \frac{2\pi}{\lambda}(\cos\varphi_1 + \cos\varphi_2)\,v\,t\right]}\,dt\right|^2. \tag{4}$$

Integration of this expression leads to

$$I \sim a^2 \frac{\sin^2\left[\frac{\pi}{\lambda}(\cos\varphi_1 + \cos\varphi_2)\,vT\right]}{\left[\frac{\pi}{\lambda}(\cos\varphi_1 + \cos\varphi_2)\,vT\right]^2}. \tag{5}$$

In the special case $\varphi_1 = \varphi_2 = 0$ (the object illuminated from the hologram side and moving in that direction) we obtain

$$I \sim a^2 \frac{\sin^2\frac{2\pi vT}{\lambda}}{\left(\frac{2\pi vT}{\lambda}\right)^2} = a^2 \frac{\sin^2\frac{2\pi r}{\lambda}}{\left(\frac{2\pi r}{\lambda}\right)^2}. \tag{6}$$

This function is plotted in Fig. 3.

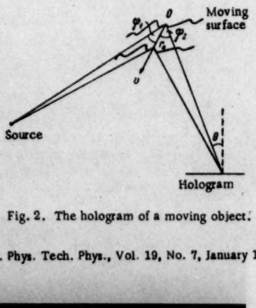

Fig. 2. The hologram of a moving object.

The time-averaging method of recording a hologram of a uniformly moving object was investigated independently by several authors from various points of view.

Considering the hologram as a linear time filter acting on the time-varying light wave propagating away from the object during the exposure time, Goodman[5] shows, using the example of an object rotating with constant angular velocity, that the luminosity of the restored image is described by Eq. (5).

Constructing a mathematical model for recording two plane waves with constant amplitudes on a hologram, but with one of the phases linearly varying during the exposure time, Redman[6] obtained the same result for the luminosity of the restored image. He suggested the use of the hologram time-averaging method to study very slowly moving surfaces, such as the surface of an evaporating liquid; for shorter exposure times, he suggested the study of isotachs (equal velocity lines used to investigate liquid flow).

The function in Eq. (5) was obtained by Lurie,[7,8] starting from an estimate of the luminosity dependence of the restored image on the degree of coherence between the reference wave and that reflected on the hologram by an object uniformly moving during the exposure time, and by Neumann,[9] who showed that the effect of motion of the object appears in the spatial modulation of the contrast of bands forming the hologram. This modulation causes a smearing of the restored image, similar to the diffuse image obtained in ordinary photography of a moving object, and a luminosity loss in the restored image, corresponding to Eq. (5).

Step motion of the object. Consider another special case of a displaced object, which is located at one place during half the exposure time and is displaced by r during the other half. This case corresponds to the two-exposures method.

In this case the integral (3) is split into two parts, corresponding to the first and second exposures:

$$I \sim \left|\frac{a}{T}\left\{\int_0^{\frac{T}{2}} e^{-i\frac{2\pi}{\lambda}\int_0^t (\cos\varphi_1 + \cos\varphi_2)\,v\,dt}\,dt + \int_{\frac{T}{2}}^{T} e^{-i\frac{2\pi}{\lambda}\left[\Delta + \int_0^t (\cos\varphi_1 + \cos\varphi_2)\,v\,dt\right]}\,dt\right\}\right|^2, \tag{7}$$

where $\Delta = r(\cos\varphi_1 + \cos\varphi_2)$ is the resulting path difference for the wave scattered by the points during motion (Fig. 2). Since v = 0, we transform (7) to the form

$$I \sim \left|\frac{a}{T}\left\{\frac{T}{2}\left[1 + e^{-i\frac{2\pi}{\lambda}\Delta}\right]\right\}\right|^2, \tag{8}$$

whence, after simple transformations,

$$I \sim a^2\cos^2\frac{\pi}{\lambda}r(\cos\varphi_1 + \cos\varphi_2). \tag{9}$$

In the special case of an object illuminated on the hologram side and moving in the same direction, when $\varphi_1 = \varphi_2 = 0$, we have

$$I \sim a^2\cos^2\frac{2\pi r}{\lambda}. \tag{10}$$

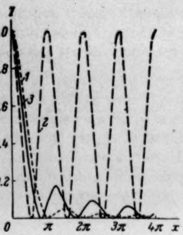

Fig. 3. Intensity distribution in the restored image of an object, moving during the exposure time. 1) Rectilinear uniform motion ($I \sim \sin^2 x/x^2$); 2) step motion [two-exposures method ($I \sim \cos^2 x$)]; 3) harmonic vibration [$I \sim J_0^2(x)$]; the abscissa is $x = 2\pi r/\lambda$ for curves 1 and 2, and $x = 4\pi A/\lambda$ for curve 3.

This function is also shown in Fig. 3. In this case we obtain band interference with nondecreasing intensity maxima.

A harmonically vibrating object. Finally, consider harmonically vibrating points of an object, i.e.,

$$\int_0^t (\cos\varphi_1 + \cos\varphi_2)\, v\, dt = A(\cos\varphi_1 + \cos\varphi_2)\sin\omega t,$$

where A is the vibrational amplitude. The general expression (3) becomes

$$I \sim \left| \frac{a}{T} \int_0^T e^{-i\left[\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\sin\omega t\right]} dt \right|^2. \tag{11}$$

Since

$$e^{-i\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\sin\omega t} = \sum_{n=-\infty}^{\infty} J_n\left[\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\right] e^{in\omega t}, \tag{12}$$

where J_n is the n-th order Bessel function, we obtain

$$I \sim \left| \frac{a}{T} \sum_{n=-\infty}^{\infty} \left\{ J_n\left[\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\right] \int_0^T e^{in\omega t} dt \right\} \right|^2. \tag{13}$$

Following integration, we have

$$I \sim \left| a \sum_{n=-\infty}^{\infty} \left\{ J_n\left[\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\right] \frac{e^{in\omega T}-1}{in\omega T} \right\} \right|^2. \tag{14}$$

If the exposure time is an integral number of the vibrational periods of the object, i.e., $T = 2k\pi/\omega$, all terms except $n = 0$ vanish and we have

$$I \sim a^2 J_0^2\left[\frac{2\pi A}{\lambda}(\cos\varphi_1+\cos\varphi_2)\right]. \tag{15}$$

For $T \gg 2\pi/\omega$ the role of the zeroth term in the sum (14) is again dominant, since the factor $(e^{in\omega T} - 1)/in\omega T$ tends to zero with increasing ωT, and the intensity distribution over the surface of the object is also expressed by Eq. (15). Physically it is clear that the transition from the exposure time $T_1 = 2k\pi/\omega$ to $T_2 = 2(k + \delta)\pi/\omega$, where k is a large integer and $\delta < 1$ is a small correction to k, does not change the hologram substantially; consequently, it does not change the luminosity of the restored image.

When $\varphi_1 = \varphi_2 = 0$ Eq. (15) becomes

$$I \sim a^2 J_0^2\left(\frac{4\pi A}{\lambda}\right). \tag{16}$$

The function in (16), like the preceding equations (5) and (10), is oscillatory and modulates the luminosity of the restored image, thus forming interference bands. This function is also shown in Fig. 3. We note that the positions of maxima and minima of the functions (10) and (16) are insignificantly displaced with respect to each other (less than a quarter of a band). Therefore the calculation of vibrational amplitudes by time averaging the interferogram, based on the simplified idea of regarding the Powell–Stetson method as a variant of the two-exposures method, does not lead to significant errors.

EXPERIMENTS IN VIBRATION ANALYSIS BY THE POWELL–STETSON METHOD

The vibration of a long, narrow steel pole, rigidly fixed at the ends, has been investigated[10] by the Powell–Stetson method. To reduce the sensitivity it was proposed to use large illumination and observation angles, since the number of bands in the interference pattern of the restored image is proportional to the sum of cosines of these angles; for high-order band resolution at large vibrational amplitudes of the object it was proposed to scan photometrically the interference pattern recovered together with the hologram.

Hologram measurements of sinusoidal vibrations of a film have been performed[11] by independent interferometer determinations of the vibrational amplitudes of this film using a Twyman–Green interferometer. A small mirror, used as an interferometer mirror, is attached to the opposite side of the film. At the interferometer output the vibrational amplitude of the mirror is measured photoelectrically with an accuracy of ± 0.04 λ.

The hologram and interferometer measurements are performed simultaneously. Comparison of the experimental data shows agreement for the vibrational amplitudes of the film by both methods.

Three types of motion of a thin steel film, sinusoidal vibration, motion with constant velocity, and their superposition have been studied experimentally[12] by the Powell–Stetson method. From the experimental results it was concluded that in studying sinusoidal vibrations one must apply careful procedures to eliminate drifting of the object during the exposure; otherwise the interpretation of the interference band pattern is difficult.

The Powell-Stetson method, however, is applicable[13] to the analysis of sinusoidal vibrations if the object as a whole exhibits significant piston-like vibrations (of several microns), of the same frequency as the sinusoidal vibrations of the surface of the object. Moreover, in this case the band intensity falls off slower with increasing band number since the band intensity is determined by the higher-order maxima of the function J_0^2.

Another method in which, on the other hand, piston components of vibration are excluded[14] is described below.

The time-averaging method has been used to study vibrations of circular membranes[15,16] oscillating in two modes simultaneously. Cases of two simultaneous vibrations at the same frequency, but with different phases, and of two vibrations at different frequencies have been treated.

The Powell–Stetson method has been applied[17,18] to the study of high-frequency sinusoidal vibrations. The vibrational modes of a cantilever have been studied[17] from the fifth to the 34th mode in the frequency regime from 500 Hz to 25.665 kHz and a hologram of the vibrating cantilever has been obtained in the 77th mode at a frequency of 99.395 kHz.

A similar study has been performed[18] for a rectangular plate up to a frequency of 76.8 kHz.

In both papers the experimental results on the resonance frequencies and modes are in agreement with the classical theory of cantilever and rectangular plate vibrations. We note that the time-averaging method is applicable only to vibrations of relatively small amplitudes.

Vibrations of simple objects, thin membranes, diaphragms, films, and beams have been studied[2,4,10–13,15–18] by the time-averaging method.

The papers of Waddell and Kennedy[19,20] were the first in which the averaging method was applied to vibration analysis of actual industrial machines, turbine blades.

In addition to determining the frequency characteristic of turbine blades, a study has been made[21] of the effect of various design factors on the vibrational distribution in an aircraft thrust reverser. The time-averaging method has been used to study fin resonances in the Concorde aircraft.[22]

Similar experiments have been performed[23–25] by the Powell–Stetson method to determine the vibrational characteristics of aircraft elements, turbine blades, and disks with hollow blade sections. A compact hologram setup is described in these papers; it is built by Rolls-Royce and can be used to study objects with transverse dimensions up to 60 cm. The setup is simple enough so that an operator without special training can operate it.

The vibrations of turbine blades and stacks of 10 turbine blades have been studied[26] by a real-time-averaging method, following the work in refs. 19 and 20. A special dye, containing minute glass globules, is used in this work to enhance the reflectivity of objects. The light reflected from the object is not depolarized so that the light diffracted by the hologram and reflected by the object has a unique direction of polarization. This enhances the band contrast, which is essential in hologram interferometry in real time. The high reflectivity allows shorter exposure times and the use of a low-power laser. The authors estimate a hologram of an object with an area of 0.3 m^2 with a 5-mW laser requires an exposure time of 0.25-0.5 sec (the "Ilford He–Ne I" plate with sensitivity 5 erg/cm^2 is used).

An original application of holography[27,28] uses the real-time-averaging method to study the vibrational characteristics of the frame of a violin.

The method of time averaging has been used[29] to determine the vibrational fields of cylinders with cone tops.

A study of the sound fields of an ultrasound transmitter in a transparent cell filled with water has been performed[30] by the time-averaging method. Equal amplitude lines of sound pressure formed by the phase modulation of the light passing through the transparent cell are obtained in the hologram image.

Limitation of the Powell – Stetson method. As follows from the analysis given above and from the short review of the experimental work, the Powell–Stetson method is experimentally very simple and convenient, and is applicable in a wide variety of problems in vibration analysis. There are, however, a number of limitations.

1. The band luminosity falls off quickly with increasing amplitude, the 10th band has a luminosity 2% of that of the node line, and the 20th, 1%. Therefore it is impossible to study objects whose vibrational amplitude[2)] exceeds 5λ.

2. In principle the Powell–Stetson method can be used to study vibrations in real time; in actuality such studies give node lines only.[4]

3. The time-averaging method does not provide objective information about the relative vibrational phases of different points of the surface of the object.

4. The time-averaging method cannot be used to analyze vibrations with very small amplitudes ($A < \lambda/4$).

The first three limitations can be removed by a hologram strobe method of vibration analysis. The fourth limitation can be overcome by phase modulation of the reference beam and by a "hologram subtraction" method, both of which are dicussed below.

HOLOGRAM STROBE METHOD

This name is given to hologram methods using repeated synchronized light pulses. The hologram strobe method was first developed in[32] 1967 to study a plasma fed by a varying current. The apparatus is presented in Fig. 4. A drum-chopper, through which a mercury–argon discharge lamp (PRK-4) is fed, is mounted on the axis of an electric motor. A disk with apertures, through which a helium–neon laser beam passes, rotates on the same axis. The disk is arranged so that the light pulses correspond alternately to breaks and to maxima of the current through the lamp. This method is thus equivalent to the two-exposures method, with two waves corresponding to two states of the lamp being recorded on the hologram. The purpose of the study was to explain the variations of the radial density distribution of the gas, which is due to the current through the lamp. The present authors did not succeed in observing variations of this type in the lamps, as those border on the sensitivity limits of the interferometer method. This very idea of strobe holography, however, is very fruitful in vibration analysis.

Hologram strobe vibration analysis. In one of the first papers devoted to hologram strobe vibration analysis[33] an approximate analysis of the possibilities of this technique was given. We start with the Powell–Stetson method. We assume that it is a two-exposures method and that an interference structure is created on the hologram due to the object stopping at the extreme positions. The restored light waves scattered by the ob-

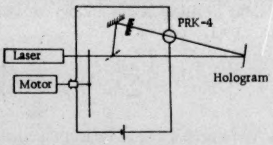

Fig. 4. Schematic of arrangement for hologram strobe investigation of a plasma.

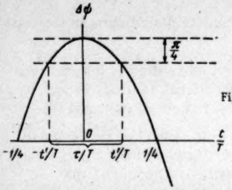

Fig. 5. For the derivation of Eq. (17).

ject interfere with each other at the extreme positions. The band luminosity is determined by the dwell time at the extreme positions τ. This dwell time is the interval during which the phase of the wave, scattered by the object in the hologram direction, changes by less than $\pi/4$, i.e., the time during which the quantity

$$\Delta\psi=\frac{2\pi}{\lambda}A\,(\cos\varphi_1+\cos\varphi_2)-\frac{2\pi}{\lambda}A\,(\cos\varphi_1+\cos\varphi_2)\cos\frac{2\pi t'}{T}\tag{17}$$

remains smaller in absolute value than $\pi/4$ (Fig. 5). Denoting by t' the time at which $\Delta\psi = \pi/4$, and taking account of $\tau = 2t'$, we have

$$\cos\frac{2\pi t'}{T}=1-\frac{\lambda}{8A\,(\cos\varphi_1+\cos\varphi_2)}\tag{18}$$

where

$$p=\frac{2\tau}{T}=\frac{2}{\pi}=\text{arc}\cos\left[1-\frac{\lambda}{8A\,(\cos\varphi_1+\cos\varphi_2)}\right].\tag{19}$$

The quantity p, defined by the last equality, is the "efficiency" of the Powell–Stetson method. It is that portion of the whole exposure which is the "duty" cycle of the exposure (the time during which the object is fixed in the sense discussed above). Since the largest number of bands observed in the Powell–Stetson method does not usually exceed 10, we have

$$2A\,(\cos\varphi_1+\cos\varphi_2)\leqslant 10\lambda;\tag{20}$$

using (19) we have $P_{\min} \simeq 0.15$. Thus, in the time-averaging method the effective exposure is at least 0.15 of the total exposure. The point luminosity of the restored object image, for which this quantity is less than 0.15, is usually insufficient to be observed. As noted above, the quantity J_0^2 for the 10th maximum of this function is equal to 0.02. Under ideal conditions one can observe even higher-order bands; this requires image restoration with a large-area hologram, so as to decrease the effect of spot noise. High stability of all components is also required. The values we use for a maximum observed number of bands (10), and the corresponding value $p_{\min} = 2\tau/T = 0.15$, correspond to ordinary conditions in obtaining holograms of vibrating objects.

By stroboscopic hologram illumination we can control the time and length of the hologram exposure. If the length of the illuminating pulse is a k-th part of a half-cycle (k is the pulse duty cycle), this causes a corresponding reduction of the total exposure without reduction of its useful part. The quantity p thus increases by a factor k, which widens the range of amplitudes that can be studied or, for a given amplitude, enhances the band luminosity

$$p=\frac{2k}{\pi}\text{arc}\cos\left[1-\frac{\lambda}{8A\,(\cos\varphi_1+\cos\varphi_2)}\right].\tag{21}$$

or

$$\frac{A\,(\cos\varphi_1+\cos\varphi_2)}{\lambda}=\frac{1}{8\left(1-\cos\frac{p\pi}{2k}\right)}.\tag{22}$$

When $\varphi_1 = \varphi_2 = 0$

$$\frac{A}{\lambda}=\frac{1}{16\left(1-\cos\frac{p\pi}{2k}\right)}=\frac{1}{32\sin^2\frac{p\pi}{4k}}.\tag{23}$$

This equation allows one to estimate the maximum value of vibrational amplitude for a given duty cycle k. For p = 0.15, which corresponds to the limiting characteristics of the Powell–Stetson method, we have

$$\left(\frac{A}{\lambda}\right)_{\max}=\frac{1}{32\sin^2\frac{0.15\pi}{4k}}\approx 2.5k^2.\tag{24}$$

Thus the hologram strobe method provides a quadratic increase in the limiting vibrational amplitude, while reducing the pulse length.

We consider more rigorously the intensity distribution over the restored image of the vibrating object.

Let the complex amplitude of the object wave incident on the hologram from some object point vibrating with amplitude A be $a\cdot\exp\{i[\varphi_0 + (4\pi A/\lambda)\sin\omega t]\}$.

The intensity of the restored image is proportional to the square of the absolute value averaged over the exposure time τ:

$$I=\left|\frac{ae^{-i\varphi_0}}{\tau}\int\limits_0^{\tau}e^{i\frac{4\pi A}{\lambda}\sin\omega t}\,dt\right|^2.\tag{25}$$

We expand the integrand in a Bessel function series

$$I=\left|\frac{a}{\tau}\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\int\limits_0^{\tau}e^{in\omega t}\,dt\right|^2.\tag{26}$$

Taking the strobe pulse length to be equal to the k-th part of the vibrational period T, i.e., $2\pi/\omega k = T/k$, and synchronizing it with an extremum of the object positions, we obtain

$$I=a^2\left|\frac{k}{T}\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\int\limits_{\frac{T}{4}-\frac{T}{2k}}^{\frac{T}{4}+\frac{T}{2k}}e^{in\frac{2\pi t}{T}}dt\right|^2. \qquad (27)$$

The integral inside the summation sign is exp(in π/2) · (T/k)[(sin nπ/k)/(nπ/k)], and we have

$$I=a^2\left|\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{n\pi}{k}}{\frac{n\pi}{k}}\right)e^{in\frac{\pi}{2}}\right|^2. \qquad (28)$$

Since $J_{-n} = (-1)^n J_n$, and $\exp(in\pi/2) = i^n$, we have $J_n \exp(in\pi/2) = J_{-n}\exp(-in\pi/2)$ and

$$I=a^2\left|J_0\left(\frac{4\pi A}{\lambda}\right)+2\sum_{n=1}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{n\pi}{k}}{\frac{n\pi}{k}}\right)i^n\right|^2. \qquad (29)$$

Considering such illumination of an object restored with a hologram and exposed by pulses of the same duration T/k, but synchronized with another position extremum of the vibrating object, we obtain

$$I=a^2\left|\frac{k}{2T}\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\int\limits_{\frac{3T}{4}-\frac{T}{2k}}^{\frac{3T}{4}+\frac{T}{2k}}e^{in\frac{2\pi t}{T}}dt\right|^2$$
$$=a^2\left|J_0\left(\frac{4\pi A}{\lambda}\right)+2\sum_{n=1}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{n\pi}{k}}{\frac{n\pi}{k}}\right)(-i)^n\right|^2. \qquad (30)$$

If the hologram is illuminated when the images (29) and (30) are restored, we observe the interference pattern formed by their superposition with the following intensity distribution:

$$I=a^2\left|\frac{k}{T}\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left\{\int\limits_{\frac{T}{4}-\frac{T}{2k}}^{\frac{T}{4}+\frac{T}{2k}}e^{in\frac{2\pi t}{T}}dt+\int\limits_{\frac{3T}{4}-\frac{T}{2k}}^{\frac{3T}{4}+\frac{T}{2k}}e^{in\frac{2\pi t}{T}}dt\right\}\right|^2$$
$$=a^2\left|J_0\left(\frac{4\pi A}{\lambda}\right)+\sum_{n=1}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{n\pi}{k}}{\frac{n\pi}{k}}\right)[i^n+(-i)^n]\right|^2. \qquad (31)$$

The quantity in the square brackets inside the summation sign is $2i^n$ for even n and vanishes for odd n. As a result all terms with odd indices drop out of the summation, and the interference pattern has the following intensity distribution:

$$I=a^2\left|J_0\left(\frac{4\pi A}{\lambda}\right)+2\sum_{p=1}^{\infty}J_{2p}\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{2p\pi}{k}}{\frac{2p\pi}{k}}\right)(-1)^p\right|^2. \qquad (32)$$

It is easily shown that in the particular case k = 2, corresponding to a continuously exposed object, sin (2pπ/k) = 0 for all p and we have the Powell–Stetson equation

$$I=a^2J_0^2\left(\frac{4\pi A}{\lambda}\right). \qquad (33)$$

The exposures method corresponds to the limit k → ∞. Indeed, replacing $(-1)^p$ by cos pπ in (32) and putting [sin (2pπ/k)]/(2pπ/k) = 1, we have

$$I=a^2\left|J_0\left(\frac{4\pi A}{\lambda}\right)+2\sum_{p=1}^{\infty}J_{2p}\left(\frac{4\pi A}{\lambda}\right)\cos 2p\frac{\pi}{2}\right|^2. \qquad (34)$$

By the well-known properties of Bessel functions of even index[3)] we have

$$I=a^2\cos^2\left(\frac{4\pi A}{\lambda}\right), \qquad (35)$$

which corresponds to the intensity distribution in the two-exposure method (Eq. 10).

Figure 6 shows maximum intensities of interference bands as a function of the vibrational amplitude (Eq. 29 for various k), calculated[4)] by Eqs. (29), (33), and (35).

We now consider the case in which the strobe pulse is not synchronized with an extremum of the object position but with an arbitrary position. Obviously, the requirement of a short pulse length is least serious in the case already considered, in which the object hologram is taken when it is almost at rest. If, however, the vibrational amplitude of the object is so large that the number of bands on the restored image is too large and they become unresolved, it is of interest to use a time-gated pulse so as to reduce the sensitivity of the method. Such attempts have been undertaken[33] (Fig. 10).

Let the duration of the gating pulse be T/k, as before, but assume that its mean is not reached at a time T/4 (and 3T/4), but at an arbitrary time αT (and αT + T/2). This case should reduce to that already considered if α = 1/4. The problem thus reduces to deriving the function (27) for new limits of integration: from αT−T/2k to αT + T/2k, i.e.,

$$I=a^2\left|\frac{k}{T}\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi}{\lambda}A\right)\int\limits_{\alpha T-\frac{T}{2k}}^{\alpha T+\frac{T}{2k}}e^{in\frac{2\pi t}{T}}dt\right|^2. \qquad (36)$$

Integrating, we obtain

$$I=a^2\left|\sum_{n=-\infty}^{\infty}J_n\left(\frac{4\pi A}{\lambda}\right)\left(\frac{\sin\frac{n\pi}{k}}{\frac{n\pi}{k}}\right)e^{i\alpha 2\pi n}\right|^2. \qquad (37)$$

The function (37) is shown in Figs. 7 and 8 for k = 100, 200 and various α.

As seen from the figures, a shift of the gating phase from the vibrational period by a few percent only causes a sharp decrease of the band luminosity, particularly in the higher orders. If, however, the duty cycle is large enough, the gating pulse shift can be applied effectively to vibration analysis.

EXPERIMENTS IN HOLOGRAM STROBE VIBRATION ANALYSIS

In 1968 it was suggested independently and simultaneously in a number of papers[33-36] that the hologram strobe method could be used to study periodic processes

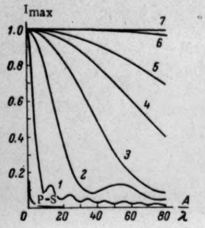

Fig. 6. Maximum intensity of interference bands as a function of the vibrational amplitude for the Powell–Stetson method (P–S) and for the hologram strobe method for various duty cycles of the strobing pulse k: 1) 10; 2) 20; 3) 30; 4) 40; 5) 50; 6) 100; 7) ∞.

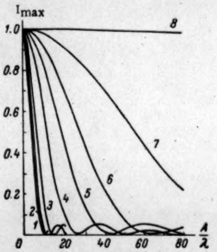

Fig. 7. Maximum intensity of interference bands as a function of vibrational amplitudes, displacing the gating pulse by αT from the passage moment of the vibrating body through the stationary position. Curves are given for different values of α. α = 0.25 corresponds to an extreme position of the object amplitude. The strobe duty cycle k = 100. α: 1) 0.05; 2) 0.10; 3) 0.15; 4) 0.20; 5) 0.22; 6) 0.23; 7) 0.24; 8) 0.25.

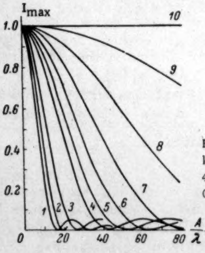

Fig. 8. Same as Fig. 7 for a duty cycle k = 200. α: 1) 0.05; 2) 0.10; 3) 0.15; 4) 0.19; 5) 0.20; 6) 0.21; 7) 0.22; 8) 0.23; 9) 0.24; 10) 0.25.

in solid transparent objects[33] and in diffuse light-scattering opaque[33–36] objects.

The scheme in Fig. 9 is used in ref. 33. A light beam from a helium–neon laser is chopped by a disk with apertures. The disk is attached to the axis of a motor–generator. The ac current generated by the latter is passed through a light coil in a constant magnetic field. The coil vibrations excite vibrations of the object under investigation, a disk of Plexiglas, in which the internal stresses arising near contractions during vibration are studied. The disk is illuminated by transmitted light (Fig. 9a) without a scatterer. Examples of the images are shown in Fig. 10a. Vibrating brass disks are also recorded by the hologram strobe (Fig. 10b). The modulator disk is attached to the axis of the motor–generator, so that the slits transmit light at specified phases. Control is achieved by the optical scheme shown by dashes in Fig. 9b. A small galvanometer mirror is glued to the vibrating object.

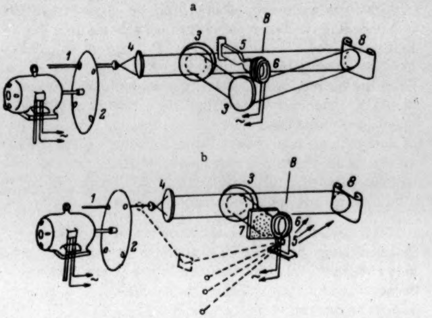

Fig. 9. Diagram of arrangement for hologram strobe vibration analysis. a) For the study of transparent objects; b) reflecting objects. 1) Laser beam; 2) modulator disk; 3) mirror; 4) telescopic system; 5) vibrating object; 6) coil placed in a magnetic field B; 7) scatterer; 8) photosensitive layer. The dashes indicate units for synchronization of the vibrational phase and light modulation.

Attempts at observing the restored images in real time are also performed on this design. In this case the hologram of an immobile object appears in place, and the vibrating object is observed through it with pulsed illumination (Fig. 11).

With this scheme the oscillation frequency of the object is determined by the motor frequency, which is 100 Hz.

The possibilities of the hologram strobe method have been demonstrated[34] in the vibration analysis of a diffusely reflecting disk, illuminated by laser light pulses obtained, as in ref. 33, with a rotating disk. The disk is driven by an electric motor which is driven by the same generator which supplies the acoustic excitation of the object. The hologram is exposed at maximum displacement. It has been shown[34] that the interpretation of the hologram strobe bands is simpler than that of bands obtained by the Powell–Stetson method. The bands are related directly to displacements and, consequently, to the vibrational amplitude of the object, as in the two-exposure method, the deformation analysis for which is given in refs. 37 and 38. The conclusions of these papers also apply to the band pattern obtained by the hologram strobe method.

A bar-shaped stroboscope with an aperture drilled in it perpendicular to its axis, through which a focused laser light beam is passed, was used in ref. 35. The bar is on the axis of a turbine driven by compressed air. The rotational velocity of the turbine can be controlled.

To eliminate one limitation of the strobe scheme,[33] the fact that the vibrational frequency cannot be varied, one can use another scheme (Fig. 12), which provides analysis at different frequencies up to $1.2 \cdot 10^4$ Hz.

The basic element controlling the object vibrations and chopping the laser pulse in this scheme is a disk with several series of apertures (Fig. 13), one of which chops the laser beam, and the other chops the light flux incident from the incandescent bulb on the photodiode. The fundamental frequency at the photodiode output is amplified and drives the membrane under investigation. The simplicity of this scheme is a considerable advantage. The disk is driven by an electric motor up to 200 Hz; since the disk has 60 apertures, this corresponds to a frequency of 12 kHz. The motor speed is controlled by a rheostat.

If a series with twice the number of apertures as those exciting the vibrations is used to chop the laser beam, thus obtaining two strobe pulses in one period of the membrane vibration, the hologram is equivalent to a two-exposure hologram.

This apparatus[39] also allows one to observe vibrations in real time. In this case the hologram of the fixed membrane is first exposed with the disk at rest; then when the disk rotates through the rest position the vibrating membrane is observed. By smoothly increasing the speed of the motor it becomes possible to follow the dynamic evolution of the vibrations. To chop the laser beam we use a series with the same number of apertures as that used to excite the current that drives the membrane (one strobe pulse per vibrational period). The strobe phase can also be changed smoothly by rotating the bulb–photodiode system around the disk axis.

The main limitations of the system are the difficulty of establishing a definite frequency, the instability of the rotating disk frequency, the restricted frequency range, and the impossibility of smoothly controlling the strobe pulse.

The hologram strobe method with a disk stroboscope has been used[40–42] for vibration analysis of circular membranes[40,41] and of a cantilever.[42]

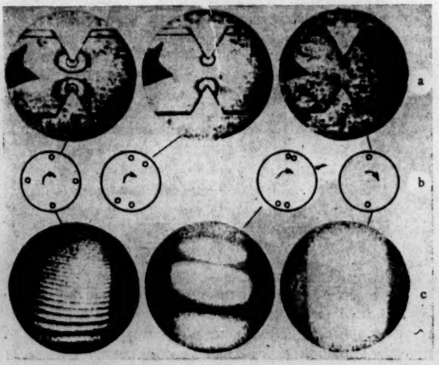

Fig. 10. Images of vibrating objects. a) Disk of Plexiglas; b) brass disk; c) corresponding aperture position in the modulator disk. (Two periods of the varying current and, consequently, two periods of the object vibration, correspond to one disk revolution.)

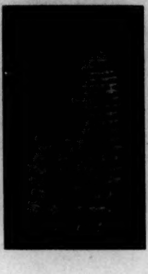

Fig. 11. Interferogram of a vibrating brass disk obtained in real time.

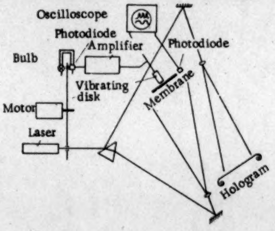

Fig. 12. Apparatus for hologram strobe vibration analysis.

The strobe capabilities described in refs. 33-35, 39-42 are not recommended for practical applications due to inherent limitations: inconvenient synchronization, limited frequency range, complexity, and inertia. An electrooptic strobe scheme eliminates these limitations completely.

Electrooptic light modulators are convenient in many respects; they are inertialess, have a wide range of frequencies (from several Hz to several hundred MHz), are of small size, weigh little, and can be synchronized easily.

Detailed information on electrooptic modulators can be found in refs. 43 and 44.

A stroboscope was first used in ref. 36; in this case, an electrooptic light modulator using a Pockels cell was employed. A thin circular disk, clamped at the periphery, is excited by a sine wave generator. A pulse generator gives rectangular voltage pulses to drive the Pockels cell with a half-wave voltage of 1300 V. Means for varying the pulse length and synchronizing pulses are provided. In the open state the cell transmits about 90% of the laser light.

It is shown in ref. 36 that in vibration analysis of an object with a large amplitude the hologram strobe method is restricted only by the hologram resolution and the quality of the photographic recording.

To analyze very large amplitudes it is suggested in that paper, as well as in refs. 33 and 34, that several holograms be recorded with strobe pulses synchronized with different phases of the object vibrational period, starting from one position of maximum displacement to another, thus spanning the total excursion.

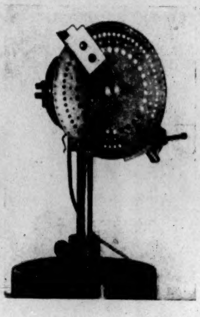

Fig. 13. Rotating disk.

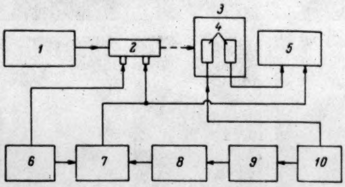

Fig. 14. Block diagram of the hologram strobe apparatus with the electrooptic chopper. 1) He–Ne; 2) modulator; 3) sample; 4) piezocrystal; 5) double-beam oscilloscope; 6) power source; 7) amplifier; 8) pulse generator; 9) phase-shift control; 10) sound generator.

This method is particularly important in nondestructive hologram testing, in which disturbances in machine parts or deviations from standard construction appear more clearly at high amplitudes.

The hologram strobe method has been used[45–47] with an electrooptic light modulator using a KDP crystal. In refs. 45 and 46 the vibration analysis is performed in real time, and in ref. 47 the holograms are exposed twice. The first exposure is in one position of the maximum displacement, and the second exposure is in the other. Another variant of this two-exposure hologram strobe method is also used, with half the sensitivity: During the first exposure the object is in a stationary state (with the modulator disconnected), and during the second exposure in one of the maximum displacement positions.

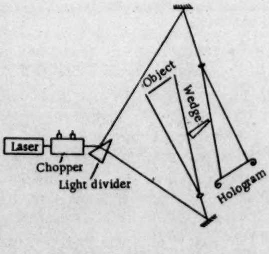

Fig. 15. Optical arrangement of apparatus with electrooptic chopper.

A schematic diagram of the apparatus with the electrooptic modulator[46,47] is given in Fig. 14. The frequency is determined by an audio generator, which drives a piezoelectric vibrator or an electromagnetic element. A rectangular pulse generator is also driven by this audio generator through a phase shifter and provides 100 V pulses.

An ML-3 electrooptic light modulator is used as the stroboscope.

Since the half-wave required by the voltage modulator is about 600 V, the pulses from the modulator are first amplified to this level.

Synchronization control of the strobe pulses is realized by a shielded double-beam oscilloscope, on one of whose channels is placed a pulse going to the modulator, and on the other a signal with a piezoelectric transducer glued to the sample.

A phase-shift control and a delay-line pulse generator are used for synchronization.

The light source is a 40 mW helium–neon LG-36 A laser power.

The intensity ratio of the reference and the object beam is 3-5. The exposure time for obtaining a good quality high-resolution (more than 2000 lines/mm) film for holograms (developed at the Kasan NIIKhim photoproject) is 10 sec in the time-averaging method. Using a strobe, the half-time exposure time (for a vibrating object) is 3 min 40 sec with a duty cycle of 20, and, correspondingly, 7 min 20 sec for a factor of 40.

The optical arrangement of the apparatus is shown is Fig. 15. The apparatus is mounted on a reinforced concrete slab weighing 1.5 ton resting on inflated self-powered chambers. Examples of interferograms of vibrating objects obtained by this object are given in Figs. 16-22.

Interferograms of a turbine blade, obtained by the Powell–Stetson method (without a chopper), are shown in Fig. 16. The same blade is also studied by the hologram strobe method, as shown in Figs. 17 and 18 (for comparison we also show the interferogram obtained under the same conditions by the Powell–Stetson method). Interferograms of a vibrating piezoelectric ceramic have also been obtained. Very small cracks (Fig. 19) are clear in some of them. An interferogram survey of vacuum tubes was performed with the purpose of explaining sites at which high voltages occur in vibrations of these tubes (Figs. 20, 21).

PHASE MODULATION OF THE REFERENCE BEAM

To increase the scope of the Powell–Stetson method it has been suggested[48–51] that the reference beam be phase-modulated while the hologram is recorded.

We consider analytically what this means. In the time-averaging method the light wave scattered by some point 0 undergoing harmonic vibrations seems to be phase-modulated with a modulation depth proportional to the vibrational amplitude of this point.

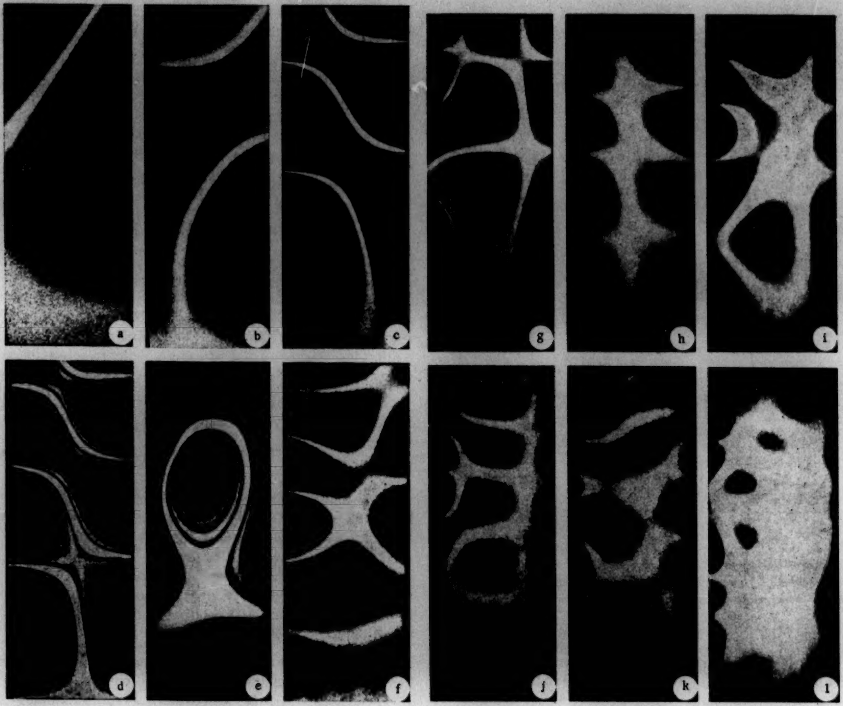

Fig. 16. Interferograms of a turbine blade vibrating at different frequencies, obtained by the Powell–Stetson method (without a chopper). ω, Hz: a) 820; b) 2720; c) 3800; d) 5650; e) 7360; f) 8800; g) 9650; h) 10,500; i) 11,250; j) 16,500; k) 18,900; l) 20,000.

The complex amplitude of the wave reaching the hologram from the vibrating object is, by Eq. (2),

$$ae^{-i\left[\psi_0+\frac{2\pi}{\lambda}\int\limits_0^t(\cos\varphi_1+\cos\varphi_2)A\sin\omega t\,dt\right]}, \tag{38}$$

where A is the vibration amplitude, which determines the phase-modulation depth of the object wave, and ψ_0 is the initial phase of the object wave.

If the reference beam is phase-modulated (for example, by displacing its source) with a frequency equal to the object vibrational frequency, its complex amplitude is written in the form

$$a_r e^{-i\left[\theta_r+\frac{2\pi}{\lambda}\int\limits_0^t M\sin\omega t\,dt\right]}, \tag{39}$$

where M is the displacement amplitude of the reference source, which determines the phase modulation depth of the reference wave, and θ_r is the initial phase of the reference wave.

As in Eq. (3), the illumination of point 0 in the restored image is determined by the equation

$$I=\left|\frac{a}{T}\int\limits_0^T e^{-i\left\{\left[\frac{2\pi}{\lambda}(\cos\varphi_1+\cos\varphi_2)A-\frac{2\pi}{\lambda}M\right]\sin\omega t+(\psi_0-\theta_r)\right\}}dt\right|^2. \tag{40}$$

When $\varphi_1=\varphi_2=0$, putting $\psi_0=\theta_r$ we have

$$I=\left|\frac{a}{T}\int\limits_0^T e^{-i\left[\frac{4\pi}{\lambda}(A-B)\sin\omega t\right]}dt\right|^2, \tag{41}$$

where we write B = M/2.

Expanding the exponent in the integrand in a series similar to Eq. (12), we have, corresponding to Eqs. (13) and (14),

$$I=a^2J_0^2\left[\frac{4\pi}{\lambda}(A-B)\right]. \tag{42}$$

This expression is similar to Eq. (15) for the Powell–Stetson method with the only difference that the argument of the zeroth-order Bessel function depends on the phase modulation depth B of the reference beam. This fact reveals the following possibilities of phase modulation of the reference beam.

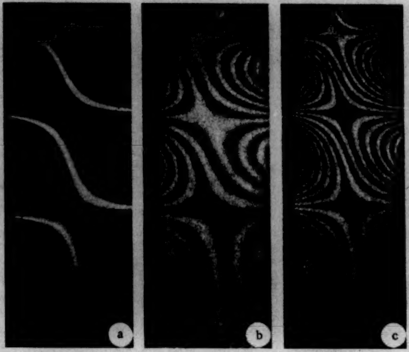

Fig. 17. Interferograms of a turbine blade, vibrating at 5650 Hz. a) The Powell–Stetson method; b) the hologram strobe method: two exposures; for the first the blade is fixed, for the second it vibrates, with the strobe activated in one of the extrema of the blade positions; c) the hologram strobe method, with the strobe activated in both extrema of the blade positions.

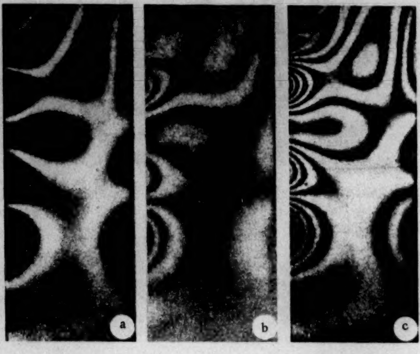

Fig. 18. Same as Fig. 17, but at a vibrational frequency of 13,000 Hz.

Determination of larger vibrational amplitudes. As seen from Eq. (42), by a suitable selection of the phase modulation phase of the reference beam one can compensate for part of the vibrating body amplitude; in the image the maximum luminosity is not that of interference bands with A = 0, as in the Powell–Stetson method, but A – B = 0; each band is the set of points of identical difference A – B.

This result was first illustrated experimentally by Aleksoff[48] in observing structural modes of an ADP crystal under zero shear stress in which standing shear waves are excited electrically.

Using phase modulation of the reference beam,[51] Aleksoff successfully investigated loudspeaker oscillations with an amplitude exceeding 6λ.

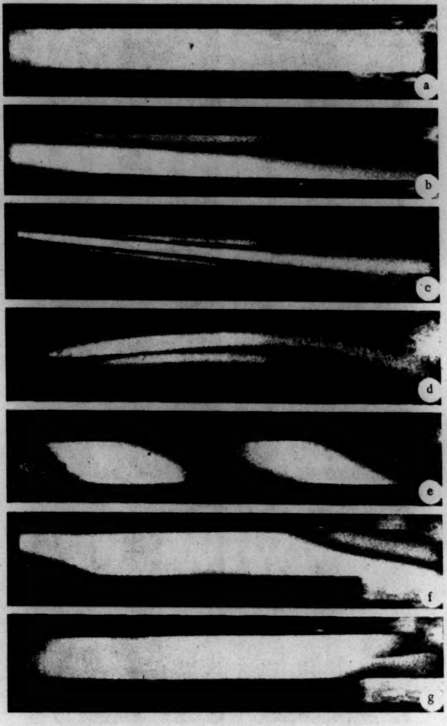

Fig. 19. Interferograms of a piezoelectric crystal vibrating with different frequencies, obtained by the Powell–Stetson method. a) At rest; ω, Hz; b)1780; c) 3660; d) 4500; e) 6760; f) 9320; g) 21,300. A sample defect (a crack) is observed at frequency 21,300 Hz.

It has been shown[55] that reference beam modulation allows one to study inhomogeneity of object vibrations in the presence of large reciprocating (piston) components in these oscillations. The surface vibrations of a piezoceramic electromechanical transformer with an amplitude exceeding 10λ have been analyzed.

Mottier[49,50] has suggested the use of automatic phase modulation of the reference beam by means of a small mirror attached to the moving object.

As shown by Caulfield,[52] Mottier's suggestion[49] is a special case of the use of a local reference beam.[53,54] This unifies all methods in which a reference beam, starting from part of the object beam, is used. A small motion of the object, illuminated by laser light, is accompanied by a phase change of the optic field of the reference beam. Mottier obtained a hologram of a sliding helix structure, in one of whose cavities a small mirror is attached, forming the reference beam when the helix is illuminated.

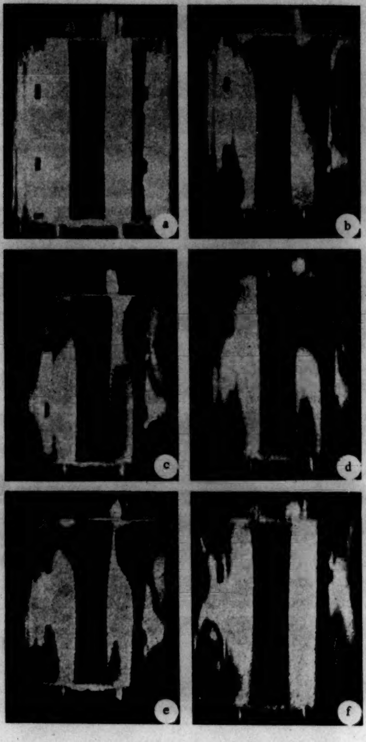

Fig. 20. Interferograms of a 6N9S vacuum tube vibrating at different frequencies, taken by the Powell–Stetson method. a) At rest; ω, Hz: b) 8350; c) 8960; d) 9140; e) 9290; f) 19,500.

In a following paper[50] Mottier proposed to synchronize the phase modulation of the reference beam by means of a mirror attached to a separate vibrating piezocrystal. The second piezoelectric vibrator was attached to a cantilever, whose vibrations were studied. This property of reference beam phase modulation was also used in ref. 55.

Determination of small vibrational amplitudes. If the modulation depth B in Eq. (42) is taken as the first root of the function $J_0^2(B)$, the possibility arises of observing the region of smallest vibrational amplitudes in the form of light spots on a general dark background of the object image.[55]

By Eq. (42), for small values of B the function $J_0[(4\pi/\lambda)(A-B)]$ can be expanded in a Taylor series

$$J_0\left[\frac{4\pi}{\lambda}(A-B)\right]=J_0\left(\frac{4\pi}{\lambda}B\right)+\frac{4\pi}{\lambda}(A-B)\,J_0'\left(\frac{4\pi}{\lambda}B\right)+\left(\frac{4\pi}{\lambda}\right)^2\frac{(A-B)^2}{2}\,J_0''\left(\frac{4\pi}{\lambda}B\right)+\dots \qquad (43)$$

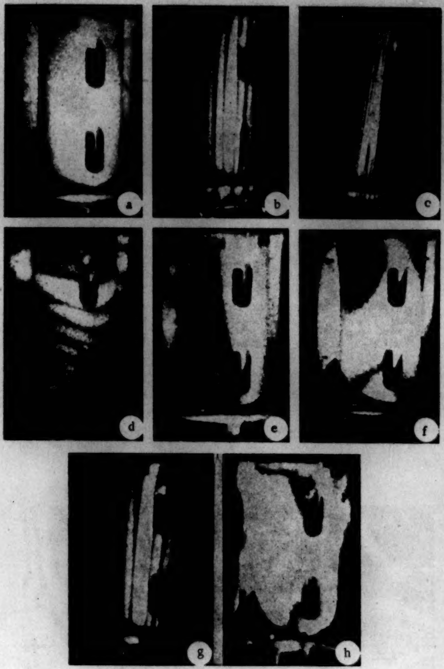

Fig. 21. Interferograms of a 6P1P vacuum tube, taken by the Powell–Stetson method. a) At rest; ω, Hz: b) 530; c) 534; d) 563; e) 595; f) 3700; g) 13,700; h) 14,200.

Restricting the discussion to the first two expansion terms and realizing that for the value of B chosen here the first expansion term vanishes, and using $J_0'(z) = -J_1(z)$, we can write for the brightness distribution in the restored object image

$$I=a^2\left[\frac{4\pi}{\lambda}(A-B)\right]^2 J_1^2\left(\frac{4\pi}{\lambda}B\right), \qquad (44)$$

i.e., in this case the intensity distribution in the restored object image is proportional to the square of the first order, rather than the zeroth-order, Bessel function.

The "dark-field" method allows one to determine[51,55] vibrational amplitudes of order 0.01λ.

Thus, to record very small vibrational amplitudes the sensitivity of the time-averaging method can be enhanced by phase modulation of the reference beam during exposure. Experimentally, however, realization of this property requires a complicated experimental procedure.

An alternative property of reference beam phase modulation for the determination of small vibrational amplitude is the relatively simple "hologram subtraction" method, suggested in ref. 56 and first experimentally carried out in ref. 57. In this method two object holograms are successively recorded on one photolayer, but with a phase shift of one beam by 180° between the exposures. The object portions not varying between exposures vanish in the restoration, and only those portions undergoing a change between exposures or during one of them are visible.[57]

To obtain a phase shift of 180° in the object beam it has been suggested[58] to superpose the object hologram in a state of rest on a vibrating object hologram taken by the Powell–Stetson method.

A similar method has been suggested[59] to observe the band pattern in real time.

Phase shifts of 180° in the reference beam have been obtained between exposures[60,61] by means of half-wave films.

In addition to the experimental complications, similar to those of the hologram strobe method, the reference beam phase modulation method also suffers from the limitation that the interpretation of band patterns and the calculational labor are quite complicated.

PHASE DETERMINATION OF A VIBRATING OBJECT

Obtaining information on the relative vibrational phases of various object points is of interest in vibration analysis in various technical areas. It has been shown[48,50,51] that reference beam phase modulation enables one to determine the vibrational phase of an object.

A method of determining vibrational phases of various object points has been suggested,[62] using the time-averaging method or its variant in real time, but with phase modulation of the reference beam, in whose arm a mirror vibrating with the object frequency is placed. The interference pattern depends on the amplitude and phase of the mirror vibrations with respect to the object vibrations. Regulating the amplitude and phase of the vibrating mirror, one can displace the node lines at any point of the object surface. The vibrational phase of object points is determined by the phase of the vibrating mirror, whose value is referred to the scale of a sinusoidal vibration generator, excited by the mirror vibrations.

To determine the vibrational phases of an object it has been suggested[63] that stroboscopic illumination be used in a hologram rotated by a small angle between exposures. If the object does not vibrate, a system of equidistant parallel bands is formed on its image. If the object vibrates during one of the exposures the parallel band pattern will be bent according to the field displacement of the vibrating object in the image restored with the hologram. Since the band system consists of lines of equal object displacements relative to the hologram with a known sign of phase variation of rotation of the hologram, the sign of vibrational phases of the different object portions is determined by the local bending of the resulting band pattern. A similar approach has been used[40] for the real-time method.

To create a system of parallel equidistant bands a simple and convenient wedge method[64] has been used,[47] allowing one to calculate uniquely the phase signs of points of the vibrating object from the bending of the band pattern in the restored image.

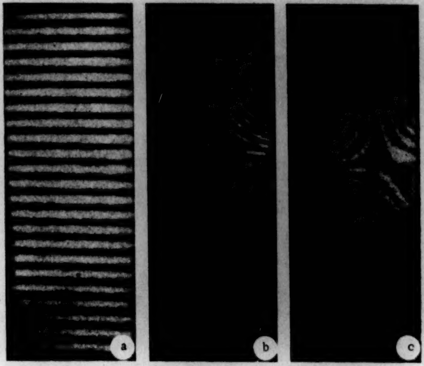

Fig. 22. Hologram strobe interferograms, obtained with a wedge. a) Interferogram of a fixed blade, obtained by the two-exposure method. The wedge is rotated before the second exposure; b) interferogram of a vibrating blade, obtained by the hologram strobe two-exposure method. Before the second exposure the strobe phase is changed by 180°, and the wedge remains fixed; c) interferogram of the vibrating blade, obtained as in case b, but with the wedge rotated before the second exposure. The vibrational frequency is 3800 Hz.

Interferograms of a vibrating turbine blade,[47] obtained with a wedge, are given in Fig. 22. Two exposures were performed to obtain this interferogram: During the first exposure the blade was stationary, and the second exposure was performed with a vibrating blade and stroboscopic hologram illumination. Before the second exposure the wedge (Fig. 15) is rotated and inclined to the object wave.

---

1) We consider idealized linear hologram recording.

2) It is shown[31] that some luminosity enhancement of high-order bands can be achieved by increasing the intensity ratio of the object and reference beams.

3) See, for example, V. I. Smirnov, A Course in Higher Mathematics, Vol. 3, Chap. 2, 5th ed., Moscow (1951), p. 531.

4) The authors are grateful to their colleagues in the computing center of the A. F. Ioffe Physicotechnical Institute, Ya. S. Uflyand, I. G. Dymnikov, and E. V. Galaktionov, for setting up the program and performing the calculations on a computer.

Stability of ball lightning

I. P. Stakhanov

(Submitted January 7, 1974)
Zh. Tekh. Fiz., 44, 1373-1379 (July 1974)

It is suggested that ball lightning consists of positive and negative ions surrounded by solvate shells of water molecules. These shells prevent the ions from approaching each other during collisions and greatly reduce the recombination rate. An attempt is made to estimate the value of the surface tensions of liquid metals and strong electrolytes. The stability of spherical lightning against the excitation of surface capillary gravity waves is calculated. The solution to this problem is used to derive conclusions about the possible size of ball lightning and about breakup.

1. One of the most astonishing properties of ball lightning is that it does not disappear as a result of recombination but can exist for a considerable period of time (1-100 sec). We may recall that in an ordinary lightning channel, which is subject to almost the same conditions, the recombination is complete a few milliseconds after the end of the discharge.[1] The radiation from ball lightning is not apparently related to a high temperature in the component material. It is well known that the intensity of this radiation undergoes sudden changes[2] and may increase or decrease by several orders of magnitude in a time of about one second. If the radiation were thermal, the temperature and volume of the lightning would also have to undergo significant changes during these pulsations. The lightning would then be unlikely to maintain stability.

Moreover, it has been shown in ref. 1 from an analysis of photographs that the radiation comes from the entire volume of the lightning. This is confirmed by the evidence of eye witnesses that it is possible to see surrounding objects through ball lightning. If the temperature of the lightning was high enough to maintain a significant degree of ionization, the lightning would radiate as a blackbody and would therefore not transmit radiation. The transparency of the lightning to both external radiation and to its own radiation shows that the temperature is not very high and that there cannot be any significant number of free electrons.

On the other hand, the lightning contains a considerable reserve of energy, which the available estimates[1,3] put as comparable with the ionization energy of a gas occupying the same volume. Thus the number of ions in 1 cm^3 of lightning must be about 10^{19}. If we take account of the low density of the material involved (which must be of the same order as that of the surrounding air), we come to the conclusion that the lightning cannot consist of charged, finely dispersed dust particles, unless the mass of these particles is comparable with atomic or molecular masses.

The suggestion is made in ref. 4 that ball lightning consists of positive and negative ions surrounded by solvate shells of water molecules. Such a shell would have a considerable bonding energy and would not be broken by collisions if the temperature were not very high. They would prevent direct contact between ions during collision and hinder recombination. It is well known that in the gas phase recombination usually takes place through highly excited atomic states.[5] The presence of water molecules around the ions disturbs the higher energy levels and makes the normal recombination mechanism ineffective. It is suggested in ref. 4 that recombination in the lightning material takes place through the fusion of two solvated ions of different sign into a single "molecule." Because the stability of such molecules is small at the temperature of lightning, we may expect that this process would be considerably slower than the usual recombination in the gas phase.

It is well known that ions surrounded by solvate shells have been found in solutions. It is natural to ask whether such a situation could be observed in gases. Positive and negative ions joined with one or more molecules of water (the so-called "ionic connections" or "clusters") have recently been discovered in rocket studies of the composition of the ionospheric D layer.[6,7] The discovery of solvated ions behind the shock front which always accompanies the rocket and at heights where the water vapor content is negligible shows the high stability of the solvate shells of these ions.

It is shown in ref. 4 that under certain circumstances slow recombination is replaced by a chain reaction of disintegration of the solvate shells ending in explosion. In the present paper we consider only quiescent recombination, which leads to a gradual "burn up" of the lightning material. We might note that the hypothesis explains why ball lightning does not rise through the surrounding cold air. This is because of the high molecular weight of the solvated ions. The reduction in density due to the rise in temperature is compensated by an increase in density due to the high molecular weight of the particles which form the lightning. It is still necessary, however, to explain why ball lightning is a rather rare phenomenon despite the fact water frequently occurs in the air and the formation of large quantities of solvated ions (clusters) should not be a rare event during the decay of a linear lightning channel.

2. Another surprising property of ball lightning is that it does not disintegrate as a result of hydrodynamic instabilities. It is easy to show that normal molecular diffusion is insignificant for the characteristic dimensions and lifetimes we are concerned with here. However, even a small difference in densities is sufficient to ensure that the development of a convective instability over a period of fractions of a second would lead to the dispersion of the lightning material into the surrounding medium. In fact, the lightning not only does not disintegrate but actually moves through the air with a velocity of the order[8] of 1 m/sec. The motion produces a tangential discontinuity in velocity at its surface, which is also absolutely unstable and this is another reason why the lightning should disappear rapidly.

The spherical shape of the lightning indicates that it must possess a considerable surface energy. Cases are known in which the lightning has disintegrated into several smaller pieces, which are also spherical.[9] It sometimes penetrates buildings through small openings or cracks but regains its shape completely after doing so.[1] We might expect the surface tension of plasma media to be anomalously high because of the large range of interaction of Coulomb forces. In fact the surface tension σ of the majority of liquid metals lies between 500 and 1000 erg/cm^2 as compared to a value of 20-30 erg/cm^2 for most organic liquids. We can assume that if the nature of the molecular forces remains the same, the value of σ should be proportional to the number of particles per unit area, i.e, to $n^{2/3}$, where n is the volume number density of the particles. Since the particle density in lightning, as in a normal gas, is about three orders of magnitude smaller than that of liquid metals, the value of σ should be 5-10 erg/cm^2.

Strong electrolytes represent another type of medium which contains ions. Despite the fact that the surface tension of water is rather high (about 80 erg/cm^2), the value of σ for all strong electrolytes except HCl increases linearly with the solute concentration. It is natural to assume that the surface tension of electrolyte σ_S is made up of the surface tension of water σ' and that of the ions into which the solute material decomposes σ''. The coefficients of σ' and σ'' in the total sum must be equal to the ratio of the number of particles of the given kind to the total number of particles per unit area of surface, i.e.,

$$\sigma_s = \sigma' \frac{N'}{N' + N''} + \sigma'' \frac{N''}{N' + N''}, \tag{1}$$

where N' and N" are the number of molecules and ions per square centimeter. We assume that the density of the solute at the surface does not differ from that in the main volume and that the dissolved molecules are fully dissociated into ions. Thus N' ~ c' and N" ~ c", where c' and c" are the molar densities of water and of the solute and α is the number of ions into which a molecule decomposes. In order that the degree of dissociation be close to 100%, we consider only very dilute solutions, i.e., c" ≪ c'. It then follows from (1) that

$$\sigma'' = \sigma' + \Delta\sigma \frac{c'}{\alpha c''}, \tag{2}$$

where $\Delta\sigma = \sigma_S - \sigma'$. Table 1 gives values of the surface energy of ions σ'', calculated from (2); the values of $\Delta\sigma$ are taken from the Handbook of Chemistry and Physics.[10] It has been assumed that $CaCl_2$ and Na_2SO_4 are fully dissociated into three ions, and the remaining molecules into two ions. The assumption of 100% dissociation, which is not completely true even for strong electrolytes, means that the values of σ'' given in Table 1 are rather too low. The same conclusion follows from the assumption that the ion density is the same in the volume and at the surface. The increase in surface energy on solution must in fact create a tendency for the density of ions to decrease at the surface. Thus the true values of the ion surface tensions must be slightly greater than in Table 1. After allowance for the $n^{2/3}$ factor, we get the surface tension of the lightning material to be about 2 erg/cm^2 and this is in order of magnitude agreement with the results obtained from the data on liquid metals. We can thus expect that the surface tension σ of lightning lies in the range 1-10 erg/cm^2.

TABLE 1

	KOH	NaOH	$MgSO_4$	NaCl	KCl	HCl	$CaCl_2$	Na_2SO_4
σ''	123	151	145	120	112	75	143	123

A result of the same order of magnitude for the surface tension follows from an estimate of the stability condition for the tangential discontinuity which arises when the lightning moves. In making this estimate we can use the dispersion relationship for waves at an infinite plane interface between two media.[11] Assuming the densities of the lightning ρ_1 and of the ambient air ρ_2 to be identical, we find that

$$\omega = \frac{ku}{2} \pm \sqrt{\frac{\sigma k^3}{2\rho_1} - \frac{k^2 u^2}{4}}, \tag{3}$$

where ω and k are the frequency and wave number of the wave and u is the velocity of movement of the lightning. The boundary of the stability region is given by the condition

$$u \leqslant \sqrt{\frac{2\sigma}{\rho_1} k}. \tag{4}$$

If the lightning has a radius R_0, then $k \gtrsim 2\pi/R_0$. Putting $\rho_1 \simeq 10^{-3}$ g/cm^3, $R_0 \simeq 10$ cm, we find that for stability at a velocity $u \approx 10^2$ cm/sec, it is necessary that $\sigma \simeq 10$ erg/cm^2. This estimate can only give an order of magnitude for σ because (3) and (4) are valid only for a plane interface.

3. We now consider the stability of lightning in more detail, assuming that the density of its material ρ_1 and that of the ambient air ρ_2 are different. For simplicity we take the lightning to be at rest. For a plane boundary the result of the problem is well known: The system is stable if the medium with the greater density is on the bottom. If not, capillary waves with long wavelengths become unstable. This criterion is not applicable to a spherical body because the difference $\rho_1 - \rho_2$ changes sign on the surface. We therefore consider the stability of capillary waves on a spherical surface.

The pressure difference on the boundary, equal to the sum of the inverse radii of curvature, gives the following expression for an incompressible liquid:[1]

$$p_1 - p_2 = -\rho_1 \frac{\partial \psi_1}{\partial t} + \rho_2 \frac{\partial \psi_2}{\partial t} - (\rho_1 - \rho_2) g z = \frac{2\xi}{R_0^2}\sigma - \frac{\sigma}{R_0^2}\hat{M}\xi, \tag{5}$$

where $\xi = R - R_0 \ll R_0$ is the deviation of the actual radius at a given point on the surface from the radius in the unperturbed state R_0; ψ_1 and ψ_2 are the velocity potentials; p_1 and p_2 are the pressures of the lightning material (subscript "1") and of the surrounding air (subscript "2"); g is the acceleration due to gravity. The operator $\hat{M}$ is defined as

$$\hat{M} = \frac{1}{\sin\theta} \frac{\partial}{\partial\theta}\left(\sin\theta \frac{\partial}{\partial\theta}\right) + \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial\varphi^2}, \tag{6}$$

where θ and φ are the angles in a spherical coordinate system and the z axis is taken vertically upwards. On the boundary we must have

$$\frac{\partial\psi_2}{\partial r}=\frac{\partial\psi_1}{\partial r}\equiv\frac{\partial\psi}{\partial r}. \tag{7}$$

Since $\psi_1, \psi_2 \sim e^{-i\omega t}$ and $z = (R_0 + \xi) \cos\theta$, on differentiating (5) with respect to t with constant R_0, θ, φ and remembering that $(\partial\xi/\partial t)_{\theta,\varphi} = v_r = \partial\psi/\partial r$, we find

$$(\rho_1\psi_1-\rho_2\psi_2)\,\omega^2-(\rho_1-\rho_2)\,g\cos\theta\,\frac{\partial\psi}{\partial r}+\frac{\sigma}{R_0^2}(\hat{M}+2)\frac{\partial\psi}{\partial r}=0. \tag{8}$$

In order to determine ψ_1 and ψ_2 we require solutions of the Poisson equation which are bounded as $r \to 0$ and $r \to \infty$ respectively (r is the radius of any point in space). These have the form

$$\psi_1=\sum_{l=1}^{\infty}\sum_{m=-l}^{m=l}A_l^{(m)}r^lY_l^{(m)}(\theta,\varphi),\quad \psi_2=\sum_{l=0}^{\infty}\sum_{m=-l}^{l}B_l^{(m)}r^{-l-1}Y_l^{(m)}(\theta,\varphi), \tag{9}$$

where the $Y_l^{(m)}$ are spherical functions. Since condition (7) must hold when $r = R_0$, we find that

$$B_0=0,\quad B_l^{(m)}=-\frac{l}{l+1}R_0^{2l+1}A_l^{(m)},\quad l\geqslant 1. \tag{10}$$

Using (10) and (9) in (8) we get

$$\sum_{l=1}^{\infty}\sum_{m=-l}^{l}C_l^{(m)}Y_l^{(m)}\left\{\left(1+\frac{l}{l+1}\frac{\rho_2}{\rho_1}\right)\Omega^2-l(l-1)(l+2)\right\}
=2\eta\sum_{l=1}^{\infty}\sum_{m=-l}^{l}C_l^{(m)}l\cos\theta\,Y_l^{(m)}, \tag{11}$$

where

$$C_l^{(m)}=A_l^{(m)}R_0^l,\quad \eta=\frac{\rho_1-\rho_2}{2\sigma}gR_0^2,\quad \Omega^2=\omega^2\frac{\rho_1R_0^3}{\sigma}. \tag{12}$$

Multiplying (11) by $Y_n^{(s)*}$ and integrating over the angles, we obtain the following system of equations:

$$C_l^{(m)}(\Omega^2-E_l)=2\eta\left(\mu_l^{(m)}C_{l-1}^{(m)}+\lambda_l^{(m)}C_{l+1}^{(m)}\right), \tag{13}$$

where

$$E_l=\frac{l(l-1)(l+2)}{1+\frac{l}{l+1}\nu}, \tag{14}$$

$$\mu_l^{(m)}=\frac{l-1}{1+\frac{l}{l+1}\nu}\sqrt{\frac{l^2-m^2}{4l^2-1}},\quad \lambda_l^{(m)}=\frac{l+1}{1+\frac{l}{l+1}\nu}\times\sqrt{\frac{(l+1)^2-m^2}{4(l+1)^2-1}},\quad \nu=\frac{\rho_2}{\rho_1}. \tag{15}$$

The system (13) can be solved approximately by considering the right side as a perturbation. The unperturbed spectrum of eigenvalues is defined by the expression $\Omega^2 = E_l$. The corrections to the unperturbed values $\Delta_l^{(m)}$ appear in second-order perturbation theory[12] and are given by the expressions

$$\Delta_l^{(m)}=-4\eta^2\left(N_{l+1}^{(m)}-N_l^{(m)}\right), \tag{16}$$

where

$$N_l^{(m)}=\frac{l^2-m^2}{4l^2-1}\,\frac{l}{l(l+2)\left(1+\frac{l-1}{l}\nu\right)-(l+1)(l-2)\left(1+\frac{l}{l+1}\nu\right)}. \tag{17}$$

The eigenfrequencies of the capillary oscillations with the surface tension perturbation included and $\rho_1 \neq \rho_2$ are

$$\Omega^2=E_l+\Delta_l^{(m)}, \tag{18}$$

and the E_l are defined by (14) with $l = 2, 3, 4 \ldots$ ($l = 1$ corresponds to movement of the sphere as a whole and not to a surface wave mode). The imposition of the perturbations leads to the removal of the degeneracy; the eigenfrequencies become dependent on m. As in the quadratic Stark effect, the change in the eigenfrequencies does not depend on the direction of the forces, i.e., on the sign of $\rho_1 - \rho_2$.

Let us consider two important cases. If the densities of the lightning and of the surrounding air are not very different we can put $\nu \simeq 1$. We are mainly interested in corrections to the lowest eigenfrequency, i.e., for $l = 2$. These are equal to

$$\Delta_2^{(0)}=\frac{2}{315}\eta^2,\quad \Delta_2^{(1)}=-\frac{2}{105}\eta^2,\quad \Delta_2^{(2)}=-\frac{2}{21}\eta^2. \tag{19}$$

The boundary of stability is defined by the condition $E_2 + \Delta_2^{(2)} = 0$, at which the corresponding eigenfrequency goes to zero. Thus the first unstable oscillation mode occurs for $\eta \geq \eta_0 = 7$. Although the perturbation method is strictly speaking, not applicable to such large changes in the eigenfrequencies, we assume that this result is correct in order of magnitude.

If a sufficiently thick layer of air around the lightning is heated to a temperature close to that of the lightning material, then $\rho_2 \ll \rho_1$, and we can put $\nu = 0$. This gives

$$\Delta_2^{(0)}=-1.4\cdot10^{-3}\,\eta^2,\quad \Delta_2^{(1)}=-0.05\,\eta^2,\quad \Delta_2^{(2)}=-0.156\,\eta^2. \tag{20}$$

Using the expression for E_2 with $\nu = 0$ we find that the critical value of the parameter remains about the same in this case as well ($\eta_0 \simeq 7$).

4. It follows from our solution that the lightning is stable if

$$\sqrt{g\frac{|\rho_1-\rho_2|}{2\sigma}}\,R_0<\sqrt{\eta_0}\simeq 2.5. \tag{21}$$

The left side of the inequality (21) represents the ratio of the lightning radius to the capillary constant of its material. It is known that this ratio must be of the order of or less than unity in order for the body to have the shape of a sphere.[11] We still have to establishd what happens when (21) is violated. The aperiodic instability which is produced could lead to the development of turbulence and the disintegration of the lightning. However, in principle the possibility is not excluded that there might be a transformation to a new, nonspherical, equilibrium shape. A final solution to this problem is not possible without further studies. It nevertheless seems probable that ball lightning cannot exist if condition (21) or some closely related condition is violated.

Equation (21) also explains both the observed sizes and lifetimes of ball lightning. It follows from this equation that the lightning is only stable if its density is nearly the same as that of the surrounding air. In fact, putting $\sigma \simeq 2$ erg/cm^2, we get

$$\Delta\rho \equiv |\rho_1 - \rho_2| \leqslant \frac{24 \cdot 10^{-3}}{R_0^2}. \quad (22)$$

When $R_0 = 15$ cm, the relative deviation $\Delta\rho/\rho_2$ must be less than 10%, i.e., we are not talking about an order of magnitude agreement but an almost exact equality of densities. This explains why the lightning often hovers in the air. It also follows that lightning with a diameter of the order of one meter or greater must be a very rare phenomenon. It can easily be seen from (22) that for $R_0 = 50$ cm, the difference between the density of the lightning and that of air must not exceed 1%. Such lightning requires very special initial conditions, which would rarely be realized in practice. This answers the question which was posed above as to why ball lightning is comparatively rarely observed although the formation of ions with a solvate shell of water molecules during lightning discharges can hardly be a rare event. In the majority of cases the clusters which are formed become scattered as a result of instability in the surrounding air and gradually recombine.

Condition (22) is not very restrictive for ball lightning with a diameter of about 10-20 cm and in fact such lightning is particularly often observed.[8] However, estimates which are not given here show that it is also difficult to observe lightning balls with diameter less than 1 cm because they burn up in less than 1 sec. We thus agree with the opinion expressed in refs. 8 and 13 that ball lightning occurs during practically every normal lightning discharge but only in comparatively rare cases does it last for any length of time (more than 1 sec). The observed diameters of ball lightning[8] do in fact lie between 1 and 100 cm.

The other result which follows from (21) is that in the majority of cases quiescent burning (without explosion) would not be expected to end in total recombination of all the ions, but in disintegration of the lightning as a result of the development of instability. This explains the short lifetimes[8,13] (average of 2-10 sec). Estimates show that in this time only a small fraction of the overall energy contained in the lightning can be disposed of (for diameters greater than 5-10 cm). The recombination of each pair of ions is accompanied by the production of a considerable number (6-10) of water molecules, whose diffusion can be neglected during the lifetime of the lightning. If the solvate shells are not completely filled, these molecules will be trapped by ions. The molecular weight and density of the material therefore increase. If the shells are filled, on the other hand, the light decay products will gradually accumulate in the lightning and lead to a reduction in the molecular weight and density. In both cases, the stability condition (21) or (22) is violated by the change in density long before a considerable fraction of the energy has been expended. This situation refers especially to lightning with a fairly large diameter (5-10 cm).

Observers confirm[9,14] that the quiet disappearance of the lightning is preceded by "sparkling" or "boiling". Every time a "spark" is emitted, the lightning recoils in the opposite direction.[14] We are obviously talking here not about an electrical discharge but about an ejection of material from the lightning as a result of instability development, which produces a recoil because of the conservation of momentum.

It is natural to consider the production of ball lightning under laboratory conditions. This might be attempted by introducing a large drop of water of about 1 cm in diameter into the channel of a high-current pulse discharge. Such a drop could produce ball lightning of 10 cm diameter. As we have shown, with a large drop of water the growth of instabilities could hinder the formation of the lightning. Lightning arising from smaller drops (a few millimeters in diameter) would probably burn up quickly but it is possible that it could be recorded by fast motion-picture film. The discharge should be short enough so that the water in the drop does not move in the surrounding air during the period of the pulse. Water drops of diameter 1 cm are unstable against motion and should probably therefore be found on the electrode; small drops (less than 3 mm) retain their stability under free fall.

Radiation from a charged particle moving close to an anisotropic dielectric

A. I. Plis and N. M. Safikhodzhaev
Moscow Power Engineering Institute
Andizhan State Pedagogical Institute
(Submitted October 11, 1973)
Zh. Tekh. Fiz., 44, 1380–1384 (July 1974)

The radiation from a charged particle moving along a uniaxial crystal cut perpendicularly to its optic axis is discussed. The problem is solved by expanding the fields in terms of the polarizations and using the Fresnel coefficients.

1. In connection with recent discussions of the possibilities of obtaining high-current relativistic beams it is of interest to consider the interaction of a beam with a dielectric. The interactions of moving line and point sources with isotropic slabs are discussed in refs. 1–3, and the interaction of line sources with an anisotropic slab is treated in ref. 4. In the present paper we discuss the radiation from a point charge moving along a plane-parallel slab of a uniaxial crystal cut perpendicularly to its optic axis.

2. Ordinarily, problems involving radiation from sources moving near interfaces are solved by matching fields or by the method of images. Both methods are well known and typical examples can be found, for example, in refs. 5 and 6.

Here we solve the Cerenkov radiation boundary-value problem by what we shall call the Fresnel-coefficient method. The Fresnel coefficients relate the amplitudes of the incident, reflected, and refracted waves in the case of a plane monochromatic wave incident on the plane interface between two media. Use of the Fresnel coefficients yields an efficient solution of boundary-value problems. The self-field of the moving charge can be expanded in plane waves by a Fourier integral. The amplitudes in the plane-wave expansion of the free fields can be found by multiplying the Fourier amplitudes of the self-field by the appropriate Fresnel coefficients. Thus, the most laborious part of the calculation involved in using Fresnel coefficients – the expansion of the field of the particle in terms of the polarizations – is much simpler than solving the system of equations in the method of matching fields or constructing dipoles in using the method of images.

3. We choose a rectangular coordinate system such that the anisotropic layer with the permittivity tensor $\hat{\varepsilon}_{ik}$ occupies the region $a > x > 0$, and the regions $x > a$ and $x < 0$ are filled with an isotropic dielectric. A charge q moves with a uniform velocity v at a distance d from the layer, so that the equations of motion can be written in the form

$$x = -d, \quad y = 0, \quad z = vt. \tag{1}$$

Thus the x axis is normal to the interface and parallel to the optic axis of the crystal. In this coordinate system the permittivity tensor has the form

$$\varepsilon_{ik} = \begin{bmatrix} \varepsilon_e & & \\ & \varepsilon_0 & \\ & & \varepsilon_0 \end{bmatrix}. \tag{2}$$

We assume that the media are nonmagnetic ($\mu_1 = \mu_2 = 1$), and denote the permittivity of the isotropic medium by ε_1.

Solving the problem by the method of Fresnel coefficients requires an expression for the self-field of a particle moving in an isotropic medium in the form of an expansion in plane inhomogeneous waves polarized in and perpendicular to the plane of incidence. By using Eqs. (A16)-(A19) of ref. 7 this expansion is easily found to be

$$\left.\begin{aligned} H_{y\parallel}^{(0)} &= -\frac{q}{2\pi v}\int\int dk_y d\omega \frac{\omega^2}{vc\varkappa^2} e^{i\nu}\,\mathrm{sign}\,(x+d), \\ H_{z\parallel}^{(0)} &= \frac{q}{2\pi v}\int\int dk_y d\omega \frac{k_y\omega}{c\varkappa^2} e^{i\nu}\,\mathrm{sign}\,(x+d); \end{aligned}\right\} \tag{3}$$

$$\left.\begin{aligned} E_{y\perp}^{(0)} &= \frac{q}{2\pi v}\int\int dk_y d\omega \frac{\omega^2 k_y}{c^2\varkappa^2\lambda_1} e^{i\nu}, \\ E_{z\perp}^{(0)} &= \frac{q}{2\pi v}\int\int dk_y d\omega \frac{v\omega k_y^2}{c^2\varkappa^2\lambda_1} e^{i\nu}, \end{aligned}\right\} \tag{4}$$

where

$$\nu = \lambda_1 |x+d| + k_y y + \frac{\omega}{v} z - \omega t,$$

$$\lambda_1 = \sqrt{\Sigma_1 \frac{\omega^2}{c^2} - \varkappa^2}, \quad \varkappa^2 = k_y^2 + \frac{\omega^2}{v^2}.$$

The superscript (0) denotes the self-field of the particle and the symbols ∥ and ⊥ refer to waves polarized in and perpendicular to the plane of incidence.

4. The Fresnel coefficients for an isotropic dielectric slab are given, for example, in ref. 8, p. 352, problem 4. Because of the choice of the orientation of the optic axis of the crystal these coefficients are easily modified for an anisotropic uniaxial crystal. Since our basic problem is the determination of the radiation loss, we need expressions only for the fields in the half-space in which the particle moves. Thus we only need the values of the reflection coefficients for waves of both polarizations. The expressions for these coefficients, taking account of the anisotropy of the slab, are

$$r_{\perp} = \frac{2i(\lambda_0^2 - \lambda_1^2)\sin\lambda_0 a}{(\lambda_1 + \lambda_0)^2 e^{-i\lambda_0 a} - (\lambda_1 - \lambda_0)^2 e^{i\lambda_0 a}}, \tag{5}$$

$$r_{\parallel} = \frac{2i[\varepsilon_1^2\lambda_e^2 - \varepsilon_0^2\lambda_1^2]\sin\lambda_e a}{(\varepsilon_0\lambda_1 + \varepsilon_1\lambda_e)^2 e^{-i\lambda_e a} - (\varepsilon_0\lambda_1 - \varepsilon_1\lambda_e)^2 e^{i\lambda_e a}}. \tag{6}$$

Here

$$\lambda_0 = \sqrt{\frac{\omega^2}{c^2}\varepsilon_0 - \varkappa^2}, \quad \lambda_e = \sqrt{\frac{\omega^2}{c^2}\varepsilon_0 - \frac{\varepsilon_0}{\varepsilon_e}\varkappa^2}.$$

It should be noted that these values of the Fresnel coefficients apply for pure transverse fields. The plane-wave expansion of the self-field of a particle also contains longitudinal field components and when these are taken into account the coefficient $r_{\parallel}$ is changed. Equations (5) and (6) can be used in our problem, however, since the correction term in $r_{\parallel}$ describes the Coulomb field of the charge in the first medium, and this does not contribute to the radiative energy loss.

The values of the Fresnel coefficients enable us to write the expressions for the free fields in the region x < 0:

$$\left.\begin{aligned}E_{y\perp}^{(1)}&=\frac{q}{2\pi v}\iint dk_y d\omega\frac{2i(\lambda_0^2-\lambda_1^2)\sin\lambda_0 a}{(\lambda_1+\lambda_0)^2e^{-i\lambda_0 a}-(\lambda_1-\lambda_0)^2e^{i\lambda_0 a}}\frac{\omega^2k_y}{c^2\varkappa^2\lambda_1}e^{i\nu_1},\\E_{z\perp}^{(1)}&=-\frac{q}{2\pi v}\iint dk_y d\omega\frac{2i(\lambda_0^2-\lambda_1^2)\sin\lambda_0 a}{(\lambda_1+\lambda_0)^2e^{-i\lambda_0 a}-(\lambda_1-\lambda_0)^2e^{i\lambda_0 a}}\frac{v\omega k_y^2}{c^2\varkappa^2\lambda_1}e^{i\nu_1},\end{aligned}\right\}\quad(7)$$

$$\left.\begin{aligned}H_{y\parallel}^{(1)}&=-\frac{q}{2\pi v}\\&\times\iint dk_y d\omega\frac{2i[\varepsilon_1^2\lambda_e^2-\varepsilon_0^2\lambda_1^2]\sin\lambda_e a}{(\varepsilon_0\lambda_1+\varepsilon_1\lambda_e)^2e^{-i\lambda_e a}-(\varepsilon_0\lambda_1-\varepsilon_1\lambda_e)^2e^{i\lambda_e a}}\frac{\omega^2}{v\varkappa^2c}e^{i\nu_1},\\H_{z\parallel}^{(1)}&=\frac{q}{2\pi v}\iint dk_y d\omega\frac{2i[\varepsilon_1^2\lambda_e^2-\varepsilon_0^2\lambda_1^2]\sin\lambda_e a}{(\varepsilon_0\lambda_1+\varepsilon_1\lambda_e)^2e^{-i\lambda_e a}-(\varepsilon_0\lambda_1-\varepsilon_1\lambda_e)^2e^{i\lambda_e a}}\frac{k_y\omega}{c\varkappa^2}e^{i\nu_1},\end{aligned}\right\}\quad(8)$$

where $\nu_1=-\lambda_1(x-d)+k_y y+(\omega/v)z-\omega t$.

5. We calculate the total radiative energy loss of a particle as the work done per unit displacement by the retarding force on the charge due to the radiation field, using the usual equation:

$$\frac{dw}{dz}=qE_z\Big|_{\substack{x=-d\\y=0\\z=vt}}=q\left(E_{z\perp}^{(0)}+E_{z\perp}^{(1)}+E_{z\parallel}^{(0)}+E_{z\parallel}^{(1)}\right)\Big|_{\substack{x=-d\\y=0\\z=vt}}.\quad(9)$$

The expressions for the fields $E_{z\parallel}^{(0)}$ and $E_{z\parallel}^{(1)}$ are found from (3) and (8) by using Maxwell's equations:

$$E_{z\parallel}^{(0)}=-\frac{q}{2\pi v}\iint dk_y d\omega\frac{\omega\left(\varepsilon_1\frac{\omega^2}{c^2}-\varkappa^2\right)}{v\varepsilon_1\lambda_1\varkappa^2}e^{i\nu},\quad(10)$$

$$E_{z\parallel}^{(1)}=\frac{q}{2\pi v}\iint dk_y d\omega\frac{2i[\varepsilon_1^2\lambda_e^2-\varepsilon_0^2\lambda_1^2]\sin\lambda_e a}{(\varepsilon_0\lambda_1+\varepsilon_1\lambda_e)^2e^{-i\lambda_e a}-(\varepsilon_0\lambda_1-\varepsilon_1\lambda_e)^2e^{i\lambda_e a}}\frac{\lambda_1\omega}{v\varepsilon_1\varkappa^2}e^{i\nu_1}.\quad(11)$$

Substituting the values of $E_{z\perp}^{(0)}$, $E_{z\perp}^{(1)}$, $E_{z\parallel}^{(0)}$, and $E_{z\parallel}^{(1)}$ from (4), (7), and (10), (11) into (9) we obtain the total energy loss:

$$\begin{aligned}\frac{dw}{dz}&=-\frac{q^2}{2\pi v}\operatorname{Re}\iint dk_y d\omega\\&\times\left\{\frac{v\omega k_y^2}{c^2\lambda_1\varkappa^2}\left[1+\frac{2i[\lambda_0^2-\lambda_1^2]\sin\lambda_0 a}{(\lambda_1+\lambda_0)^2e^{-i\lambda_0 a}-(\lambda_1-\lambda_0)^2e^{i\lambda_0 a}}e^{2i\lambda_1 d}\right]\right.\\&\left.+\frac{\lambda_1\omega}{v\varepsilon_1\varkappa^2}\left[1-\frac{2i[\varepsilon_1^2\lambda_e^2-\varepsilon_0^2\lambda_1^2]\sin\lambda_e a}{(\varepsilon_0\lambda_1+\varepsilon_1\lambda_e)^2e^{-i\lambda_e a}-(\varepsilon_0\lambda_1-\varepsilon_1\lambda_e)^2e^{i\lambda_e a}}e^{2i\lambda_1 d}\right]\right\}.\end{aligned}\quad(12)$$

Equation (12) is obtained under the assumption that the Cerenkov condition is satisfied everywhere.

6. If the isotropic medium in which the particle moves is replaced by vacuum ($\varepsilon_1=1$), and the uniaxial crystal by an isotropic dielectric ($\varepsilon_0=\varepsilon_2=\varepsilon$), this equation goes over into Eq. (7) of ref. 3. However, Eq. (7) is obtained in ref. 3 by a cumbersome calculation.

We now examine certain special cases. First we consider a frequency range such that the Cerenkov condition is not satisfied in the isotropic medium but is satisfied in the slab. This is the most interesting case for the production of radio waves by Cerenkov radiation. Clearly, in the isotropic medium in which the particle moves

$$\beta^2\varepsilon_1-1<0.\quad(13)$$

Consequently λ_1 becomes pure imaginary:

$$\begin{aligned}\lambda_1&=ig_1,\\g_1&=\sqrt{\frac{\omega^2}{v^2}(1-\varepsilon_1\beta^2)+k_y^2}.\end{aligned}\quad(14)$$

Substituting the value of λ_1 into (12) and performing some simple transformations we obtain

$$\begin{aligned}-\frac{dw}{dz}&=\frac{q^2}{\pi v^2}\operatorname{Re}i\int_{\beta^2\varepsilon_1<1}\frac{\omega d\omega}{\varepsilon_1}\int\frac{g_1}{\left(\frac{\omega^2}{v^2}+k_y^2\right)}\\&\times\left\{\left[1+\frac{(\varepsilon_1^2\lambda_e^2+\varepsilon_0^2g_1^2)\sin(\lambda_e a)e^{-2g_1 d}}{(\varepsilon_1^2\lambda_e^2-\varepsilon_0^2g_1^2)\sin(\lambda_e a)-2\varepsilon_0\varepsilon_1g_1\lambda_e\cos\lambda_e a)}\right]\right.\\&\left.-\frac{\beta^2k_y^2}{g_1^2}\left[1-\frac{(\lambda_0^2+g_1^2)\sin(\lambda_0 a)e^{-2g_1 d}}{(\lambda_0^2-g_1^2)\sin(\lambda_0 a)-2g_1\lambda_0\cos(\lambda_0 a)}\right]\right\}dk_y.\end{aligned}\quad(15)$$

Equation (15) can be integrated over k_y by using the theory of residues. In integrating (15) the first terms in the square brackets can be eliminated since they do not have poles within the path of integration and do not contribute to the energy loss. From the physical point of view these terms describe the energy lost by a charge in an infinite medium in which the Cerenkov radiation conditions are not satisfied, i.e. these terms are actually zero.

As a result of integrating (15) we obtain

$$\begin{aligned}\frac{dw}{dz}&=\frac{2q^2}{v^2}\int_{\varepsilon_1\beta^2-1<0}\frac{\omega d\omega}{\varepsilon_1}\sum_m\frac{1}{a}\left[\operatorname{sign}(\sin x_{lm})\frac{\varepsilon_0\varepsilon_1x_{em}\left[p^2(\varepsilon_e-\varepsilon_1)-\frac{\varepsilon_e}{\varepsilon_0}x_{em}^2\right]}{\left(p^2\varepsilon_e-\frac{\varepsilon_e}{\varepsilon_0}x_{em}^2\right)\Phi'_{em}}\right.\\&\times\exp\left(-\frac{2d}{a}\sqrt{p^2(\varepsilon_e-\varepsilon_1)-\frac{\varepsilon_e}{\varepsilon_0}x_{em}^2}\right)+\operatorname{sign}(\sin x_{0m})\\&\left.\times\frac{x_{0m}[p^2(\varepsilon_0\beta^2-1)-\beta^2x_{0m}^2]}{(p^2\varepsilon_0-x_{0m}^2)\Phi'_{0m}}\exp\left(-\frac{2d}{a}\sqrt{p^2(\varepsilon_0-\varepsilon_1)-x_{0m}^2}\right)\right],\end{aligned}\quad(16)$$

where x_{lm} and x_{0m} are roots of the equations

$$\operatorname{tg}x_e=\frac{2\varepsilon_0\varepsilon_1x_e\sqrt{p^2(\varepsilon_e-\varepsilon_1)-\frac{\varepsilon_e}{\varepsilon_0}x_e^2}}{x_e^2(\varepsilon_0\varepsilon_e+\varepsilon_1^2)-\varepsilon_0^2(\varepsilon_e-\varepsilon_1)p^2},\quad(17)$$

$$\operatorname{tg}x_0=\frac{2x_0\sqrt{p^2(\varepsilon_0-\varepsilon_1)-x_0^2}}{2x_0^2-p^2(\varepsilon_0-\varepsilon_1)},\quad(18)$$

and in addition the following notation is used:

$$x_e=\lambda_e a,\quad x_0=\lambda_0 a,\quad p=\frac{\omega}{c}a,\quad(19)$$

$$\Phi'_{em}=\frac{d}{dk_y}\left[(\varepsilon_1^2\lambda_e^2-\varepsilon_0^2g_1^2)\sin(\lambda_e a)-2\varepsilon_0\varepsilon_1g_1\lambda_e\cos(\lambda_e a)\right]_{x_e=x_{em}},\quad(20)$$

$$\Phi'_{0m}=\frac{d}{dk_y}\left[(\lambda_0^2-g_1^2)\sin(\lambda_0 a)-2g_1\lambda_0\cos(\lambda_0 a)\right]_{x_0=x_{0m}}.\quad(21)$$

The number of roots of Eqs. (17) and (18) depends on the frequency ω and the layer thickness a.

It is easy to see that the first term in the square brackets in (16) gives the energy loss due to the excitation of extraordinary waves in the slab, and the second term the energy loss due to ordinary waves.

It should be noted that in the limiting case of vanishing anisotropy and for $\varepsilon_1=1$, Eq. (16) agrees[1)] with Eq. (8) of ref. 3. In addition, formally writing in Eq. (16)

$$q^2=2\pi p\delta(k_y),$$

gives an expression for the energy loss of an infinite charged

filament carrying a charge density ρ which agrees with the corresponding equation of ref. 4.

The use of Fresnel coefficients also significantly simplifies the solution of transition radiation problems, as is seen, for example, in refs. 9 and 10.

In conclusion the authors thank B. M. Bolotovskii for discussion.

---

1) A factor $1/h$ is missing in Eq. (8) of ref. 3.

Estimate of the angular divergence in intense electron beams

V. S. Kuznetsov, Yu. P. Vakhrushin, O. L. Komarov, and R. P. Fidel'skaya

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 1385-1388 (July 1974)

The focusing of intense electron beams in a longitudinal magnetic field is discussed. Analytical expressions are derived for the maximum angular divergence arising from nonlinear Coulomb forces. A comparative analysis is given of the angular divergence as a function of the method used to shape the electron beam.

In many problems, for example collective acceleration,[1] a limitation is imposed on the angular divergence of the particles in an intense electron beam. An accurate determination of the value of the angular divergence involves the numerical integration of the self-consistent field equations. It is shown in ref. 2 that in the focusing of intense electron beams by longitudinal magnetic fields the angular divergence of the beam electrons is determined mainly by the effect of nonlinear Coulomb forces.

We derive below some simple equations for estimating the maximum angular divergence due to nonlinear Coulomb forces in intense beams. A comparative analysis is made of the angular divergence as a function of the method of shaping the electron beam.

We first consider the focusing of a beam in a magnetic field in which the cathode is completely shielded from the magnetic field. The equation of motion of the electrons in an intense beam focused by a longitudinal field B has the form

$$\ddot{r}=\frac{\eta I}{2\pi\varepsilon c\beta\gamma^3 r}-\frac{\eta^2 B^2}{4\gamma^2}r. \qquad (1)$$

Here, r is the radial coordinate of an electron, I is the beam current inside a cylinder of radius r, $\eta = e/m_0$ is the ratio of charge to rest mass of the electron, $\gamma = m/m_0$, and $\beta = v_z/c$ is the relative longitudinal velocity of the electrons. When the current density is not uniform over the cross section of the beam the repulsive Coulomb forces and the focusing forces of the external magnetic field are not in equilibrium for all beam particles. Numerical experiments[2] show that ordinarily the maximum angles are

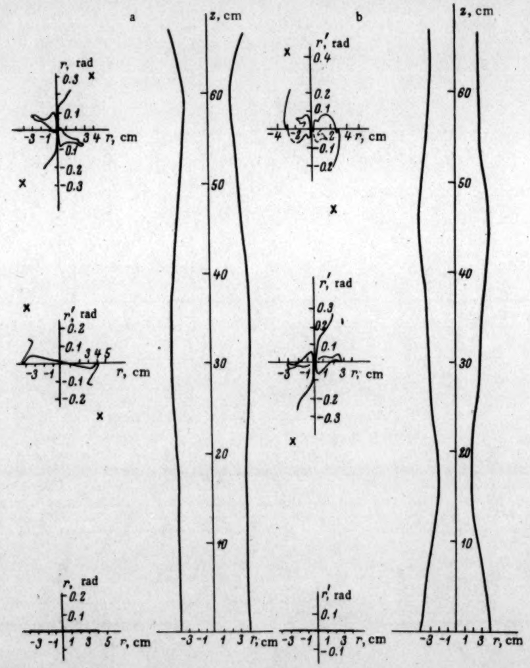

Fig. 1. A beam in a longitudinal magnetic field. $B_k = 0$, I = 5kA, W = 0.7 MeV, $r_0 = 4$ cm, B: a) $5\cdot10^{-2}$; b) $7.5\cdot10^{-2}$ Wb/m².

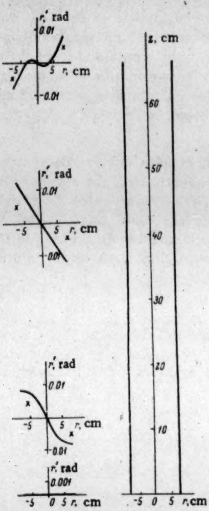

Fig. 2. A beam in a longitudinal magnetic field. $B_k = B$, $I = 10$ kA, $W = 1$ MeV, $r_0 = 7$ cm, $N = 0.73$ Wb/m².

acquired by particles which are initially at the periphery of the beam. For these particles the magnetic focusing forces are appreciably larger than the repulsive Coulomb forces. These particles cross the beam in the radial direction almost as though the beam current were zero. Thus, the maximum transverse velocities which the electrons can acquire can be obtained from Eq. (1) by setting $I = 0$:

$$\ddot{r}+\omega^2 r=0, \tag{2}$$

where

$$\omega=\frac{\eta B}{2\gamma}.$$

Using the initial conditions $r|_{t=0} = r_0$; $\dot{r}|_{t=0} = 0$ we obtain the solution of Eq. (2) in the form

$$r=r_0\cos\omega t. \tag{3}$$

From this we find an approximate equation for the maximum angular divergence of the beam particles $r_1' = \dot{r}_{max}/v_z$:

$$r_1'=\frac{\eta r_0 B}{2c\beta\gamma}. \tag{4}$$

Equation (4) essentially determines the maximum slope of the trajectory of a peripheral particle of a linear beam for zero initial divergence and zero beam current. In addition, this value determines approximately the maximum beam spread for a nonlinear distribution of Coulomb forces.

Thus the maximum angular divergence of the particles is proportional to B, or, as follows from the relation between the field and the beam current for Brillouin flow, $r_1' \sim I^{1/2}$.

The degree of reliability of (4) can be established by comparing the angular divergence calculated from (4) with numerical or experimental results. Figure 1 shows the results of a numerical solution of the equations of motion of a nonlaminar electron beam by the method described in ref. 2. The crosses show values of r_1' obtained from Eq. (4). The agreement is satisfactory.

Let us now consider the focusing of a beam when the cathode is in a magnetic field B_k.

To simplify the analysis we consider the special case $B_k = B$.

In this case the equation of motion of the electrons has the form

$$\ddot{r}=\frac{\eta I}{2\pi\varepsilon c\beta\gamma^3 r}-\frac{\eta^2 B^2}{4\gamma^2}r\left(1-\frac{r_k^4}{r^4}\right), \tag{5}$$

where r_k is the radius of the cathode.

From the condition for equilibrium between the Coulomb force and the magnetic force the equilibrium radius r_p is

$$r_p=r_k\sqrt{\frac{1}{2b^2}+\sqrt{\frac{1}{4b^4}+1}}, \tag{6}$$

where $b = B/B_B$, and B_B is the value of the Brillouin magnetic field for $r = r_k$:

$$B_B=\frac{1}{r_k}\sqrt{\frac{2I}{\pi\varepsilon\eta c\beta\gamma}}. \tag{7}$$

For values of the magnetic field $B \geq B_B$ and initial particle radii close to the equilibrium value, r is close to r_p. Therefore we take

$$r=r_p+x. \tag{8}$$

Substituting (8) into (5) we obtain the equation for x in the linear approximation:

$$\ddot{x}+\left[\frac{\eta I}{2\pi\varepsilon c\beta\gamma^3 r_p^2}+\frac{\eta^2 B^2}{\gamma^2}\left(1+3\frac{r_k^4}{r_p^4}\right)\right]x=0. \tag{9}$$

By using (7) we obtain

$$\ddot{x}+\omega^2 x=0, \tag{10}$$

where

$$\omega^2=\frac{\eta^2 B^2}{\gamma^2}\left[1-\frac{1}{4b^2}\left(\frac{r_k}{r_p}\right)^2\right].$$

The solution of Eq. (10) for the initial values $x|_{t=0} = x_0 = r_k - r_p$ and $\mathring{x}|_{t=0}$ has the form

$$x=x_0\cos\omega t. \tag{11}$$

Hence the maximum angular divergence of the beam particles $r_2' = \dot{x}_{max}/v_z$ is

$$r_2'=\frac{x_0\omega}{c\beta}. \tag{12}$$

Let us express the amplitude of the oscillations x_0 in terms of the magnetic field B. For equilibrium it follows from (5) that

$$1-\frac{r_k^4}{r_p^4}=\frac{1}{b^2}\frac{r_k^2}{r_p^2}. \tag{13}$$

Substituting into (13) $r_p = r_k - x_0$ and expanding $1/r_p^4$ in a series we obtain

$$x_0 \simeq \frac{r_k}{4b^2}. \tag{14}$$

Taking account of (7) and (14) we obtain an expression for r_2':

$$r_2' = \frac{I}{2\pi\varepsilon\,(c\beta\gamma)^2 r_k B}\sqrt{1 - \frac{1}{4b^2}\frac{r_k^2}{r_p^2}}. \tag{15}$$

When b ≫ 1 Eq. (15) becomes

$$r_2' = \frac{I}{2\pi\varepsilon\,(c\beta\gamma)^2 r_k B}. \tag{16}$$

Equation (15) can also be obtained by considering the azimuthal motion of a peripheral particle in a magnetic field. By calculating the maximum azimuthal component of the velocity of a peripheral particle it is easy to obtain Eq. (15) for r_2'.

It is clear from (16) that when $B_k \neq 0$ the maximum divergence of the beam electrons is inversely proportional to B.

The degree of reliability of Eq. (15) can be determined by comparing the values of the angular divergence found from (15) with the values obtained from the numerical solution of the equations of motion of a nonlaminar beam. Figure 2 shows the calculated results and the crosses give the values of r_2' obtained from Eq. (15). The agreement is satisfactory.

The following conclusions can be drawn. When the cathode is in a magnetic field the angular divergence of the beam decreases with increasing B, and in the absence of a magnetic field it increases [Eqs. (4) and (16)]. Therefore to decrease the angular divergence of the particles it is advantageous to place the cathode in a magnetic field.

Parametric instability of a spatially moderated electron beam in a magnetic field

N. S. Repalov and V. F. Tyrnov

(Submitted September 9, 1973; resubmitted December 10, 1973)
Zh. Tekh. Fiz., 44, 1389-1394 (July 1974)

The parametric instability of an electron beam modulated by a spatially periodic electric field and focused by a uniform magnetic field is studied. It is shown that the development of a longitudinal instability characteristic of a beam in a magnetic field broadens the range of frequencies for which parametric amplification is possible and lowers the requirements imposed on the perveance of the beam.

The instability of an electron beam arising from its spatial modulation by an external electrostatic field is studied in refs. 1-3. The theoretical model used in these paper assumes either that the electron beam is focused by a strong enough magnetic field so that the particles move strictly along the lines of force,[1-2] or that there is no magnetic field at all.[3] Under these conditions an interaction leading to the development of an instability always involves the participation of the electron plasma wave. Although the parametric instability due to the electron plasma wave is rather effective and easily controlled, there is a limitation on the frequency range because of the interaction of the waves with the beam particles. Under actual conditions, in which the electron beam is produced by emission from a hot cathode, the upper limit of the instability[4] is about 500 MHz. In addition, the conditions for parametric resonance involving plasma waves ($k_0v_0 = 2\omega_0$) are equivalent to requiring a certain perveance of the beam, and this cannot always be achieved. There are two ways to extend the range of frequencies which can be amplified by the transfer of energy from the electrostatic field to the electromagnetic wave: reducing the energy spread of the beam particles or using a different instability.

In the present paper we study a parametric instability in an electron beam involving waves associated with the magnetic field and the transverse motion of the particles. This instability is less sensitive to the thermal motion of the particles and the perveance of the beam.

Assuming that the perturbations are electrostatic we start from the kinetic equation

$$\frac{df}{\partial t}+\mathbf{v}\frac{\partial f}{\partial \mathbf{r}}+\frac{e}{m}\mathbf{E}_{\text{st}}\frac{\partial f}{\partial \mathbf{v}}-\omega_H\frac{\partial f}{\partial \theta}=\frac{e}{m}\nabla\varphi\frac{\partial F^{(0)}(\mathbf{v};\,\mathbf{r})}{\partial \mathbf{v}}, \tag{1}$$

where $\mathbf{E}_{\text{st}}$ is the stationary field, described by the potential $\varphi_{\text{st}} = \varphi_0 \cos k_0 z$, θ is the polar angle in velocity space, and ω_H is the cyclotron frequency. If all the beam particles in velocity space are far from the region of trapping by the stationary field ($|\xi| = e\varphi_0/mv_0^2 \ll 1$, where v_0 is the average velocity of the beam in the direction of the magnetic field along the z axis), the steady-state distribution function of the particles depends only on the energy integral, i.e., $[\mathbf{v}-\mathbf{v}_0(1+2\xi\cos k_0 z)^{1/2}]^2$, and, to terms of order ξ, can be written

$$F^{(0)}(\mathbf{v};\,z)=f_0(\mathbf{v})+\xi\sigma(\mathbf{v})\cos k_0 z, \tag{2}$$

where $f_0(\mathbf{v})$ and $\sigma(\mathbf{v})$ are the first coefficients in the expansion of the steady-state distribution function in the Taylor's series in ξ. Taking the Fourier transforms of Eq. (1) with respect to time and coordinates we obtain

$$\frac{a_0\xi}{\gamma}\frac{\partial f(\mathbf{k}_{-1})}{\partial v_z}+f(\mathbf{k})-\frac{a_0\xi}{\gamma}\frac{\partial f(\mathbf{k}_1)}{\partial v_z}+\frac{i\omega_H}{\gamma}\frac{\partial f(\mathbf{k})}{\partial \theta}$$

$$=\frac{e}{m}\left\{\xi\frac{\mathbf{k}_{-1}}{2\gamma}\frac{\partial\sigma}{\partial\mathbf{v}}\varphi(\mathbf{k}_{-1})-\frac{\mathbf{k}}{\gamma}\frac{\partial f_0}{\partial\mathbf{v}}\varphi(k)+\xi\frac{\mathbf{k}_1}{2\gamma}\frac{\partial\sigma}{\partial\mathbf{v}}\varphi(\mathbf{k}_1)\right\}. \tag{3}$$

In Eq. (3) $a_0 = k_0v_0^2/2$, $\gamma = \omega - \mathbf{kv}$, and $\mathbf{k}_m = \mathbf{k} + m\mathbf{k}_0$. We solve Eq. (3) by successive approximations. In the zeroth approximation ($\xi = 0$), writing all the vectors in the form $\mathbf{R} = \mathbf{e}_z R_\parallel + \mathbf{R}_\perp$, we find[5-6]

$$f(\mathbf{k})=-\frac{e\varphi(\mathbf{k})}{m\omega_H}\sum_{ll'=-\infty}^{\infty}\frac{J_l(a)J_{l'}(a)}{b-l}\left[k_\parallel\frac{\partial f_0}{\partial v_\parallel}+\frac{l\omega_H}{v_\perp}\frac{\partial f_0}{\partial v_\perp}\right]e^{i(l-l')\theta}, \tag{4}$$

where

$$b=\frac{\omega-k_\parallel v_\parallel}{|\omega_H|};\quad a=\frac{k_\perp v_\perp}{|\omega_H|};$$

and J_l is the Bessel function. Assuming that the true value of $f(\mathbf{k})$ differs from the value calculated by Eq. (4) by a small correction $f^{(1)}$ of order ξ, and substituting Eq. (4) into the terms proportional to ξ, we obtain the first-approximation equation

$$\frac{i\gamma}{\omega_H}f^{(1)}(\mathbf{k})-\frac{\partial f^{(1)}}{\partial\theta}=i\left\{\xi\left[\frac{e\mathbf{k}_{-1}}{2m\omega_H}\frac{\partial\sigma}{\partial\mathbf{v}}\varphi(\mathbf{k}_{-1})-\frac{a_0}{\omega_H}\frac{\partial f(\mathbf{k}_{-1})}{\partial v_\parallel}\right]\right.$$

$$\left.-\frac{e\mathbf{k}}{m\omega_H}\frac{\partial f_0}{\partial\mathbf{v}}\varphi(\mathbf{k})+\xi\left[\frac{e\mathbf{k}_1}{2m\omega_H}\frac{\partial\sigma}{\partial\mathbf{v}}\varphi(\mathbf{k}_1)+\frac{a_0}{\omega_H}\frac{\partial f(\mathbf{k}_1)}{\partial v_\parallel}\right]\right\}. \tag{5}$$

Solving this equation for $f^{(1)}$ and performing the angle integration of $f^{(1)}$ in velocity space we find

$$f^{(1)}(\mathbf{k};\,v_\parallel;\,v_\perp)=\frac{2\pi e}{m\omega_H}\xi\sum_{l,l',p}\left\{\frac{1}{2}\psi_l(\mathbf{k})S_l(\mathbf{k}_{-1};\,\sigma)\right.$$

$$\left.+\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\,\mathbf{k}_{-1})S_l(\mathbf{k}_1;\,f_0)\right\}\varphi(\mathbf{k}_{-1})+\frac{2\pi e}{m\omega_H}\xi\sum_{ll'p}\left\{\frac{1}{2}\psi_l(\mathbf{k})S_l(\mathbf{k}_1;\,\sigma)\right.$$

$$\left.-\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\,\mathbf{k}_1)S_l(\mathbf{k}_1;\,f_0)\right\}\varphi(\mathbf{k}_1), \tag{6}$$

where

$$\psi_l(\mathbf{k})=\frac{J_l^2(a)}{b-l};\quad S_l(\mathbf{k}_m;\,q)=k_{\parallel m}\frac{\partial q}{\partial v_\parallel}+\frac{l\omega_H}{v_\perp}\frac{\partial q}{\partial v_\perp},$$

$$\psi_{ll'p}(\mathbf{k};\,\mathbf{k}_m)=\frac{J_p(a)J_{l-l'+p}(a)}{b-(l-l'+p)}\frac{\partial}{\partial v_\parallel}\frac{J_l(a)J_{l'}(a)}{b_m-l}.$$

In our case the transverse component of the wave vector is conserved, and therefore the subscript on $k_\perp$ is omitted. Knowing the distribution function, which is the sum of the expressions in Eqs. (4) and (6), we find the Fourier component of the electron density:

$$n(\mathbf{k})=\frac{2\pi e}{m\omega_H}\xi\sum_{ll'p}\int\left\{\frac{1}{2}\psi_l(\mathbf{k})S_l(\mathbf{k}_{-1};\,\sigma)\right.$$

$$\left.+\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\,\mathbf{k}_{-1})S_l(\mathbf{k}_{-1};\,f_0)\right\}\varphi(\mathbf{k}_{-1})v_\perp dv_\perp dv_\parallel$$

$$-\frac{2\pi e}{m\omega_H}\sum_l\int\psi_l(\mathbf{k})S_l(k;\,f_0)\varphi(\mathbf{k})v_\perp dv_\perp dv_\parallel+$$

$$+\frac{2\pi e}{m\omega_H}\xi\sum_{ll'p}\int\left\{\frac{1}{2}\psi_l(\mathbf{k}_1)S_l(\mathbf{k}_1;\ \sigma)\right.$$
$$\left.-\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\ \mathbf{k}_1)S_l(\mathbf{k}_1;\ f_0)\right\}\varphi(\mathbf{k}_1)v_\perp dv_\perp dv_\parallel.$$

Substituting ... n($\mathbf{k}_{-m}$) ... n($\mathbf{k}$) ... n($\mathbf{k}_m$) ... into Poisson's equation we obtain an infinite set of equations relating the amplitudes of the interacting waves. We consider the stability of a modulated beam with respect to two waves satisfying the conservation law for wave number $\mathbf{k}_1 = \mathbf{k} + \mathbf{k}_0$ (the law of conservation of frequency is satisfied automatically), assuming that other waves are not excited. Mathematically this means that only $\varphi(\mathbf{k})$ and $\varphi(\mathbf{k}_1)$ are different from zero. The set of equations relating $\varphi(\mathbf{k})$ and $\varphi(\mathbf{k}_1)$ has the form

$$\left.\begin{aligned}&\varepsilon(\mathbf{k};\ \omega)\varphi(\mathbf{k})-\frac{8\pi^2e^2}{k^2\omega_H}\xi\sum_{ll'p}\int\left\{\frac{1}{2}\psi_l(\mathbf{k})S_l(\mathbf{k}_1;\ \sigma)\right.\\&\left.-\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\ \mathbf{k}_1)S_l(\mathbf{k}_1;\ f_0)\right\}\varphi(\mathbf{k}_1)v_\perp dv_\perp dv_\parallel=0,\\&\frac{8\pi^2e^2}{k_1^2\omega_H}\xi\sum_{ll'p}\int\left\{\frac{1}{2}\psi_l(\mathbf{k}_1)S_l(k;\ \sigma)\right.\\&\left.+\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k}_1;\ \mathbf{k})S_l(\mathbf{k};\ f_0)\right\}\varphi(\mathbf{k})v_\perp dv_\perp dv_\parallel\\&-\varepsilon(\mathbf{k}_1;\ \omega)\varphi(k_1)=0,\end{aligned}\right|\quad(7)$$

where

$$\varepsilon(\mathbf{k};\omega)=1+\frac{8\pi^2e^2}{k^2\omega_H}\sum_l\int\frac{J_l^2(a)}{b-l}\left[k_\parallel\frac{\partial f_0}{\partial v_\parallel}+\frac{l\omega_H}{v_\perp}\frac{\partial f_0}{\partial v_\perp}\right]v_\perp dv_\perp dv_\parallel.\quad(8)$$

The condition for the solvability of Eqs. (7) leads to the dispersion relation

$$\frac{64\pi^4e^4}{k^2k_1^2\omega_H^2}\xi^2\left\{\sum_{ll'p}\int\left[\frac{1}{2}\psi_l(\mathbf{k})S_l(\mathbf{k}_1;\ \sigma)\right.\right.$$
$$\left.\left.-\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k};\ \mathbf{k}_1)S_l(\mathbf{k}_1;\ f_0)\right]v_\perp dv_\perp dv_\parallel\right\}$$
$$\times\left\{\sum_{ll'p}\int\left[\frac{1}{2}\psi_l(\mathbf{k}_1)S_l(\mathbf{k};\ \sigma)+\frac{a_0}{\omega_H}\psi_{ll'p}(\mathbf{k}_1;\ \mathbf{k})S_l(\mathbf{k};\ f_0)\right]v_\perp dv_\perp dv_\parallel\right\}$$
$$=\varepsilon(\mathbf{k})\varepsilon(\mathbf{k}_1).\quad(9)$$

Equation (9) contains an arbitrary steady-state distribution function. The simplest distribution function which can be used to describe effects related to transverse motion in an electron beam in an external magnetic field is[7]

$$f_0=\frac{n_0}{2\pi v_{0\perp}}\delta(v_\perp-v_{0\perp})\delta(v_\parallel-v_0).\quad(10)$$

It is easy to show that

$$\sigma=-\frac{n_0v_0^2}{2\pi v_{0\perp}v_\parallel}\delta(v_\perp-v_{0\perp})\frac{d}{dv_\parallel}\delta(v_\parallel-v_0).\quad(11)$$

Substituting (10) into the expression for ε we obtain

$$\varepsilon(\mathbf{k};\ \omega)=1-\frac{\omega_0^2}{k^2\omega_H^2}\sum_l\left\{\frac{k_\parallel^2J_l^2(a)}{(b-l)^2}+\frac{k_\perp^2\,[J_{l-1}^2(a)-J_{l+1}^2(a)]}{2(b-l)}\right\},$$

and the zero-order dispersion relation ($\xi = 0$) takes the form $\varepsilon(\mathbf{k};\ \omega) = 0$. This equation cannot be solved in analytic form. The case $k_\parallel \gg k_\perp$ is the simplest to investigate. In this case the zero-order dispersion relation is simplified close to its root:

$$1-\frac{\omega_0^2J_l^2(a)}{(\omega-k_\parallel v_0-l\omega_H)^2}=0.$$

Solving this equation for $k_\parallel$ we find

$$k_\parallel^l=\frac{\omega-l\omega_H-\omega_0J_l(a)}{v_0};\ k_{\parallel 1}^l=\frac{\omega-l\omega_H+\omega_0J_l(a)}{v_0}.\quad(12)$$

Since $\omega_H \gg \omega_0$ it is clear from Eq. (12) that the relative phase velocities of the waves ($|v_\varphi - v_0|$) for $l \neq 0$ is much larger than the relative phase velocities of the plasma waves. The boundary for parametric complication is found by setting the relative phase velocity of the wave equal to the thermal velocity of the beam particles. When this equality is satisfied the particles interact effectively with the electric field of the wave, and the parametric instability is suppressed.[3] Consequently, use of an instability associated with a longitudinal wave in a magnetic field extends to the frequency range for parametric amplification.

Conservation of wave number, the condition for parametric resonance, can be ensured by the choice of the distance between the branches of the dispersion diagram corresponding to the same l and different l, say l and l'. We consider these two possibilities separately.

In the first case the resonance condition has the form $k_0v_0 = 2\omega_0J_l(a)$. In evaluating the left-hand side of Eq. (9) we retain only those terms which contain the resonance denominator $b \approx l$. By using the resonance condition, the identity $\sum_p J_p^2(a) = 1$, and the inequality $k_\parallel \gg k_\perp$ it is easy to write Eq. (9) in the form

$$\varepsilon(\mathbf{k})\varepsilon(\mathbf{k}_1)=\frac{9}{4}\xi^2.\quad(13)$$

Let ω be the frequency of excitable waves in the absence of modulation. We seek the solution of Eq. (13) in the form $\omega + i\gamma_l$, where $\gamma_l \ll \omega$. Then when the resonance condition is satisfied exactly we obtain the parametric instability growth rate γ_l:

$$\gamma_l=\frac{3}{4}\xi\omega_0J_l(a).$$

It is clear that γ_l decreases rapidly with increasing l and oscillates for a monotonic change in the parameter a. The value of a corresponding to optimum amplification is given by the first root of the equation $J'_l(a) = 0$. It is also clear that in this case a broad amplification band imposes rigid requirements on the perveance of the beam.

We turn to the investigation of the second case $l \neq l'$. These instabilities are ensured by satisfying the conservation laws

$$k_\parallel^l+k_0=k_\parallel^{l'}\text{ and }k_\parallel^l+k_0=k_{\parallel 1}^{l'}.\quad(14)$$

The corresponding resonance conditions are

$$k_0v_0=(l-l')\omega_H+\omega_0[J_l(a)-J_{l'}(a)],\quad(14a)$$

$$k_0v_0=(l-l')\omega_H+\omega_0[J_l(a)+J_{l'}(a)].\quad(14b)$$

Since $l \neq l'$, $(l - l')\omega_H \gg \omega_0J_l(a)$. Hence it follows that the resonance conditions (14) are weakly dependent on the plasma frequency and, consequently, on the perveance of the beam. This condition permits the use of low-perveance beams.

Using the latter inequality and assuming, as before, that $k_\parallel \gg k_\perp$ and $b \approx l$, Eq. (9) determining the growth rate of the instability when resonance condition (14a) is satisfied can easily be put in the simple form

$$\varepsilon(k^{l})\,\varepsilon(k^{l'})=\frac{\xi^2}{4}\left[1-\frac{\omega-l'\omega_H}{(l-l')\,\omega_H}\right]\left[1+\frac{\omega-l\omega_H}{(l-l')\,\omega_H}\right]. \qquad (15)$$

Solving Eq. (15) in the same way as Eq. (13) we obtain the frequency correction

$$\Upsilon_{ll'}=\frac{\xi}{2}\left\{\left[1-\frac{\omega-l'\omega_H}{(l-l')\,\omega_H}\right]\left[1+\frac{\omega-l\omega_H}{(l-l')\,\omega_H}\right]\left(\frac{\partial\varepsilon(k^{l})}{\partial\omega}\,\frac{\partial\varepsilon(k^{l'})}{\partial\omega}\right)^{-1}\right\}^{1/2}.$$

Since

$$\left.\frac{\partial\varepsilon}{\partial\omega}\right|_{k=k^{l}}\left.\frac{\partial\varepsilon}{\partial\omega}\right|_{k=k^{l'}}=\frac{4}{\omega_0^2 J_l(a)\,J_{l'}(a)},$$

we obtain

$$\Upsilon_{ll'}=\frac{\xi\omega_0}{4}\left\{\left[1-\frac{\omega-l'\omega_H}{(l-l')\,\omega_H}\right]\left[1-\frac{\omega-l\omega_H}{(l-l')\,\omega_H}\right]\right\}^{1/2}\sqrt{J_l(a)\,J_{l'}(a)}. \qquad (16)$$

This expression can be either real or imaginary. In the latter case there is an instability. The expression in curly brackets is positive if the frequency ω satisfies the inequalities

$$l'\omega_H<\omega<l\omega_H, \qquad (17)$$

and the product of the Bessel functions is positive if the value lies between the n-th roots of the Bessel functions of order l and l', which we denote by $\varkappa_n^{l}$ and $\varkappa_n^{l'}$:

$$\varkappa_n^{l'}<a<\varkappa_n^{l}. \qquad (18)$$

The simultaneous satisfaction or violation of inequalities (17) and (18) determines the regimes under which the electron beam is stable. If only one of the indicated inequalities is violated, a parametric instability develops with a growth rate given by Eq. (16).

If resonance condition (14b) is satisfied the product of the derivatives of the permittivity with respect to frequency changes sign. The expression for the growth rate remains the same (16) but the simultaneous satisfaction or violation of (17) and (18) now determines the instability modes of the beam.

Although we have used a model distribution function, it is adequate to describe the physical processes occurring in a plasma in a magnetic field[7] if the relative phase velocities of the excited waves differ appreciably from the thermal velocity of the particles. Taking account of the finite width of the distribution function must lead to a threshold for the parametric instability[3] due to the resonance interaction of beam particles with the electric field of the excited waves.

Thus it has been shown that a parametric instability can be excited which is associated with plasma modes in a magnetic field. This result relaxes many of the rigid limitations characteristic of a parametric instability based on electron plasma waves: The range of useful frequencies is broadened, and the requirements imposed on the perveance of the beam are significantly reduced. The development of a parametric instability leads to the formation of intense charge density waves which may have many important practical applications such as the generation and amplification of microwaves and the collective acceleration of heavy ions.

Magnetohydrodynamic channel flow in a tapered magnetic field

S. A. Regirer

Institute of Mechanics, M. V. Lomonosov Moscow State University

(Submitted September 12, 1973)
Zh. Tekh. Fiz., 44, 1395-1400 (July 1974)

Fully developed flows of a viscous incompressible isotropically conducting fluid are investigated in a rectangular channel in the presence of a transverse magnetic field $\mathbf{B} = (B_0/a)(-\mathbf{e}_y y + \mathbf{e}_z z)$. An exact solution of the problem is obtained in general form and for the limiting case corresponding to a flow in a plane slit. It is shown that at high Hartmann numbers a region of elevated velocities can form near the axis of the channel. In this regard, a flow in a plane slit exhibits a paradox: The reason is that the limiting case "carries" the region with an infinitely large emf to infinity; in the region considered the flow acts as a pump. In conclusion, some other flows in inhomogeneous fields with tapered geometry are considered.

1. Developed flows of a conducting fluid in channels have been studied in great detail,[1] and the possibilities of obtaining new exact analytic solutions are extremely limited. The possibilities exist nevertheless and it is possible, as will be shown below, to find even simple new solutions which have fairly interesting qualitative properties as well.

Let a plane slit bounded by infinite nonconducting planes $z = \pm a$ (Fig. 1) contain a totally developed flow of an incompressible viscous conducting fluid with constant and isotropic properties; the flow velocity **v** is coplanar with the boundaries and depends only on z: $\mathbf{v} = [u(z), v(z), 0]$. The external (independent of motion) magnetic field is

$$\mathbf{B}^e = \left(0, -\frac{B_0 y}{a}, \frac{B_0 z}{a}\right), \tag{1}$$

where $B_0 = \text{const}$. For the geometry of the induced magnetic field we take the same hypotheses used for the velocity, setting $\mathbf{B}^i = [b(z), b_1(z), 0]$. Thus, the total field is

$$\mathbf{B} = \left(b(z), b_1(z) - \frac{B_0 y}{a}, \frac{B_0 z}{a}\right). \tag{2}$$

Finally, we assume that the effective pressure $p^* = p + B^2/8\pi$ depends on all three coordinates

$$p^* = \frac{B_0^2}{8\pi a^2}(y^2 + z^2) - Px - P_1 y + \text{const},$$

where P and P_1 are constants either given or dependent on given flow rates Q and Q_1 in the x and y directions, respectively.

Considering the general equations of magnetohydrodynamics, we can easily be convinced that the above assumptions are not contradictory[1)] and lead to the following boundary problem in u, v, b, and b_1:

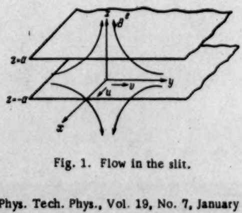

Fig. 1. Flow in the slit.

$$\left.\begin{aligned} &\mu v'' + \frac{B_0 z}{4\pi a} b_1' - \frac{B_0}{4\pi a} b_1 + P_1 = 0, \\ &\frac{B_0 z}{a} v' + \nu_m b_1'' = -\frac{B_0}{a} v, \ v(\pm a) = 0, \ b_1(\pm a) = 0; \end{aligned}\right\} \tag{3}$$

$$\left.\begin{aligned} &\mu u'' + \frac{B_0 z}{4\pi a} b' + P = 0, \\ &\frac{B_0 z}{a} u' + \nu_m b'' = 0, \ u(\pm a) = 0, \ b(\pm a) = 0. \end{aligned}\right\} \tag{4}$$

Obviously, flows in the x and y directions are hydrodynamically independent. The flow along the y axis is governed by Eq. (3) and was analyzed in ref. 1. It is a plane analog of an axially symmetric flow in a tube of radius *a* for $\mathbf{v} = u(r)\mathbf{e}_x$ and

$$\mathbf{B}^e = \frac{B_0 r}{a}\mathbf{e}_r - \frac{2B_0 x}{a}\mathbf{e}_x. \tag{5}$$

This axially symmetric problem was first solved by S. I. Pai prior to the renewed interest in magnetohydrodynamics;[2] the solution was derived twice later.[3,4]

Problem (4), which describes the flow along the x axis, i.e., parallel to the zero magnetic field line, is studied below.

2. We now consider the dimensionless variables, choosing as the length, velocity, and induced field scales the quantities

$$l_* = a, \ u_* = \frac{Pa^2}{\mu}, \ b_* = \frac{4\pi P a^2}{c}\sqrt{\frac{\sigma}{\mu}}, \tag{6}$$

and introducing the Hartmann number $H = (B_0 a/c)\sqrt{\sigma/\mu}$. Then, from (4)

$$\left.\begin{aligned} &u'' + Hzb' = -1, \ b'' + Hzu' = 0, \\ &u(\pm 1) = 0, \ b(\pm 1) = 0, \end{aligned}\right\} \tag{7}$$

or, in symmetric variables,

$$\left.\begin{aligned} &w_1'' + Hzw_1' = -1, \ w_2'' - Hzw_2' = -1, \\ &w_1(\pm 1) = 0, \ w_2(\pm 1) = 0, \end{aligned}\right\} \tag{8}$$

where

$$w_1 = u + b, \ w_2 = u - b. \tag{9}$$

The solution of the problem is symmetric in u, b, and w_i – even functions of z. From (8) we find

$$w_1=\int_z^1 e^{-\frac{Ht^2}{2}}\int_0^t e^{\frac{Hs^2}{2}}ds\,dt,\quad w_2=\int_z^1 e^{\frac{Ht^2}{2}}\int_0^t e^{-\frac{Hs^2}{2}}ds\,dt. \tag{10}$$

Then, the velocity and the dimensionless y component of the current density $j_y = 1/2(w_1-w_2)'$ are

$$u=\int_z^1\int_0^t \operatorname{ch}\frac{H}{2}(t^2-s^2)\,ds\,dt,\quad j_y=\int_0^z \operatorname{sh}\frac{H}{2}(z^2-s^2)\,ds. \tag{11}$$

The total current across the system is zero, and the flow rate (per unit width of the channel in the y direction) is

$$Q=\frac{1}{H}\int_0^1 \operatorname{sh}\frac{H}{2}(1-s^2)\,ds. \tag{12}$$

When H ≫ 1 we find from (11) and (12)

$$u(0)\sim\sqrt{\frac{\pi}{8H^3}}\,e^{\frac{H}{2}},\quad Q\sim\sqrt{\frac{\pi}{8H^3}}\,e^{\frac{H}{2}}. \tag{13}$$

Equations (11) - (13) lead to conclusions directly opposite to those that are well known for Hartmann and similar-type flows: a) for $z > 0$ ($z < 0$) the current j_y has a positive (negative) direction, i.e., everywhere the opposite electromotive force $(\mathbf{v}\times\mathbf{B})_y$; b) the Lorentz force is everywhere in the same direction as the velocity, i.e., it accelerates rather than retards the stream; c) the current, the Lorentz force, and the velocity increase exponentially everywhere with increasing Hartmann number H.

3. The proposed explanation for these paradoxical facts is the following. Consider a channel of finite, but greatly extended, rectangular cross section (Fig. 2) with insulated walls $y = \pm h$, $z = \pm 1$, $h \gg 1$. Near the remote walls $y = \pm h$ the dimensional emf is of the order of $h(B_0u/c)$ and is h times greater than in the middle of the channel. One can expect, therefore, that the emf in the distant lateral regions determines the direction of the current in the middle part, i.e., the distant regions operate as generators, and the middle section acts as a pump fed by the voltage from the "generator section." For increasing Hartmann number in a certain range (probably broadened with increasing h), the work of the "pump section" intensifies. The solution constructed above corresponds to the case h → ∞ for a fixed H, and describes the "pump section" with a voltage source at infinity.

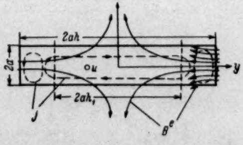

Fig. 2. Pattern of currents in a transverse channel cross section. $|y| < ah_1$ is the "pump" section, $ah_1 < |y| < ah$ is the "generator" section. In the $|y| = ah_1$ cross sections, roughly $j_z = 0$ and $E_z = -uB_y/c$ (all quantities are dimensional).

The equations for a fully developed flow in a rectangular channel with insulated walls have the form, in the variables of Sec. 2,

$$\left.\begin{aligned}&\Delta w_{1,2}\pm H\left(-y\frac{\partial w_{1,2}}{\partial y}+z\frac{\partial w_{1,2}}{\partial z}\right)=-1,\\ &w_{1,2}=0\ \text{when}\ \begin{cases}y=\pm h, & |z|\leqslant 1,\\ |y|\leqslant h, & z=\pm 1.\end{cases}\end{aligned}\right\} \tag{14}$$

Assume that in the region $|y| < h_1 < h$ (Fig. 2) the solution of this problem varies slowly with y; this requires that $\partial w_{1,2}/\partial y$, $\partial u/\partial y$, $j_z \sim \partial b/\partial y$ be close to zero for $|y| = h_1$. On a purely theoretical basis, this condition can probably be obtained by decreasing the viscosity and by arranging the electric field $E_z \approx uB_y/c$ in the region $|y| \approx h_1$. For a "pump section" $|y| < h_1$ this field is the external field. Since here $E_z(-h_1, z) = -E_z(h_1, z)$ an external potential difference appears between the points $(-h_1, z)$ and (h_1, z).

Partial confirmation of these considerations is obtained from an analysis of the exact solution of problem (14), which is constructed in the following manner.

Let $V_n(z, q)$ and $\gamma_n = \gamma_n(q)$ be eigenelements of the Sturm–Liouville equation

$$\frac{d}{dz}e^{\frac{qz^2}{2}}\frac{dV}{dz}+\gamma e^{\frac{qz^2}{2}}V=0,\quad V(\pm1)=0. \tag{15}$$

The normalized eigenfunctions V_n are expressed in terms of the Whittaker function

$$V_n=\frac{1}{a_n\sqrt{z}}\,e^{-\frac{qz^2}{4}}M_{k_n,-\frac{1}{4}}\left(\frac{qz^2}{2}\right),$$
$$a_n(q)=\left[\int_{-1}^{1}\frac{1}{z}M^2_{k_n,-\frac{1}{4}}\left(\frac{qz^2}{2}\right)dz\right]^{1/2},$$

where $k_n = k_n(q)$ are successive roots of $M_{k,-1/4}(q/2) = 0$. The eigenvalues γ_n are related to k_n by $\gamma_n = 2qk_n$. Changing in (15) to the variable $U = V\exp(qz^2/4)$ it is easy to show that $\gamma_n > q/2$ and thus $k_n > 1/4$ for $q > 0$. One can also show that $k_1 \to 1/4$ as $q \to \infty$. The following equations hold:

$$\int_{-1}^{1}e^{\frac{qz^2}{2}}V_k(z,q)\,V_l(z,q)\,dz=\delta_{kl},$$

$$a_n(-q)=a_n(q),\quad \gamma_n(-q)=\gamma_n(q),\quad k_n(-q)=-k_n(q),$$
$$e^{-\frac{qz^2}{4}}V_n(z,-q)=e^{\frac{qz^2}{4}}V_n(z,q).$$

The solutions of problem (14) can be represented in the form of expansions

$$w_1=\sum_{n=1}^{\infty}w_{1n}(y)\,V_n(z,H),\quad w_2=\sum_{n=1}^{\infty}w_{2n}(y)\,V_n(z,-H). \tag{16}$$

The coefficients

$$w_{in}(y)=\int_{-1}^{1}w_i e^{\pm\frac{Hz^2}{2}}V_n(z,\pm H)\,dz\quad (i=1,\ 2),$$

indicate direct calculations and are also expressed in terms of the Whittaker function

$$w_{in}=\frac{\alpha_{in}}{\gamma_n(H)}\left[1-\sqrt{\frac{h}{y}}\,e^{\pm\frac{H}{4}(y^2-h^2)}M_{s_n,-\frac{1}{4}}\left(\frac{Hy^2}{2}\right)M^{-1}_{s_n,-\frac{1}{4}}\left(\frac{Hh^2}{2}\right)\right]. \quad (17)$$

Here,

$$\alpha_{in}=\int_{-1}^{1}e^{\pm\frac{Hz^2}{2}}V_n(z,\ \pm H)\,dz,\ \ s_n(H)=-\frac{\gamma_n(H)}{2H}=-k_n(H).$$

Equations (16) and (17) give a formal solution to problem (14). We note that it is not difficult to write another expansion, equivalent to that given, in eigenfunctions dependent on y and with coefficients dependent on z. Therefore, conclusions unrelated to h as to the behavior of the solution for one coordinate are also valid for the other coordinate.

The solution of problem (8) can also be represented in the form of expansions in V_n; it is easy show that they are

$$w_i=\sum_{n=1}^{\infty}\frac{\alpha_{in}}{\gamma_n}V_n(z,\ \pm H). \quad (18)$$

For large $h(Hh^2 \gg 1)$

$$M_{s_n,-\frac{1}{4}}\left(\frac{Hh^2}{2}\right)\sim\frac{\Gamma\left(\frac{1}{2}\right)}{\Gamma\left(\frac{1}{4}+k_n\right)}e^{\frac{Hh^2}{4}}\left(\frac{Hh^2}{2}\right)^{k_n},$$

and thus

$$w_{in}\sim\frac{\alpha_{in}}{\gamma_n}\left[1-\frac{1}{\sqrt{y}}\frac{\Gamma\left(\frac{1}{4}+k_n\right)}{\Gamma\left(\frac{1}{2}\right)}e^{\frac{H}{4}(\pm y^2-h^2\pm h^2)}\right.$$

$$\left.\times\left(\frac{H}{2}\right)^{-k_n}h^{\frac{1}{2}-2k_n}M_{s_n,-\frac{1}{4}}\left(\frac{Hy^2}{2}\right)\right].$$

Since α_{in}, γ_n, S_n are independent of h and $k_n > 1/4$, then as $h \to \infty$, and H = const, y = const ≠ 0,

$$w_{in}\to\frac{\alpha_{in}}{\gamma_n}. \quad (19)$$

This ratio is valid for y = 0 also, since

$$M_{s_n,-\frac{1}{4}}\left(\frac{Hy^2}{2}\right)\sim\left(\frac{Hy^2}{2}\right)^{1/4}\ \ \text{as}\ \ y\to 0.$$

However, the larger H is, the closer k_1 comes to 1/4 and, thus, the larger h must be for some $w_{in} \approx \alpha_{in}\gamma_n^{-1}$ in a certain range $|y| \ll h$. The size of this range obviously decreases with an increasing Hartmann number, since for it

$$\left(\frac{y}{h}\right)^{2k_1-\frac{1}{2}}\ll 1.$$

Thus, the limiting case $h \to \infty$, as can be seen by comparing (18) to (16) and (19), actually leads to the solution in Sec. 2, which is independent of y.

This solution is a satisfactory approximation of the exact solution with $h \gg 1$ only for a certain range $|y| \ll h$ whose size decreases with an increasing Hartmann number, only if h does not increase fast enough with H.

A rigorous investigation of the asymptotic behavior of the solution of (16) and (17) for fixed h and $H \to \infty$ represents a fairly difficult task since a termwise analysis of the series does not produce the desired result and evidently indicates only the existence of a difference in asymptotic behavior for the wall boundary layers, for free boundary layers[2)] along the y = 0 and z = 0 lines, for the region near the zero point y = 0, z = 0, and finally for four cores of the flow.

4. The distribution of the external magnetic field expressed by Eq. (1) is a particular case of the more general solution of Maxwell's equations

$$\mathbf{B}^e=\left(0,\ -B_0\frac{r^n}{a^n}\sin n\vartheta,\ B_0\frac{r^n}{a^n}\cos n\vartheta\right) \quad (20)$$

for n = 1. When n = 0, we obtain a homogeneous field $\mathbf{B}^e = (0, 0, B_0)$. If, as proposed by Yakubenko,[5] we introduce new independent variables ζ and η related to $\mathbf{B}^e$ by $\mathbf{B}^e = \nabla\zeta$ and $\mathbf{B}^e = \mathbf{e}_x\cdot\nabla\eta$ then the r = const and ϑ = const lines in the plane (y, z) will correspond to the arcs of the circles and the radii in the plane (ζ, η). This allows the solution for the problem of the flow in a circular tube for the field (20) with arbitrary n to be written comparatively simply as a series, by analogy[3)] with the solutions of Uflyand and Yakubenko.[5,6]

An exact solution can also be obtained for the problem of the flow in an annular tube in the presence of an external magnetic field of type (20) with positive or negative integers n. For n = −1 the solution is well known (an annular tube with a purely radial magnetic field).

We note in conclusion that the Pai problem[2] for a circular pipe mentioned at the beginning of this paper admits several generalizations when the solution is found in finite form, or reduces to integration of ordinary differential equations. In particular, if the magnetic field has the form (5) and the stream becomes helical due to the longitudinal current J, then

$$\left.\begin{array}{c}\mathbf{v}=(0,\ v_\vartheta(r),\ v_x(r)),\quad \mathbf{B}=\mathbf{B}^e+\mathbf{B}^i,\\ \mathbf{B}^i=(0,\ b_\vartheta(r),\ b_x(r)),\quad \mathbf{j}=(0,\ j_\vartheta(r),\ j_x(r)),\\ p=p\,(r,\ x).\end{array}\right\} \quad (21)$$

Cylindrical coordinates and dimensional variables are used above. Omitting the calculations, we show that the problems in which v_x, b_x, j_ϑ and v_ϑ are to be found are separate; the first term has been solved in ref. 2 and the solution of the second has the form

$$v_\vartheta=\frac{Jr}{2\pi a^2\theta\sqrt{\sigma\mu}}\int_{\rho}^{1}\frac{1}{t}I_1\left(\frac{Ht^2}{2}\right)dt,$$

$$b_\vartheta=\frac{2J}{r}\left[1-\frac{1}{\theta}\int_{\rho}^{1}tI_0\left(\frac{Ht^2}{2}\right)dt\right],\ \ j_x=\frac{J}{2\pi a^2\theta}I_0\left(\frac{H\rho^2}{2}\right),$$

$$\theta=\int_{0}^{1}tI_0\left(\frac{Ht^2}{2}\right)dt,\ \ \rho=\frac{r}{a},$$

where a is the tube radius. It is interesting that the electric current has a cross-sectional distribution that is essentially nonuniform by comparison to the case of the absence of a magnetic field or a rigid conductor $(\mu \to \infty)$. With an increasing Hartmann number the current tends to concentrate near the axis of the tube.

If we consider anisotropic conductivity (Hall effect), then the solution retains the structure of (21), but the longitudinal and rotational motions are interrelated. The problem again reduces to ordinary linear equations, but the solution cannot be obtained in closed form.

---

1) The considerations on which they are based are closely related to the conditions for the existence of fully developed flows.[1]

2) Proof of the existence of these layers and some estimates of them are given by Todd, to whom the author is indebted for making available the results of his unpublished work.

3) This transformation was also proposed by Todd,[7] who used it for the case $n \geq 1$ and $H \gg 1$ to obtain a direct estimate of the asymptotic behavior of a flow in a channel of arbitrary cross section having roughly the same characteristic dimensions along the y and z axes (see the second footnote).

Nonstationary magnetohydrodynamic flow and wave propagation

M. Ya. Antimirov and Yu. Ya. Boguslavskii

(Submitted July 16, 1973; resubmitted November 19, 1973)
Zh. Tekh. Fiz., 44, 1401-1404 (July 1974)

It is well known that propagation of waves in an absorbing medium is accompanied by a unidirectional motion of this medium – a flow that arises because the wave loses momentum as well as energy. In accordance with momentum conservation these losses are compensated by the flow. The present paper considers a system of equations describing nonstationary flow in a conducting medium in a magnetic field. The nonstationary solutions obtained relax after a time to the steady state. It is shown that the transition to the steady state depends on the Hartmann number and that it can be oscillatory or monotonic.

The motion of a conducting fluid in a magnetic field is described by the magnetohydrodynamic equations[1]

$$\left.\begin{array}{c}\operatorname{div}\mathbf{H}=0,\\ \frac{\partial\rho}{\partial t}+\operatorname{div}\rho\mathbf{V}=0,\\ \frac{\partial\mathbf{H}}{\partial t}=\operatorname{curl}(\mathbf{V}\times\mathbf{H})+\frac{c^2}{4\pi\sigma}\Delta\mathbf{H},\\ \frac{\partial\mathbf{V}}{\partial t}+(\mathbf{V}\nabla)\mathbf{V}=-\frac{\nabla P}{\rho}-\frac{1}{4\pi\rho}\mathbf{H}\times\operatorname{curl}\mathbf{H}\\ +\frac{\eta}{\rho}\Delta\mathbf{V}+\frac{1}{\rho}\left(\xi+\frac{\eta}{3}\right)\operatorname{grad}\operatorname{div}\mathbf{V},\\ P=P(\rho,\ T),\\ \rho T\left(\frac{\partial S}{\partial t}+\mathbf{V}\nabla S\right)=\sigma'_{ik}\frac{\partial V_i}{\partial x_k}\\ +\operatorname{div}(\varkappa\nabla T)+\frac{c^2}{16\pi^2\sigma}(\operatorname{curl}\mathbf{H})^2\end{array}\right\} \quad (1)$$

where V is the velocity, ρ is the fluid density, η and ξ are two viscosity coefficients of the fluid, P is the pressure, H is the magnetic field, T_1 is the temperature, σ'_{ik} is the viscous stress tensor,[1] σ is the conductivity of the fluid, and c is the speed of light. We consider an infinite plane layer of thickness $2a$ bounded by plane solid walls and filled with a conducting fluid. A beam of waves of width 2b propagates along the axis of the layer. The ends of the layer are filled with films that are transparent to the waves. An external perpendicular magnetic field H_0 is applied to the planes that bound the layer. The flow generated in the system is to be determined.

We consider a wave of the form

$$v=v_0\cos(\omega t-\mathbf{kx})e^{-\alpha x}, \quad (2)$$

where v_0 is the velocity, ω is the frequency, k is the wave vector, and α is the absorption coefficient (see ref. 2). The value of α is assumed to be small $\alpha L \ll 1$ where L is the length of the layer.

A system of equations for a nonstationary magnetohydrodynamic flow can be obtained, as in ref. 2, by considering system (1) in the second approximation, taking expressions of type (2) for the magnetohydrodynamic waves as the first approximation. In the present case, in contrast to ref. 2, it is necessary to average the equations obtained over a time interval larger than $T=2\pi/\omega$ but much smaller than the time for generating the flow.

We are interested in the flow generated by wave absorption only in the middle section of the layer; end effects are neglected.

We assume further that the velocity of the flow U is everywhere in the direction of the x axis and depends only on the y coordinate in the direction perpendicular to the planes.

Then, the continuity equation is satisfied automatically, and the problem reduces to integration of the following system of equations:

$$\left.\begin{array}{c}D\frac{\partial^2 h}{\partial y^2}+H_0\frac{\partial U}{\partial y}=\frac{\partial h}{\partial t},\\ \nu\frac{\partial^2 U}{\partial y^2}+\frac{H_0}{4\pi\rho}\frac{\partial h}{\partial y}+C(t)=\frac{\partial U}{\partial t}-F\end{array}\right\} \quad (3)$$

with the boundary condition and initial conditions

$$\left.\begin{array}{c}h|_{y=0}=\left.\frac{\partial U}{\partial y}\right|_{y=0}=h|_{y=a}=U|_{y=a}=0,\\ h|_{t=0}=U|_{t=0}=0.\end{array}\right\} \quad (4)$$

The condition that the total flow of the fluid be zero over the cross section of the layer must be satisfied:

$$\int_0^a U dy=0. \quad (5)$$

In system (3), $F=\alpha(v_0^2/2)\theta(b-y)$ is the force that generates the flow

$$\theta(b-y)=\begin{cases}1\,\text{when}\,0\leqslant|y|\leqslant b,\\ 0\,\text{when}\,b<|y|\leqslant a,\end{cases}$$

$C(t)=(-1/\rho_0)(\partial P/\partial x)$ is an unknown pressure gradient, and h is the magnetic field induced by the flow.

When y = 0, condition (4) applies because U(y, t) is even and h (y, t) is odd in the range $-a\leq y\leq a$.

The solution of the problem (3)-(5) is obtained by using the Laplace transform:

$$U(\bar{y},t)=U_e(\bar{y})+\sum_{n=1}^{\infty}\frac{D\varphi_1(p_n)}{aH_0\varphi_2'(p_n)}\left\{(k_{1n}-\mu k_{2n})\frac{\operatorname{ch}k_{1n}-\operatorname{ch}k_{1n}\bar{y}}{\operatorname{sh}k_{1n}}\right.$$
$$\left.-(k_{2n}-\mu k_{1n})\frac{\operatorname{ch}k_{2n}-\operatorname{ch}k_{2n}\bar{y}}{\operatorname{sh}k_{2n}}\right\}e^{p_n t}, \quad (6)$$

$$h(\bar{y},\ t)=h_e(\bar{y})+\sum_{n=1}^{\infty}\frac{\varphi_1(p_n)}{\varphi_2'(p_n)}\left(\frac{\operatorname{sh}k_{1n}\bar{y}}{\operatorname{sh}k_{1n}}-\frac{\operatorname{sh}k_{2n}\bar{y}}{\operatorname{sh}k_{2n}}\right)e^{p_n t},$$

$$C(t)=\frac{\alpha}{2}v_0^2a_1+\sum_{n=1}^{\infty}\frac{\alpha D}{a^3H_0}\frac{\varphi_1(p_n)}{\varphi_2'(p_n)}$$
$$\times\sqrt{(\mu+1)^2\frac{a^2p_n}{a}+H_a^2}\sqrt{(\mu-1)^2\frac{a^2p_n}{a}+H_a^2}e^{p_n t},$$

where[1]

$$U_e(\bar{y})=\begin{cases}\frac{\alpha v_0^2a^2}{2\alpha H_a^2}\left\{a_1+1-\frac{1}{\operatorname{ch}H_a}\left(a_1+\operatorname{ch}\left(1-\frac{b}{a}\right)H_a\right]\operatorname{ch}H_a\bar{y}\right\}\\ \qquad\text{when }0<\bar{y}<\frac{b}{a},\\ \frac{\alpha v_0^2a^2}{2\lambda H_a^2\operatorname{ch}H_a}\left\{a_1[\operatorname{ch}H_a-\operatorname{ch}H_a\bar{y}]+\operatorname{sh}\frac{b}{a}H_a\operatorname{ch}H_a(1-\bar{y})\right\}\\ \qquad\text{when }\frac{b}{a}<\bar{y}<1,\end{cases} \quad (7)$$

$$h_e(\bar{y}) = \left\{ \begin{array}{c} \frac{\alpha a^2 v_0^2 H_0}{2\nu D H_a^2} \left\{ \left[a_2 + \frac{a \operatorname{sh}\left(1-\frac{b}{a}\right) H_a}{H_a} \right] \frac{\operatorname{sh} H_a \bar{y}}{\operatorname{sh} H_a} \right. \\ \left. -(1+a_1) a \bar{y} \right\} \\ \text{when } 0 < \bar{y} < \frac{b}{a}, \\ \frac{\alpha v_0^2 a^2 H_0}{2\nu D H_a^2} \left\{ \frac{a_2 H_a \operatorname{sh} H_a \bar{y} + a \operatorname{sh} H_a \frac{b}{a} \operatorname{sh} H_a (1-\bar{y})}{H_a \operatorname{sh} H_a} \right. \\ \left. -(a a_1 \bar{y} + b) \right\} \\ \text{when } \frac{b}{a} < \bar{y} < 1, \end{array} \right\} \qquad (8)$$

$$\phi_1(p_n) = \alpha \frac{v_0^2 a H_0}{\mu D \sqrt{A_n B_n}} \Big[k_{2n}(k_{1n} - \mu k_{2n}) \operatorname{sh} k_{1n} \frac{b}{a} \operatorname{sh} k_{2n} - k_{1n}(k_{2n} - \mu k_{1n})$$

$$\times \operatorname{sh} k_{2n} \frac{b}{a} \operatorname{sh} k_{1n} - \mu \frac{b}{a} \sqrt{A_n B_n} \operatorname{sh} k_{1n} \operatorname{sh} k_{2n} \Big],$$

$$A_n = (\mu+1)^2 \frac{a^2 p_n}{\nu} + H_a^2; \quad B_n = (\mu-1)^2 \frac{a^2 p_n}{\nu} + H_a^2;$$

$H_a = \frac{a H_0}{c} \sqrt{\frac{\sigma}{\rho \nu}}$ is the Hartmann number.

$$\mu = \sqrt{\frac{\nu}{D}}; \; D = \frac{c^2}{4\pi\sigma}; \; \bar{y} = \frac{y}{a}; \; k_{1n} = \frac{1}{2}(\sqrt{A_n} + \sqrt{B_n});$$

$$K_{2n} = \frac{1}{2}(\sqrt{A_n} - \sqrt{B_n}); \; n = 1,\ 2,\ 3\ldots$$

$$a_1 = \frac{\operatorname{sh} \frac{b}{a} H_a - \frac{b}{a} H_a \operatorname{ch} H_a}{H_a \operatorname{ch} H_a - \operatorname{sh} H_a}; \quad a_2 = \frac{a \operatorname{sh} \frac{b}{a} H_a - b \operatorname{sh} H_a}{H_a \operatorname{ch} H_a - \operatorname{sh} H_a};$$

the p_n are the roots of the equation

$$\varphi_2(p) = p^2 \Big[(\mu-1)\sqrt{A} \operatorname{sh} \sqrt{B} + (\mu+1)\sqrt{B} \operatorname{sh} \sqrt{A}$$

$$- \frac{\nu}{a^2 p} \sqrt{AB} (\operatorname{ch} \sqrt{A} - \operatorname{ch} \sqrt{B}) \Big] = 0. \qquad (9)$$

Here,

$$A = (\mu+1)^2 \frac{a^2 p}{\nu} + H_a^2; \quad B = (\mu-1)^2 \frac{a^2 p}{\nu} + H_a^2.$$

Equation (9) differs from the corresponding equation for a nonstationary Hartmann flow[3] by the last term in the left-hand side.

In the general case the roots of Eq. (9) can be calculated only by numerical methods. However, for $\mu \ll 1$ simple approximations can be obtained.

1. Let $\mu = \sqrt{\nu/D} \ll 1$ and let $\mu H_a^2 \ll 1$; then

$$p_n \simeq -\frac{\nu}{a^2} \Big[x_n^2 + H_a^2 + \Big(\frac{5}{3} - \frac{x_n^2}{6} \Big) \mu^2 H_a^2 + 0(\mu^2 H_a^4) \Big], \qquad (10)$$

where x_n are the roots of the equation

$$\operatorname{tg} x = x.$$

It follows from (10) that the transition to the steady state is monotonic.

2. Let $\mu \ll 1$ and let $H_a^2 \sim 0(1/\mu^2)$; then

$$p_n \simeq -\frac{\nu n \pi}{2a^2\mu^2} \Big[\frac{n\pi}{2} \pm i \sqrt{4H_a^2\mu^2 - n^2\pi^2} \Big] + 0(\mu). \qquad (11)$$

It can then be seen that in the given case the transition to the steady state is oscillatory. It is interesting to note that (11) coincides with the similar value for a nonstationary Hartmann flow. There is a difference only in the terms $0(\mu)$. When $\mu = 1$, Eq. (9) only has real roots.

---

1) We note that an error was made for $\langle v_{2x} \rangle$ in Eq. (17) in ref. 2. The true value of $\langle v_{2x} \rangle$ is determined from Eq. (7) for $U_c(\bar{Y})$.

Propagation and stability of large amplitude ionization waves

M. S. Gorelik and L. D. Tsendin
M. I. Kalinin Leningrad Polytechnic Institute
(Submitted October 5, 1973)
Zh. Tekh. Fiz., 44, 1405-1409 (July 1974)

Nonlinear ionization waves are investigated in a weakly ionized plasma which carries a current. Stationary and nonstationary waves with parameters which vary slowly in space and time are considered for various cases with weak dissipation. The stability regions for self-modulation and the propagation velocities of amplitude and frequency perturbations are found. The influence of dissipative effects on stability is considered.

INTRODUCTION

The linear theory of ionization waves in a plasma has been developed in refs. 1-3. Nonlinear periodic ionization waves with strong temperature or density nonlinearities have been considered in ref. 4. For a number of reasons ionization waves are a convenient medium for studying the properties of large-amplitude wave motion. It is therefore interesting to consider the evolution of slow changes (in comparison with the wavelength and period) in amplitude and frequency. In this paper we use the asymptotic method of Whitham[5] to investigate nonlinear waves with slowly varying amplitude frequency and wave number. Since the medium exhibits competing dissipative mechanisms which are analogous to positive and negative friction in mechanical systems, the method can be generalized to cover nonconservative systems. The boundaries of the instability regions against self-modulation are defined as functions of the amplitude and wave velocity. The propagation of small amplitude and velocity perturbations is analyzed for the case of a stable wave. In contrast to small amplitude waves, for which such perturbations propagate with the group velocity, nonlinear wave perturbations have two velocities[5] and the difference between them increases with amplitude.

BASIC EQUATIONS

We write the basic equations in the form[4] ($n_e = n_p = n$)

$$\left.\begin{aligned}&\frac{\partial n}{\partial x}+\frac{\partial}{\partial x}nv_p=Z(n,\ T_e)n-\frac{n}{\tau_0},\\&v_p=b_pE,\\&v_e=-b_e(T_e)\left(E+\frac{T_e}{en}\frac{\partial n}{\partial x}+\frac{\gamma}{e}\frac{\partial T_e}{\partial x}\right),\\&\frac{\partial}{\partial x}n(v_e-v_p)=0,\\&\left(\frac{3}{2}+\gamma\right)nv_e\frac{\partial T_e}{\partial x}-\frac{\partial}{\partial x}\frac{anb_e}{e}\frac{\partial T_e}{\partial x}+enEv_e+nH(T_e)=0.\end{aligned}\right\}\qquad(1)$$

Here, H is the energy interchange between electrons and neutrals, Z is the number of ionization events per electron per unit time, b_e and b_p are the electron and ion mobilities, v_e and v_p are the drift velocities, $\gamma \sim 1$ is the thermal diffusion, a is the dimensionless electron thermal conductivity and τ_0 is the lifetime of the plasma particles. The conditions for which (1) is valid are discussed in ref. 4. For the ionization rate we take the model expression

$$Z=\frac{1}{\tau_0}[1+\zeta(n)]\exp\frac{\varepsilon_1(T-T_0)}{TT_0};\quad \zeta(n)\ll 1;\quad \frac{\varepsilon_1}{T}\gg 1,$$

where ε_1 is the ionization energy and T_0 is the unperturbed electron temperature. The system (1) has homogeneous stationary solutions n_0, E_0, T_0. If we assume that all quantities vary as $(x-Vt) \sim (\eta-b\theta) = \eta'$ and introduce the notation

$$\eta=\frac{eE_0\varepsilon_1}{aT_0^2}x,\quad \theta=\frac{t}{\tau_0},\quad b=\frac{eE\varepsilon_1\tau_0}{aT_0^2}V,$$

$$q=\ln\frac{n}{n_0},\quad \tau=1-\exp\frac{\varepsilon_1(T-T_0)}{T_0^2},$$

we obtain a system equivalent to the equations for an anharmonic oscillator

$$-\frac{\partial q}{\partial\theta}=b\frac{dq}{d\eta'}=\tau+F_1,\quad \frac{e^q}{1-\tau}\frac{d\tau}{d\eta'}+q=Q+F_2\qquad(2)$$

together with the additional condition

$$\oint(e^q-e^{-q})\frac{dq}{q'}=0,\qquad(3)$$

F_1 and F_2 are small terms corresponding to the damping and buildup of the oscillations. When F_1, $F_2 = 0$, the system (2) has the energy integral

$$-\tau-\ln(1-\tau)+be^{-Q}+be^{-q}(Q-q-1)=T(\tau)+U(q)=A;\qquad(4)$$

Q is the dimensionless electron heat flux along the x axis. Condition (3) follows from the balance between ohmic heating and thermal losses in collisions with neutrals. It defines the connection between the amplitude of the oscillations and Q. A property of the equivalent mechanical problem is therefore that the shape of the "potential well" depends, through Q(A, b), on the amplitude of the oscillations; this leads, in particular, to the absence of soliton type solutions in the system. The shape of a progressive periodic wave in the limiting cases $A \ll 1$ ($A/b \ll 1$ is a small nonlinearity; $A \gg 1$, $A/b \ll 1$ is temperature nonlinearity and $A \ll 1$, $A/b \gg 1$ is density nonlinearity) has been analyzed in ref. 4. The system (2) without F_1 and F_2 describes stationary progressive waves. We now obtain equations which will enable us to describe nonstationary effects in a locally progressive wave caused by dispersion and dissipation. In the general case it follows from (1) that

$$\left.\begin{aligned}&-\frac{\partial q}{\partial\theta}=\tau+F_1,\\&\frac{e^q}{1-\tau}\frac{\partial\tau}{\partial\eta}+q=Q+F_2.\end{aligned}\right\}\qquad(2a)$$

Here, $\theta = t/\tau_0$. Multiplying the second equation of (2a) by

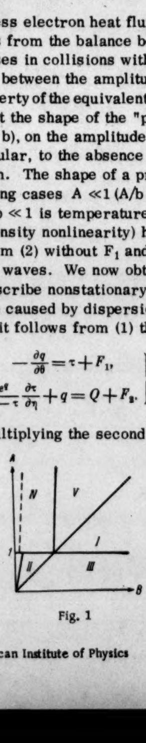

Fig. 1

dq/dθ, using the first equation of the system and averaging over a wavelength, we get

$$\frac{\partial}{\partial\eta}\langle T\rangle-\frac{\partial}{\partial\theta}\frac{\langle U\rangle}{b}=\langle R\rangle. \tag{5}$$

The kinetic and potential energies T and U are defined in (4) and an explicit expression for the dissipative term R is given in ref. 4. Averaging means, for example,

$$\langle T\rangle=\frac{1}{\lambda}\oint\frac{T\,dq}{dq/d\eta'}, \tag{6}$$

where the integrals are calculated using the unperturbed solution of (2). The function R is linear in the dissipative coefficients so that the given approximation corresponds to the inclusion of the first two terms of the iterative series in these coefficients.[6] Equation (5) together with the condition for wave conservation

$$\frac{\partial\omega(A,\,b)}{\partial\eta}+\frac{\partial k(A,\,b)}{\partial\theta}=0 \tag{7}$$

defines the A(η, θ) b(η, θ) relationship. We first take the dissipation to be small and put ⟨R⟩ = 0.

TEMPERATURE NONLINEARITY

In this case (region I in Fig. 1) it follows from (4) that the τ oscillations in a periodic wave are large, while $|q| \ll 1$. In (3) we can limit ourselves to terms which are linear in q and we then get $\oint 2q(dq/q') = \lambda\langle q\rangle = 0$. For small oscillations $Q \sim \langle q\rangle$; in this case Q = 0 and $U(q) = bq^2/2$. The energy integral (4) has the form

$$-\tau-\ln(1-\tau)+\frac{bq^2}{2}=A. \tag{4a}$$

For any values of A the quantity $\tau < 1$. It follows from (4a) that the main contribution to the integral (6), which defines the wavelength, comes from the motion of a "particle" from left to right (with $\tau > 0$); then $1-\tau \ll 1$, $q' \sim 1/b \ll 1$. This condition breaks down in a narrow region $[\Delta q = (2Ab)^{-1/2} \ll 1]$ near the right turning point, which gives a small contribution to (6). We can therefore put q' = 1/b. The contribution from the small neighborhood of the point $q_0 = \sqrt{2A/b}$, where τ is much less than unity, to the value of ⟨V⟩ is also small, so that

$$\lambda\approx\int_{-q_0}^{q_0} b\,dq=2\sqrt{2Ab},$$

$$\langle U\rangle\simeq\frac{1}{\lambda}b\int_{-q_0}^{q_0}\frac{bq^2}{2}dq=\frac{A}{3}, \tag{8}$$

Thus ⟨T⟩ = A − ⟨U⟩ = 2A/3.

Linearizing (5) and (7) over small perturbations A and b, we can get expressions for the velocities of the wave envelopes:[7]

$$W_{1,2}=-\frac{b}{2}\pm i\,\frac{b\sqrt{3}}{2}. \tag{9}$$

Thus a stationary wave in this case is unstable against buildups in the small envelope wave, i.e., against self-modulation.

DENSITY NONLINEARITY

When $b \ll A \ll 1$, the q oscillations are large while $|\tau| \ll 1$. Condition (4) takes the form

$$\frac{b(q')^2}{2}+be^{-Q}+be^{-q}(Q-q-1)=A. \tag{4b}$$

It is easy to show that $\langle T\rangle \ll A$ so that ⟨U⟩ = A. The wavelength $\lambda \approx b^{1/3}A^{1/6}$.

Averaging, we get

$$\langle T\rangle=\alpha A\left(\frac{b}{A}\right)^{2/3}, \tag{10}$$

where $\alpha \cong 8\sqrt{e}(\sqrt{\pi}/4-1/6\sqrt{2})$. The velocities of the envelope waves are

$$W_{1,2}=-\frac{b}{2}\pm b\sqrt{\frac{1}{4}-\frac{2\alpha}{3}\left(\frac{b}{A}\right)^{2/3}}. \tag{11}$$

The wave is unstable when $A/b < (8\alpha/3)^{3/2}$ (region II in Fig. 1). This is fully compatible with the original inequality $A/b \gg 1$ (it should be noted that density nonlinearity becomes significant as early as $A/b \leqslant 1$).

NONLINEARITY IN BOTH VARIABLES

The oscillations in both electron temperature and plasma density are large. When $b \ll 1$ (region IV) we find from (3) that

$$\frac{\sqrt{b}\,e^{3/2\,q_2}}{\sqrt{q_2+|Q|}}=be^{|Q|}. \tag{12}$$

Here, q_2 is the right turning point. Thus $q_2 = |Q|/3$ as in the case of density nonlinearity.[4] Therefore $be^{|Q|} - A \ll 1$ and the main contribution to (6) comes from the region near q_2. In this region $\tau \ll 1$ and $T(\tau) = \tau^2/2$:

$$\lambda\sim\int_{Q}^{q_2}\frac{b\,dq}{\sqrt{2[A-be^{|Q|}-be^{-q}(Q-q-1)]}}\sim b^{1/3}A^{1/6}. \tag{13}$$

In order to calculate ⟨T⟩ we recall that the basic "time" of a particle moves to the right ($|\tau_{\max}/\tau_{\min}| \sim A^{-1}$). In the region where T is nonzero, $\tau \cong 1$. Thus

$$\langle T\rangle\approx\frac{b}{\lambda}\int_{Q}^{q_2}[A-be^{|Q|}-be^{-q}(Q-q-1)]\,dq=2b^{2/3}A^{5/6}\ll A. \tag{14}$$

The phase velocities of the envelopes waves are

$$W_{1,2}=-\frac{b}{2}-\frac{b^{2/3}}{3A^{1/6}}\pm b\sqrt{\frac{1}{4}+\frac{b^{4/3}}{9A^{1/3}}\frac{7b^{2/3}}{3A^{1/6}}}. \tag{15}$$

These correspond to instability when $21b^{2/3}A^{-1/6} > 1$.

In region V with $A/b^2 < 1$, it can be shown by using $A/b \gg 1$, $b \gg 1$ that the section where $|\tau| \ll 1$ and $T = \tau^2/2$ is close to q_2, i.e., the principal time of the equivalent oscillator moves to the right with a "velocity" $\tau \cong 1$, and only in a narrow neighborhood ($\sim A/b^2$) of the point q_2 does this velocity fall to zero. Proceeding as before, we get

$$q_2\approx|Q|=\ln\frac{A}{b}; \tag{16}$$

$$\lambda=2b\ln\frac{A}{b}; \tag{17}$$

$$\langle T\rangle=\frac{A}{\ln\frac{A}{b}}\ll A;\quad\langle U\rangle=A. \tag{18}$$

In this region the wave is stable

$$\left.\begin{aligned} W_1 &= -\left(\ln\frac{A}{b}-1\right)^{-1}, \\ W_2 &= -b\left(\ln\frac{A}{b}-1\right)^{-1}. \end{aligned}\right\} \qquad (19)$$

The connection between A and b in progressive envelope waves (the Riemann invariants) is of the form

$$\left.\begin{aligned} dI_1 &= dA\left(\frac{1}{z}-\frac{1}{Az^2}-\frac{1}{z-1}\right)+\frac{db}{bz^2}=0, \\ dI_2 &= dA\left(\frac{1}{z}-\frac{1}{Az^2}-\frac{b}{z-1}\right)+\frac{db}{bz^2}=0, \end{aligned}\right\} \qquad (20)$$

where z = ln(A/b).

Expressions (19) represent the nonlinear generalization of the group velocity.

THE EFFECT OF DISSIPATION

So far we have neglected dissipative effects. When we include these we find that the wave amplitude increases for $\langle R \rangle > 0$ and decreases for $\langle R \rangle < 0$. It is therefore of interest to consider the stability of a stationary wave for which the nonlinear dissipation reduces to zero (like the limit cycle in the theory of nonlinear oscillations[8]). For small perturbations of this wave

$$\langle R \rangle = (\alpha A' + \beta b')\, e^{i(\varkappa\eta-\Omega\theta)}.$$

For temperature nonlinearity, in place of (9) we have

$$\frac{W}{b}=\frac{1}{2}\left[-1-\frac{i\alpha}{2\varkappa}+\frac{i\beta}{2\varkappa A}\pm\sqrt{-3-\frac{\alpha^2}{4\varkappa^2}-\frac{\beta^2}{4\varkappa^2A^2}-2\frac{i\beta b}{A\varkappa}}\right], \qquad (9a)$$

while for the density mechanism

$$\frac{W}{b}=-\frac{1}{2}+\frac{i\beta b}{6A\varkappa}-\frac{i\alpha}{3\varkappa}$$
$$\pm\frac{1}{6}\sqrt{9-24\left(\frac{b}{A}\right)^{1/3}-\frac{i\beta b73}{6A\varkappa}-\frac{i143\alpha}{3\varkappa}-\frac{\beta^2b^2}{36A^2\varkappa}-\frac{\alpha^2}{9\varkappa^2}+\frac{\beta\alpha b}{9A\varkappa^2}}. \qquad (11a)$$

When dissipation is taken into account the wave can be unstable in a case where it would be stable without dissipation or with the inclusion of only one dissipative effect.

Surface waves in periodic plasma systems

V. F. Dryakhlushin and Yu. A. Romanov

Gor'kovskii Physicotechnical Research Institute

(Submitted July 13, 1973)
Zh. Tekh. Fiz., 44, 1410-1417 (July 1974)

Surface waves in periodic plasma systems with finite periodicity are investigated. The spectrum is similar to the Tamm electronic levels in bounded crystals.

Plasma waves in unbounded periodic systems are considered in refs. 1 and 2. In the present paper we consider the spectrum of plasma waves in a stratified periodic structure of finite thickness. Particular attention is given to surface waves; like Tamm electronic levels, these appear in systems with a terminated periodicity in the bands which are forbidden for volume waves.

GENERAL RELATIONSHIPS

We consider a periodic structure of finite thickness L which consists of 2N alternating layers 1 and 2. We denote the thicknesses of the layers by d_1 and d_2 so that the structure period $d = d_1 + d_2$. The edge layers (zeroth and 2N + 1-th) are taken to be infinitely thick. We choose a Cartesian coordinate system such that the xy plane is parallel to the layer boundaries and the z axis is perpendicular. The x axis coincides with the direction of the wave vector k_1 of a wave propagating in the multilayer waveguide. The coordinates of the lower and upper boundaries of the ν-th layer are denoted by a_ν and $a_{\nu+1}$. We take the coordinate and time variation of the field in the form $f(z)\exp[i(k_1x-\omega t)]$.

We limit the analysis to an E wave with nonzero components E_x, E_z and H_y. We assume for simplicity that the layer boundaries cannot be penetrated by electrons. The electromagnetic fields inside each layer are then uniquely defined (when the interaction mechanism between the particles and the boundary is given) by the boundary values of the tangential magnetic field components. We can therefore write

$$\left.\begin{aligned} E_x^\nu(z) &= \sigma_\nu^-(z)\,H_y^\nu(a_\nu) - \sigma_\nu^+(z)\,H_y^\nu(a_{\nu+1}),\\ E_z^\nu(z) &= \bar{\sigma}_\nu^-(z)\,H_y^\nu(a_\nu) - \bar{\sigma}_\nu^+(z)\,H_y^\nu(a_{\nu+1}). \end{aligned}\right\} \tag{1}$$

We assume that there are no surface currents in the boundaries; therefore, the tangential components of the E and H fields are continuous. These conditions lead to the following system of homogeneous equations:

$$T_1(\nu)\begin{pmatrix} H_y^\nu(a_\nu) \\ H_y^\nu(a_{\nu+1}) \end{pmatrix} = T_2(\nu-1)\begin{pmatrix} H_y^{\nu-1}(a_{\nu-1}) \\ H_y^{\nu-1}(a_\nu) \end{pmatrix}, \tag{2}$$

where

$$T_1(\nu) = \begin{pmatrix} \sigma_\nu^-(a_\nu), & -\sigma_\nu^+(a_\nu) \\ 1, & 0 \end{pmatrix}, \quad T_2(\nu) = \begin{pmatrix} \sigma_\nu^-(a_{\nu+1}), & -\sigma_\nu^+(a_{\nu+1}) \\ 0, & 1 \end{pmatrix}. \tag{3}$$

By means of (2) we can express $H_y^m(a_{m,m+1})$ in terms of the values of the magnetic field on the boundaries of the l-th layer

$$\begin{pmatrix} H_y^m(a_m) \\ H_y^m(a_{m+1}) \end{pmatrix} = \prod_{\nu=l}^{m-1} T_1^{-1}(\nu+1)\,T_2(\nu)\begin{pmatrix} H_y^l(a_l) \\ H_y^l(a_{l+1}) \end{pmatrix}. \tag{4}$$

Putting $m = 2N + 1$, $l = 0$ in (4) and remembering that $H_y^0(a_0) = H_y^{2N+1}(a_{2N+2}) = 0$, we obtain the dispersion equation for electromagnetic waves propagating in the plane multilayer waveguide:

$$\mathrm{Tr}(L\bar{M}^{(N)}(1)) = 0, \tag{5}$$

where

$$L = \begin{pmatrix} \sigma_0^+(a_1), & -\sigma_0^+(a_1)\,\sigma_{2N+1}^-(a_{2N+1}) \\ -1, & \sigma_{2N+1}^-(a_{2N+1}) \end{pmatrix}, \tag{6}$$

$$\bar{M}(m) = T_2(m+1)\,T_1^{-1}(m+1)\,T_2(m)\,T_1^{-1}(m). \tag{7}$$

The matrix $\bar{M}$ is related to the M derived in ref. 1 by the equation

$$\bar{M}(m) = T_1(m)\,M(m)\,T_1^{-1}(m). \tag{8}$$

It is easy to see that

$$\det\bar{M} = \det M, \quad \mathrm{Tr}\,\bar{M} = \mathrm{Tr}\,M. \tag{9}$$

For convenience in the following calculations we reduce $\bar{M}$ to diagonal form by means of the transformation (which in general, is not unitary)

$$A\bar{M}A^{-1} = \sqrt{\det\bar{M}}\begin{pmatrix} \lambda, & 0 \\ 0, & \lambda^{-1} \end{pmatrix}, \tag{10}$$

where

$$\lambda = \frac{1}{2\sqrt{\det\bar{M}}}\left[\mathrm{Tr}\,\bar{M} - \sqrt{(\mathrm{Tr}\,\bar{M})^2 - 4\det\bar{M}}\right]. \tag{11}$$

We can choose either branch for the square root. The above transformation does not affect the values of Tr $\bar{M}$ and det $\bar{M}$.

Putting $\bar{M}$ in the form

$$\bar{M} = \begin{pmatrix} \bar{a}, & \bar{b} \\ \bar{c}, & \bar{d} \end{pmatrix}, \tag{12}$$

from (10) we have

$$\left.\begin{gathered} A = \begin{pmatrix} \alpha, & 1 \\ 1, & \delta \end{pmatrix}, \\ \alpha = \frac{\lambda\sqrt{\det\bar{M}} - \bar{d}}{\bar{b}}, \quad \delta = \frac{\bar{b}}{\lambda^{-1}\sqrt{\det\bar{M}} - \bar{d}}. \end{gathered}\right\} \tag{13}$$

The Floquet theorem is valid for a periodic medium. Thus for the particular solutions of the Maxwell equations we can choose functions corresponding to

$$\begin{pmatrix} H_y^m(a_m) \\ H_y^m(a_{m+1}) \end{pmatrix} = M(m)\begin{pmatrix} H_y^{m-2}(a_{m-2}) \\ H_y^{m-2}(a_{m-1}) \end{pmatrix} = e^{iqd}\begin{pmatrix} H_y^{m-2}(a_{m-2}) \\ H_y^{m-2}(a_{m-1}) \end{pmatrix}, \tag{14}$$

where q is the wave vector of the Bloch wave. From (14) we get the dispersion relationship

$$\det(M - e^{iqd}) = 0. \tag{15}$$

A comparison of (15) with (11) shows that we can put

$$\lambda = \frac{1}{\sqrt{\det\bar{M}}}e^{iqd}, \tag{16}$$

and the meaning of the quantity λ thus becomes clear.

Using the transformation (10), we can write the dispersion equation (5) in the form

$$\mathrm{Sp}\left[ALA^{-1}\begin{pmatrix}\lambda^{N}, & 0\\ 0, & \lambda^{-N}\end{pmatrix}\right]=0 \tag{17}$$

or

$$[a\sigma_0^+(a_1)-1][\delta+\sigma_{2N+1}^-(a_{2N+1})]\lambda^N + [\delta-\sigma_0^+(a_1)][1+a\sigma_{2N+1}^-(a_{2N+1})]\lambda^{-N}=0. \tag{18}$$

We consider a structure with a large number of periods. Putting N → ∞ in (18) and taking $|\lambda|<1$, we get two dispersion equations which describe the propagation of surface waves along the boundary of a semiinfinite periodic system with edge layers of type "1" or "2":

$$\delta-\sigma_0^+(a_1)=0, \tag{19}$$

$$1+a\sigma_{2N+1}^-(a_{2N+1})=0. \tag{20}$$

Substituting (19) into (3), (8), (11), and (13) we get

$$\sigma_1^-(a_2)[\sigma_2^+(a_3)+\sigma_1^-(a_1)]-\frac{\sigma_0^+(a_1)+\sigma_1^-(a_1)}{\sigma_1^+(a_1)}\{[\sigma_2^+(a_3)-\sigma_0^+(a_1)] \times[\sigma_1^+(a_2)+\sigma_2^-(a_2)]-\sigma_2^-(a_3)\sigma_2^+(a_2)+\sigma_1^-(a_2)\sigma_1^+(a_1)\}=0. \tag{19'}$$

After solving (19') we have to verify that $|\lambda|<1$ by using the relationship

$$\lambda=\frac{\sqrt{\det M}}{\frac{\delta}{\sigma_0^+(a_1)}+d}, \tag{21}$$

which follows from (13) and (19).

The supposition that $|\lambda|>1$ leads to a valid system of equations. The parameter region where $|\lambda|=1$ is singular and this means in fact that the surface wave disappears; it becomes a volume wave.

In order to study the dispersion equations we need explicit expressions for $\sigma^\pm$. For homogeneous layers in the kinetic approximation with the plasma particles undergoing mirror reflection from the boundaries these quantities have the form[1]

$$\sigma^-(z)=\sigma^+(d_\nu-z)=\frac{ic}{\omega d_\nu}\sum\left[\frac{k_1^2}{k^2\varepsilon^l}+\frac{k_3^2}{k^2\left(\varepsilon^{t_\nu}-\frac{c^2k^2}{\omega^2}\right)}\right]\exp(ik_3z), \tag{22}$$

where $k^2 = k_1^2 + k_3^2$, $k_3 = n\pi/d_\nu$, $n = 0, \pm1, \pm2, \ldots$, ε^l and ε^{t_2} are the longitudinal and transverse permittivities of the material forming the ν-th layer. The origin for z is chosen to be at the left-hand boundary of the ν-th layer.

We now investigate the dispersion equations (18)-(20); we first use the approximations of elementary theory and then take thermal effects into account for a particular case.

ELEMENTARY THEORY

In (22) we write

$$\varepsilon_{1,2}^l=\varepsilon_{1,2}^{tr}=\varepsilon_{1,2}(\omega)=\varepsilon_{01,2}\left(1-\frac{\omega_{01,2}^2}{\omega(\omega+i\nu_{1,2})}\right), \tag{23}$$

whence

$$\sigma^+(z)=\frac{ic}{\varepsilon\omega}\varkappa\frac{\mathrm{ch}(\varkappa z)}{\mathrm{sh}(\varkappa d)}, \tag{24}$$

where

$$\varkappa=\sqrt{k_1^2-\varepsilon\frac{\omega^2}{c^2}}. \tag{25}$$

Before going on to surface waves we give some results for waves in an unbounded periodic system. The appropriate dispersion solution, which follows from (15) and (24), has the form

$$\cos(qd)=\frac{1}{2}\left(\frac{\varkappa_1\varepsilon_2}{\varkappa_2\varepsilon_1}+\frac{\varkappa_2\varepsilon_1}{\varkappa_1\varepsilon_2}\right)\mathrm{sh}(\varkappa_1d_1)\,\mathrm{sh}(\varkappa_2d_2)+\mathrm{ch}(\varkappa_1d_1)\,\mathrm{ch}(\varkappa_2d_2). \tag{26}$$

This equation is studied, in the quasistatic approximation, in ref. 1. For long waves, more precisely

$$\varkappa_{1,2}d_{1,2}\ll 1,\quad qd\ll 1, \tag{27}$$

Equation (25) simplifies in accordance with the equivalence of a periodic system in a quasihomogeneous anisotropic medium[3-5] and takes the form

$$q^2\varepsilon_\parallel+k_1^2\varepsilon_\perp=\frac{\omega^2}{c^2}\varepsilon_\parallel\varepsilon_\perp, \tag{28}$$

where

$$\varepsilon_\perp=\frac{1}{d}\int\varepsilon(z)\,dz,\quad \varepsilon_\parallel=\frac{1}{d}\int\frac{dz}{\varepsilon(z)}. \tag{29}$$

In the general case, Eq. (26) describes an infinite set of E-wave frequency zones in a periodic system. A qualitative picture of the first three zones is given in Fig. 1. The corresponding isofrequency surfaces are shown in Fig. 2. The difference between Figs. 1 and 2 and the results in ref. 1 is due to the fact that we have here allowed for electrodynamic retardation.

As with Tamm electronic levels, surface electromagnetic waves can appear in the forbidden bands of a semibounded periodic system. The appropriate dispersion equation in the elementary theory follows from (19') and (24)

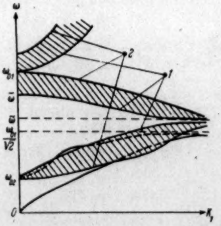

Fig. 1. Relative positions of the volume wave (shaded regions) and surface wave (continuous lines) regions. The dashed curves are the solutions of $\bar{\omega}^2 = (\omega_{01}^2+\omega_{02}^2)/2$, $\bar{\bar{\omega}}^2 = (d_1\omega_{01}^2+d_2\omega_{02}^2)/d$; q: 1) 0; 2) π/d.

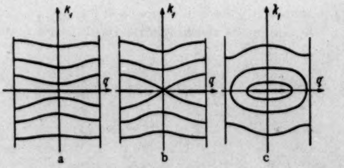

Fig. 2. Isofrequency surfaces of the first three zones of volume plasmons.

and has the form

$$\left(\frac{\varkappa_0}{\varepsilon_0}\right)^2\left[\frac{\varkappa_2}{\varepsilon_2}\operatorname{sh}(\varkappa_1 d_1)\operatorname{ch}(\varkappa_2 d_2)+\frac{\varkappa_1}{\varepsilon_1}\operatorname{ch}(\varkappa_1 d_1)\operatorname{sh}(\varkappa_2 d_2)\right]$$
$$+\frac{\varkappa_0}{\varepsilon_0}\left[\left(\frac{\varkappa_1}{\varepsilon_1}\right)^2-\left(\frac{\varkappa_2}{\varepsilon_2}\right)^2\right]\operatorname{sh}(\varkappa_1 d_1)\operatorname{sh}(\varkappa_2 d_2)$$
$$-\frac{\varkappa_1\varkappa_2}{\varepsilon_1\varepsilon_2}\left[\frac{\varkappa_1}{\varepsilon_1}\operatorname{sh}(\varkappa_1 d_1)\operatorname{ch}(\varkappa_2 d_2)+\frac{\varkappa_2}{\varepsilon_2}\operatorname{ch}(\varkappa_1 d_1)\operatorname{sh}(\varkappa_2 d_2)\right]=0, \qquad (30)$$
$$\varkappa_0=\sqrt{k_1^2-\varepsilon_0\frac{\omega^2}{c^2}}, \quad \operatorname{Re}\varkappa_0>0, \ |\lambda|<1.$$

For long waves [see (27)] it follows from (30) that

$$\frac{\varkappa_0}{\varepsilon_0}=-\frac{\varkappa}{\varepsilon_\perp}, \qquad (31)$$

where

$$\varkappa=\sqrt{k_1^2\frac{\varepsilon_\perp}{\varepsilon_\parallel}-\frac{\omega^2}{c^2}\varepsilon_\perp}, \ \operatorname{Re}\varkappa>0. \qquad (32)$$

As expected, Eq. (31) is identical in form with the dispersion equation for surface waves in a semibounded anisotropic medium.

Solving (31) for k_1 we get

$$k_1=\frac{\omega}{c}\left\{\frac{\varepsilon_0\varepsilon_1\varepsilon_2[d_1(\varepsilon_1-\varepsilon_0)+d_2(\varepsilon_2-\varepsilon_0)]}{d_1\varepsilon_2(\varepsilon_1^2-\varepsilon_0^2)+d_2\varepsilon_1(\varepsilon_2^2-\varepsilon_0^2)}\right\}^{1/2}. \qquad (33)$$

We now consider the quasistatic region, i.e.,

$$\varepsilon_{1,2}\frac{\omega^2}{c^2}\ll k_1^2. \qquad (34)$$

Equation (30) now takes the form

$$\varepsilon_2(\varepsilon_1^2-\varepsilon_0^2)\operatorname{th}(k_1d_1)+\varepsilon_1(\varepsilon_2^2-\varepsilon_0^2)\operatorname{th}(k_1d_2)$$
$$-\varepsilon_0(\varepsilon_1^2-\varepsilon_2^2)\operatorname{th}(k_1d_1)\operatorname{th}(k_1d_2)=0. \qquad (35)$$

In particular, when $d_1 = d_2$ we get the two solutions:

$$\varepsilon_1+\varepsilon_2=0, \qquad (36)$$
$$\operatorname{th}(k_1d_1)=\frac{\varepsilon_1\varepsilon_2-\varepsilon_0^2}{\varepsilon_0(\varepsilon_1-\varepsilon_2)}. \qquad (37)$$

The qualitative shape of the solutions of (30) for various relations between the parameters ω_{01}, ω_{02}, d_1, and d_2 for $\nu_{1,2} = 0$ is shown in Fig. 3.

For certain parameter values the solutions are spurious, i.e., there are windows in which the surface wave does not exist if the radiation conditions

$$\operatorname{Re}\varkappa_0>0, \qquad (38)$$
$$\operatorname{Im}q>0. \qquad (39)$$

are not satisfied.

We consider this problem for long waves in the quasistatic region. For long waves, from (21) we find

$$\lambda\simeq 1+\frac{\varkappa_0}{\varepsilon_0}(\varepsilon_1d_1+\varepsilon_2d_2). \qquad (40)$$

Since $\operatorname{Re}\varkappa_0 > 0$, from (40) we find

$$\varepsilon_1d_1+\varepsilon_2d_2<0. \qquad (41)$$

Using (23) with $\varepsilon_{01} = \varepsilon_{02}$ for $\varepsilon_{1,2}$, we find that for long waves the surface states exist only in the band

$$\omega^+<\omega<\bar{\omega}, \qquad (42)$$

where

$$\bar{\omega}^2=\frac{d_1\omega_{01}^2+d_2\omega_{02}^2}{d}, \qquad (43)$$

$$\omega^{+2}=\frac{d\omega_{01}^2\omega_{02}^2}{d_1\omega_{01}^2+d_2\omega_{02}^2}.$$

The conditions (41) only impose restrictions on the upper branch. We now consider the quasistatic region. For simplicity we put $d_1 = d_2$. Substituting (24) and (37) into (21), we get

$$e^{iqd}=\frac{(\varepsilon_1^2-\varepsilon_0^2)\varepsilon_2}{(\varepsilon_0^2-\varepsilon_2^2)\varepsilon_1}. \qquad (44)$$

Using (23) for $\varepsilon_{1,2}$ and putting $\varepsilon_{01} = \varepsilon_{02} = \varepsilon_0$, we find that the surface wave does not exist in the region

$$\left.\begin{array}{c}\dfrac{\omega_{01}^2+\omega_{02}^2-\sqrt{\omega_{01}^4+\omega_{02}^4-6\omega_{01}^2\omega_{02}^2}}{4}\leqslant\omega^2\\ \leqslant\dfrac{\omega_{01}^2+\omega_{02}^2+\sqrt{\omega_{01}^4+\omega_{02}^4-6\omega_{01}^2\omega_{02}^2}}{4},\\ \omega_{01}>\omega_{02}.\end{array}\right\} \qquad (45)$$

Condition (45) leads to the appearance of windows in the lower dispersion curve for $\omega_{01} \geq (1 + \sqrt{2})\omega_{02}$. For the entire upper curve, $\operatorname{Im} q = 0$.

The case where d_1 and d_2 are different can only be investigated by numerical methods. Surface waves do not exist for particular values of the parameters in the dispersion curves. In all cases where windows are formed the surface wave dispersion curves break away from the boundaries of the volume wave zones. Figure 1 shows one possible picture for the surface and volume waves.

What we have said above refers to a semiinfinite system. The transition to a periodic structure with finite thickness leads to a discrete spectrum for the volume waves and to some change in the surface states. In thin layers [see (27)], for example, the E-wave spectrum is described by the dispersion equation

$$\frac{\varkappa_0}{\varepsilon_0}=-\frac{1\pm e^{-\varkappa L}}{1\mp e^{-\varkappa L}}\frac{\varkappa}{\varepsilon_\perp}, \qquad (46)$$

where the upper sign refers to symmetric waves (tangential plasmons) and the lower sign to asymmetric waves (normal plasmons).

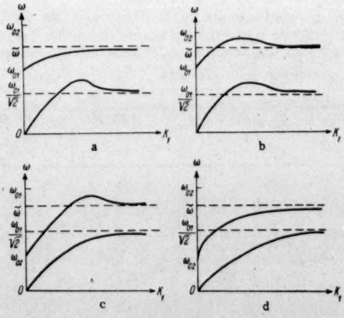

Fig. 3. Dispersion curves of surface waves for various relations between the structure parameters. a) $\omega_{01} < \omega_{02}$, $d_1 < d_2$; b) $\omega_{01} < \omega_{02}$, $d_1 > d_2$; c) $\omega_{01} > \omega_{02}$, $d_1 < d_2$; d) $\omega_{01} > \omega_{02}$, $d_1 > d_2$.

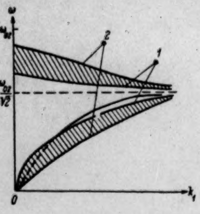

Fig. 4. Zones for volume waves (shaded regions) and surface waves (continuous curves) for structures with layers at different temperatures. q: 1) 0; 2) π/d.

In the quasistatic approximation the solutions of (46) can be written as

$$\frac{k_1 L}{2}=\frac{in\pi-\operatorname{arc\,th}\left(\varepsilon_{\parallel}\sqrt{\frac{\varepsilon_{\perp}}{\varepsilon_{\parallel}}}\right)}{\sqrt{\frac{\varepsilon_{\perp}}{\varepsilon_{\parallel}}}}\tag{47}$$

for normal plasmons and

$$\frac{k_1 L}{2}=\frac{in\pi-\operatorname{arc\,th}\left(\varepsilon_{\parallel}\sqrt{\frac{\varepsilon_{\perp}}{\varepsilon_{\parallel}}}\right)}{\sqrt{\frac{\varepsilon_{\perp}}{\varepsilon_{\parallel}}}}\tag{47'}$$

for tangential plasmons.

THERMAL EFFECTS

As a second example, we consider a semiinfinite periodic structure consisting of layers at different temperatures; in one layer we neglect the time dispersion (layer 1) and in the other the spatial dispersion (layer 2) in the dielectric permittivity. In the quasistatic approximation, using (22) we find

$$\sigma_1^{+}(z)=\frac{ic}{\varepsilon_{01}\omega}\frac{k_1^2}{\varkappa_1^l}\frac{\operatorname{ch}(\varkappa_1^l z)}{\operatorname{sh}(\varkappa_1^l d)},\tag{48}$$

where

$$\varkappa_1^l=\sqrt{k_1^2+\frac{2\omega_{01}^2}{v_{T1}^2}},$$

and $\sigma^{\pm}(z)$ is defined by (24).

From (19'), (24), and (48) we get the dispersion equation

$$\left.\begin{aligned}&\varepsilon_2\left[\left(\frac{\varepsilon_{01}\varkappa_1^l}{k_1}\right)^2-\varepsilon_0^2\right]\operatorname{th}(\varkappa_1^l d_1)+\frac{\varepsilon_{01}\varkappa_1^l}{k_1}(\varepsilon_2^2-\varepsilon_0^2)\operatorname{th}(k_1 d_2)\\&\quad-\varepsilon_0\left[\left(\frac{\varepsilon_{01}\varkappa_1^l}{k_1}\right)^2-\varepsilon_2^2\right]\operatorname{th}(\varkappa_1^l d_1)\operatorname{th}(k_1 d_2)=0,\\&\qquad|\lambda|<1.\end{aligned}\right\}\tag{49}$$

If there is no spatial dispersion in layer 1 and no time dispersion in layer 2 (i.e., a layer in which only time dispersion is significant is bounded by a vacuum), (49) is replaced by

$$\left.\begin{aligned}&\frac{\varepsilon_{02}\varkappa_2^l}{k_1}(\varepsilon_1^2-\varepsilon_0^2)\operatorname{th}(k_1 d_1)+\varepsilon_1\left[\left(\frac{\varepsilon_{02}\varkappa_2^l}{k_1}\right)^2-\varepsilon_0^2\right]\operatorname{th}(\varkappa_2^l d_2)\\&\quad-\varepsilon_0\left[\varepsilon_1^2-\left(\frac{\varepsilon_{02}\varkappa_2^l}{k_1}\right)^2\right]\operatorname{th}(k_1 d_1)\operatorname{th}(\varkappa_2^l d_2)=0,\\&\qquad|\lambda|<1,\end{aligned}\right\}\tag{50}$$

where

$$\varkappa_2^l=\sqrt{k_1^2+\frac{2\omega_{02}^2}{v_{T2}^2}}.$$

Solving (49) and (50) for ω with $\varepsilon_{01} = \varepsilon_{02} = \varepsilon_0$ we find

$$\begin{aligned}\omega(\omega+i\nu_2)=\omega_{02}^2\Biggl\{&\frac{\varkappa_1^l}{k_1}\operatorname{cth}(\varkappa_1^l d_1)+1+\frac{1}{2}\left[\left(\frac{\varkappa_1^l}{k_1}\right)^2-1\right]\operatorname{cth}(k_1 d_2)\\&-\sqrt{\frac{1}{4}\left[\left(\frac{\varkappa_1^l}{k_1}\right)^2-1\right]^2\operatorname{cth}^2(k_1 d_2)+\frac{\varkappa_1^l}{k_1}\left[\frac{\varkappa_1^l}{k_1}\operatorname{cth}(\varkappa_1^l d_1)+1\right]\left[\operatorname{cth}(\varkappa_1^l d_1)+\frac{\varkappa_1^l}{k_1}\right]}\Biggr\}\left[\left(\frac{\varkappa_1^l}{k_1}\right)^2-1\right]^{-1}[\operatorname{cth}(k_1 d_2)-1]^{-1},\end{aligned}\tag{51}$$

$$\begin{aligned}\omega(\omega+i\nu_1)=\omega_{01}^2\Biggl\{&\frac{\varkappa_2^l}{k_1}\operatorname{cth}(\varkappa_2^l d_2)-1+\frac{1}{2}\left[\left(\frac{\varkappa_2^l}{k_1}\right)^2-1\right]\operatorname{cth}(k_1 d_1)\\&-\sqrt{\frac{1}{4}\left[\left(\frac{\varkappa_2^l}{k_1}\right)^2-1\right]^2\operatorname{cth}^2(k_1 d_1)+\frac{\varkappa_2^l}{k_1}\left[\operatorname{cth}(\varkappa_2^l d_2)-\frac{\varkappa_2^l}{k_1}\right]\left[\frac{\varkappa_2^l}{k_1}\operatorname{cth}(\varkappa_2^l d_2)-1\right]}\Biggr\}\left[\left(\frac{\varkappa_2^l}{k_1}\right)^2-1\right]^{-1}[\operatorname{cth}(k_1 d_1)+1]^{-1}.\end{aligned}\tag{52}$$

The qualitative shape of the dispersion curve defined by (51) with $\nu_2 = 0$ and the corresponding zones for volume plasmons are shown in Fig. 4. The dashed line corresponds to the spurious solution.

Solitary waves in anisotropic plasma waveguide

V. I. Kurilko and A. P. Tolstoluzhskii

Physicotechnical Institute,
Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted August 17, 1973)
Zh. Tekh. Fiz., 44, 1418-1423 (July 1974)

An analytical and numerical study is made of the field configuration and dispersion of solitary waves of finite amplitude propagating along the axis of a cylindrical plasma waveguide with conducting walls in a strong external magnetic field. Curves are given which show the potential distribution on the waveguide axis and the phase velocity of the solitary waves as a function of amplitude. Even when the amplitudes of the fields are comparable with the maximum permissible amplitude, when effects associated with the intersection of the trajectories of the plasma electrons become significant the main contribution to the field configuration and the dispersion comes from a single radial harmonic of the field. The dependence of the characteristics of a solitary wave on the linear density of the plasma is investigated.

1. Theoretical studies on the dispersion and the field configuration of regular waves of finite amplitude propagating in bounded plasma waveguide systems are important in connection with the development of collective methods of accelerating charged particles[1,2] and methods of controlling convective instabilities that utilize the nonlinear properties of a plasma.[3,4] Special interest attaches to solitary waves, the energy of which is concentrated in a bounded region of coordinate space. One-dimensional low-frequency solitary waves in a plasma have been studied in detail (see refs. 5 and 6, for example). That solitary waves can exist in a bounded anisotropic plasma was first shown in refs. 7 and 8 for waveguides with cylindrical and planar geometries respectively. In these papers the dispersion characteristics and field configuration of nonrelativistic ($V \ll c$) solitary waves were investigated analytically assuming weak nonlinearity. However, in order to assess the practical usefulness of these waves it is necessary to know the parameters (phase velocity, half-width, and so on) in the region in which the potential reaches its maximum value. For example, the possibility of increasing the amplitude of a soliton is restricted by effects associated with the intersection of the trajectories of the plasma electrons and capture by the wave field.[9-11] It is these effects that set an upper limit on the acceleration of a soliton by an electron beam.[10,11] A weak-signal theory[7] gives a value of about 1.18 for the maximum Mach number of a nonrelativistic soliton in a waveguide with cylindrical geometry and conducting walls. This means that in a homogeneous plasma waveguide it is not possible to obtain a solitary wave with a phase velocity more than 18% above the value for an infinitesimal amplitude. The question as to what extent this estimate is true can be answered only by a theory of solitary waves of finite amplitude. Of no less interest for applications is the question of the existence and characteristics of solitary waves with phase velocities close to the velocity of light.

In the present paper we make a theoretical study of the dispersion and field configuration of solitary waves of finite amplitude propagating along the axis of an anisotropic plasma waveguide.

2. Consider a cylindrical waveguide with conducting walls of radius a filled with a homogeneous plasma of density n_p in a strong external magnetic field ($H_0^2 \gg 4\pi n_p m_0 c^2$). The self-consistent set of equations describing the propagation of regular waves in such a waveguide consists of Maxwell's equations for the fields and the equations of motion of the plasma particles in these fields. In the axially symmetric case these equations are

$$\left.\begin{aligned} &\frac{dp}{dt} = eE_\parallel; \quad \frac{\partial\rho}{\partial t} + \frac{\partial}{\partial z}(\rho v) = 0,\\ &\frac{\partial H_\perp}{\partial z} + \frac{1}{c}\frac{\partial E_\perp}{\partial t} = 0,\\ &\frac{1}{c}\frac{\partial H_\perp}{\partial t} + \frac{\partial}{\partial z}E_\perp - \frac{\partial E_\parallel}{\partial r} = 0,\\ &\frac{1}{r}\frac{\partial}{\partial r} rH_\perp - \frac{1}{c}\frac{\partial E_\parallel}{\partial t} = \frac{4\pi}{c} e\rho v. \end{aligned}\right\} \tag{1}$$

The solutions of solitary-wave type in which we are interested contain a broad spectrum of wave numbers and can exist in the frequency range in which dispersion is insignificant.[6] In the present case the phase velocity of a linear axially symmetric periodic TM wave depends on frequency as follows:

$$\left.\begin{aligned} &V_m^2(\omega) = \frac{c^2}{1 + \dfrac{\lambda_m^2 c^2}{(\omega_p^2 - \omega^2)a^2}},\\ &\omega_p^2 \equiv \frac{4\pi n_p e^2}{m_0}, \quad J_0(\lambda_m) = 0, \; m = 1, 2, 3 \ldots, \end{aligned}\right\} \tag{2}$$

from which it can be seen that there is no dispersion at frequencies $\omega \ll \omega_p$ ($\omega^2 \gg \omega_{cl}\omega_{ci}$). This means that waves in the form of a superposition of space harmonics moving with the same velocity $V \sim V_s(0)$ can propagate in the waveguide.

Axially symmetric solutions of this type can be determined by introducing the new variables: $\xi \equiv (\omega_p/V)(z - Vt)$; $\eta \equiv r/a$ in Eq. (1). In these variables Eq. (1) exhibits three first integrals

$$\rho(\eta, \xi)u(\eta, \xi) = \beta[\rho(\eta, \xi) - \rho_+], \tag{3a}$$

$$\frac{1 - \beta u}{(1 - u^2)^{1/2}} + \frac{e\varphi}{m_0 c^2} = 1, \quad \beta \equiv V/c, \tag{3b}$$

$$H_\perp(\eta, \xi) - \beta E_\perp(\eta, \xi) = 0, \quad u \equiv v/c, \tag{3c}$$

$$E_\perp \equiv -\gamma^2 \frac{1}{a}\frac{\partial\varphi}{\partial\eta}, \quad E_\parallel \equiv -\frac{\omega_p}{V}\frac{\partial\varphi}{\partial\xi}, \quad \gamma \equiv (1 - \beta^2)^{-1/2},$$

in which the constants of integration are determined from the conditions at infinity, where the potential φ and the particle velocities vanish: $\varphi(\pm\infty, \eta) = v(\pm\infty, \eta) = 0$.

Using (3) in (1) and transforming to the dimensionless potential $\Phi \equiv e\varphi/(m_0 V^2)$, we find that the problem of finding the function $\Phi(\eta, \xi)$ reduces to solving the following quasilinear equation of elliptic type:[12]

$$\left.\begin{aligned}&M_0^2\frac{1}{\eta}\frac{\partial}{\partial\eta}\eta\frac{\partial\Phi}{\partial\eta}+\frac{\partial^2\Phi}{\partial\xi^2}+R(\Phi)=0,\\&R(\Phi)\equiv\frac{w(\Phi)}{1-w(\Phi)},\\&w(\Phi)\equiv\frac{u(\Phi)}{\beta}=\frac{1-(1-\beta^2\Phi)\sqrt{1-2\Phi+\beta^2\Phi^2}}{(1-\beta^2\Phi)^2+\beta^2},\\&\Phi_{\max}=\frac{\gamma}{\gamma+1},\quad M_0^2\equiv\frac{V^2\gamma^2}{\omega_p^2a^2},\quad\omega_p^2\equiv\frac{4\pi e^2n_+}{m_0}.\end{aligned}\right\}\qquad(4)$$

We now find the solution to this equation which satisfies the condition that the potential Φ vanish at infinity and at the waveguide walls and the condition that the derivatives of the potential vanish on the axis of the waveguide, i.e.,

$$\Phi(\eta,\ \pm\infty)=\Phi'_\xi(\eta,\ \pm\infty)=\Phi'_\eta(0,\ \xi)=\Phi'_\xi(1,\ \xi)=0. \qquad (5)$$

3. In a frame of reference in which the soliton is at rest, its amplitude decreases (increases) exponentially at large distances from the maximum of potential. A similar dependence holds for time in a laboratory frame of reference. This means that the equivalent soliton frequencies are purely imaginary, so that their phase velocities at small amplitudes are given by expression (2) with the substitution $\omega^2 \to -\Omega^2(\Omega^2 > 0)$. Evidently the phase velocity of an s-type soliton is always greater than the threshold phase velocity $V_m(0)$ of a linear wave with a corresponding radial-harmonic index ($V_c > V_m(0)$). Thus, in order-of-magnitude terms the phase velocity of a solitary wave is determined by the linear density of the plasma and increases monotonically with the latter.

By inserting the constant $V_m(0)$ into Eq. (4) it can be shown that in general this equation does not contain a small parameter. An exception is the case of small amplitudes ($\Phi \ll 1$) considered by Ikezi et al.[7] In this case, for the fundamental solitary wave (with minimum variation of the potential along the radius), it is possible to find analytic expressions for the dependence of the field configuration and dispersion of the wave on its amplitude.

We shall show below that the problem of finding the field configuration and the phase velocity of solitary waves of finite amplitude can be reduced to solving a set of integrodifferential equations. These equations can be used to carry out a semianalytic study up to amplitudes comparable with the maximum possible value.

We represent the potential $\Phi(\eta, \xi)$ as a superposition of waves satisfying boundary conditions (5) on the axis and walls of the waveguide in the linear theory:

$$\Phi(\eta,\ \xi)=\sum_{s=1}^{\infty}J_0(\lambda_s\eta)Z_s(\xi). \qquad (6)$$

Inserting this expression into the initial equation (4) gives a set of coupled nonlinear differential equations[12] for the amplitudes $Z_m(\xi)$:

$$\left(\frac{d^2}{d\xi^2}-M_m^2\right)Z_m(\xi)=-\langle R[\Phi(\eta,\ \xi)]\rangle_\eta^{(m)},\quad M_m^2\equiv\lambda_m^2M_0^2, \qquad (7)$$

where the angular brackets denote an average taken over the cross section of the waveguide with the weight of the harmonic with index s:

$$\langle f(\eta,\ \xi)\rangle_\eta^{(m)}\equiv\frac{\int\limits_0^1 f(\eta,\ \xi)J_0(\lambda_m\eta)\,\eta d\eta}{\int\limits_0^1 J_0^2(\lambda_m\eta)\,\eta d\eta}. \qquad (7a)$$

4. The fundamental mode (m = 1) is the one of most interest for applications, and the rest of the paper will be concerned with it. It is necessary to discuss separately the cases of a low and high linear density of the plasma in the waveguide, which correspond to nonrelativistic and relativistic soliton phase velocities.

Nonrelativistic solitons ($\beta^2 \ll 1$). By neglecting terms of order β^2 in the right sides of (7) and estimating the ratio of the amplitudes of higher ($m \geq 2$) radial harmonics to the amplitude of the fundamental ($m = 1$), it is not hard to see that, even for amplitudes of potential comparable with the maximum permissible for this case [$\Phi_{\max} = 1/2 + 0(\beta^2)$], the contribution of higher radial harmonics is comparatively small.

Remembering that the potential is a slowly varying function of the coordinate (for reasonable amplitudes), the second derivative in the left sides of (7) can be neglected for $m \geq 2$. The problem of finding the dependence of the amplitude of the potential Z_1 on the axial coordinate thus reduces to solving the equation of motion of a particle with coordinate Z_1 in a potential field of force

$$\left(\frac{d^2}{d\xi^2}-M_1^2\right)Z_1=\left\langle\left[1-2\sum_{m=1}^{\infty}J_0(\lambda_m\eta)Z_m(\xi)\right]^{-1/2}-1\right\rangle_\eta^{(1)}, \qquad (8a)$$

$$Z_m(\xi)=\frac{1}{M_m^2}\langle 1-[1-2Z_1J_0(\lambda_1\eta)]^{-1/2}\rangle_\eta^{(m)},\quad m\geqslant 2. \qquad (8b)$$

A numerical solution of (8) shows that these relationships can be used to find the form of the potential and its phase velocity up to $\Phi \simeq 0.8\Phi_{\max}$. At the upper end of this interval the contribution to (8a) resulting from the incorporation of (8b) does not exceed 10% of the total potential. These terms can thus be neglected in the region $\Phi \leq (0.5\text{-}0.6)\Phi_{\max}$, and we obtain an explicit expression for the first integral of (8a):

$$\left(\frac{dZ_1}{d\xi}\right)^2-M_1^2Z_1^2=\frac{4Z_1}{J_1(\lambda_1)\lambda_1}+\frac{2}{N_1}\int\limits_0^1\{[1-2Z_1J_0(\lambda_1\eta)]^{1/2}-1\}\,\eta d\eta, \qquad (9)$$

$$N_1\equiv\int\limits_0^1 J_0^2(\lambda_1\eta)\,\eta d\eta=\frac{1}{2}J_1^2(\lambda_1),$$

in which the constant of integration and the relative phase velocity of the wave M_1 (the Mach number of this wave) are expressed through the amplitude A:

$$M_1^2\equiv\frac{1}{N_1A^2}\left\{1-2\int\limits_0^1\eta d\eta\left[\sqrt{1-2AJ_0(\lambda_1\eta)}-AJ_0(\lambda_1\eta)\right]\right\}. \qquad (10)$$

For $A \ll 1$, (9) and (10) give the dispersion and field configuration of the small-amplitude nonrelativistic solitary wave investigated by Ikezi et al.[7]

Equations (8)-(10) are used to calculate the potential on the waveguide axis ($\eta = 0$) as a function of the axial coordinate and the phase velocity of the wave M_1 as a function of amplitude A. The results of the calculation are shown

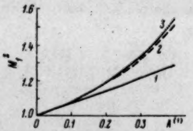

Fig. 1. Phase velocity of nonrelativistic soliton vs amplitude $A^{(1)}$ of first harmonic of potential. 1) Ikezi et al.[7] theory of weakly nonlinear soliton; 2) single-mode approximation ($Z_m = 0$, $m \geq 2$); 3) dispersion allowing for second harmonic ($m = 2$).

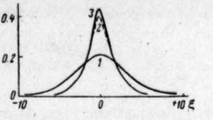

Fig. 2. Potential of nonrelativistic soliton on waveguide axis ($\eta = 0$) vs axial coordinate. $A^{(1)}$: 1) 0.2; 2) 0.4 (ignoring second harmonic); 3) 0.4 (allowing for second harmonic).

in Figs. 1 and 2. With increasing amplitude the soliton phase velocity increases more rapidly than the linear law predicted by the weakly nonlinear theory.[7] However, even for A = 0.4 this velocity of the soliton exceeds the threshold value $[V_1(0)]$ by no more than 25% ($M_1 = 1.25$). Allowing for terms (8b) gives a correction to the phase velocity which is less than 1.5%.

Physically, the relatively small contribution made by the harmonics to the field configuration and the dispersion of the fundamental wave (m = 1) comes about because the potential of this wave reaches a maximum only in a restricted (with respect to ξ and η) region near the waveguide axis. Only in this region of coordinates is the dependence of the dimensionless plasma density R on the potential Φ essentially nonlinear [see (4)]. The phase velocity of the wave and the amplitude of the harmonics of the potential [see (8)] are, however, determined by integrals over the entire cross section of the waveguide, in which the region of strong nonlinearity ($\eta < 1$) gives a relatively small contribution.

It can be seen from Fig. 1 that even for the maximum of the considered values of A the half-width of the pulse is quite large, $\Delta(A = 0.4) = 3.0$. Neglecting terms $\sim d^2/d\xi^2$ in the left sides of (8b) is thus justified. These terms begin to play a significant role when $\Phi \sim \Phi_{\max}$. However, in this region of soliton amplitudes the solution of the present problem in the hydrodynamic approximation probably has no physical significance, since one must allow for the thermal spread of the plasma particles and the damping of the solitary wave resulting from trapping of these particles.[9-11] The maximum plasma temperature for which it is permissible to neglect this damping is given by the inequality $T_{\max} \ll mV^2(1-2A_{\max})$, where $A_{\max}$ is the amplitude of the potential at the maximum.

Relativistic soliton ($\gamma^2 \gg 1$). Equation (2) implies that the phase velocity of the regular waves of an anisotropic plasma waveguide increases linearly with increasing linear density of the plasma at small values of the latter ($\omega_p^2 a^2 < \lambda_1^2 c^2$), approaching the velocity of light when $\omega_p^2 a^2 > \lambda_1^2 c^2$. It is clear that in the latter case the solitary waves can have relativistic phase velocities. There are no solitary waves, however, in a one-dimensional plasma and so one would expect that with subsequent increase of the linear density of the plasma effects would arise preventing such waves from existing. The physical nature of one such effect can be elucidated from an investigation of the initial equation for the potential (4). It can be seen from this equation that for a two-dimensional soliton, unlike the one-dimensional, the average (over the axial coordinate) value of the charge density and so also the electron current [see (3a)] is nonzero:

$$\left.\begin{aligned}\langle R(\Phi)\rangle_\xi &= -M_0^2 \frac{1}{\eta}\frac{d}{d\eta}\left(\eta \frac{d}{d\eta}\langle\Phi\rangle_\xi\right) \neq 0,\\ \langle\rho u\rangle_\xi &= \beta\rho_+ \langle R(\Phi)\rangle_\xi.\end{aligned}\right\} \tag{11}$$

Thus, increasing the linear density of the plasma leads to an increase in the current of electrons in the wave and to an increase in the transverse electric and magnetic fields of this wave:

$$E_\perp \sim \gamma^2 \frac{m_0 c^2}{|e|a}\frac{\partial\Phi}{\partial\eta} \sim 4\pi|e|n_p a, \quad H_\perp \sim E_\perp.$$

The collective properties of the plasma can be conserved only so long as the energy density of the field of the wave propagating in it does not greatly exceed the rest energy density of the plasma particles (the opposite limiting case corresponds to the motion of a rarefied plasma in external fields). This leads to the following estimate for the upper bound on the permissible values of the linear density of the plasma:

$$E_\perp^2 \simeq 4\pi n_p m_0 c^2 \frac{\omega_p^2 a^2}{c^2} \leqslant n_p m_0 c^2 \ll H_0^2. \tag{12a}$$

A second constraint follows from the requirement that the transverse velocity of the plasma particles in the wave ($\nu_\perp \sim cE_\perp/H_0$) be small compared with the axial velocity ($\nu_\parallel \sim c$):

$$4\pi|e|n_p a^2 \ll H_0 a. \tag{12b}$$

The latter inequality is the weaker, and can be satisfied by increasing the external magnetic field.

Solitary waves with amplitudes of the order of the maximum possible value thus cannot exist in plasma waveguides with large values of the plasma linear density; accordingly the phase velocities cannot be arbitrarily close to the velocity of light c.

The dispersion and field configuration of solitary waves for $\beta \sim 1$ can be calculated by the method described above by utilizing Eqs. (6) and (7a) transformed to relationships of form (8):

$$\left(\frac{d^2}{d\xi^2} - M_1^2\right) Z_1 = -\langle R(\Phi)\rangle_\eta^{(1)}, \tag{13a}$$

$$Z_s = \frac{\lambda_1^2}{\lambda_s^2 M_1^2}\langle R[Z_1 J_0(\lambda_1\eta)]\rangle_\eta^{(s)}, \quad s \geqslant 2. \tag{13b}$$

The results of such a calculation show that the characteristics of solitary waves in the region $\beta \sim 1$ (the calculations were performed up to $\gamma_{\max} = 3$) are weakly dependent on the parameter γ: The dispersion and the field configuration of the potential on the waveguide axis in the above-adopted dimensionless variables coincide to within

10% with the results of Figs. 1 and 2 (the absolute values of the potential and the square of the phase velocity of the wave increase in proportion to β^2).

5. The main results of the above analysis can be summarized as follows.

A study has been made of the dispersion and the pulse shape of a solitary wave of finite amplitude propagating along the axis of an anisotropic plasma waveguide with conducting walls. It is shown that up to amplitudes comparable with the maximum permissible value the main contribution to the field configuration of these waves and their phase velocities comes from a single radial harmonic of the field. It is also shown that, under the investigated conditions (a conducting wall), the phase velocity increases monotonically as the potential increases in amplitude. However, even at the maximum possible potential the Mach number for the first radial harmonic (m = 1) does not exceed 1.25. The growth of the amplitude of the transverse electric field with increasing linear density of the plasma keeps the phase velocity from rising to values of the order of c.

Low pressure discharge with high-energy electrons

R. A. Demirkhanov, Yu. V. Kursanov, and L. P. Skripal'

(Submitted May 29, 1973; resubmitted October 20, 1973)
Zh. Tekh. Fiz., 44, 1424-1431 (July 1974)

The potential distribution current and ion energy are found in a plasma with a non-Maxwellian electron distribution. If the density of high-energy electrons is above a critical value, the potential and ion energy at the boundary of the plasma are of the same order as the electron energy. Depending on the form of the electron distribution, the potential is either continuous or undergoes a jump across a space-charge double layer.

The theory of low-pressure discharges initiated by Tonks and Langmuir[1] and developed by others,[2-6] makes use of an equilibrium electron velocity distribution function; the resulting solutions are determined to a large extent by the choice of the distribution. This theory is widely used to explain the physical phenomena occurring in various gaseous discharge devices, in particular the emission properties of plasma ion sources, the interpretation of the results of probe measurements, etc.

In a number of cases the electron velocity distribution may deviate strongly from equilibrium and the results of the theory[1-6] may not be directly applicable. Two examples are reflex and plasma-beam discharges in which, at low pressures, two groups of electrons with differing energies are observed.[7-9] In these cases a theory of the discharge must be based on the kinetic equation; however, the electron velocity distribution often is only known approximately (from experiments). Then, results can be obtained from the theory mentioned above,[1-6] with changes due to the non-Maxwellian electron distribution.

In the present paper, the potential distribution, ion current, and energy spectrum are found for a discharge with plane geometry and an electron velocity distribution in the form of two Maxwellian distributions, and a Maxwellian distribution and a beam. These approximations are often used to describe the electron distributions observed in experiments.[7-9]

We consider a plasma enclosed between two plane electrodes. The potential of the electrons with respect to the plasma is kept negative. As in refs. 1-6 we assume the plasma to consist of electrons, positive ions, and neutral gas at sufficiently low densities that scattering of the ions can be neglected. The ion velocity is taken to be zero when the plasma is produced. We write the Poisson equation for the dimensionless potential, $\eta = -e\varphi/T_1$, in the form of the Tonks–Langmuir equation,[1] taking the z coordinate from the plane of symmetry and taking $\eta(0) = 0$:

$$\left(\frac{T_1}{4\pi e^2}\right)\frac{d^2\eta}{dz^2}=\left(\frac{M}{2T_1}\right)^{1/2}\int\limits_0^{\eta}\frac{g(u)\,du}{\frac{du}{ds}(\eta-u)^{1/2}}-n_e(\eta). \tag{1}$$

Here, $g(u) = n_e(u)n_0(u)\langle\sigma_i\nu_e\rangle$ is the number of ions formed in 1 cm^3/sec; $n_e(u)$ is the electron density; $n_0(u)$ is the neutral gas density; $\langle\sigma_i\nu_e\rangle$ is the average of the product of the effective ionization cross section and the electron velocity; e is the charge of the electron; and T_1 is the temperature (in energy units) of one of the groups of electrons. The integration is carried out with respect to the dimensionless potential $u = -e\varphi/T_1$ from $u = 0$ to $u = \eta$, and S is the coordinate corresponding to potential u.

We limit ourselves to consideration of the region of plasma in which Eq. (1) yields the neutrality condition

$$\left(\frac{M}{2T_1}\right)^{1/2}\int\limits_0^{\eta}\frac{g(u)\,du}{\frac{du}{ds}(\eta-u)^{1/2}}=n_e(\eta). \tag{2}$$

We take the electron distribution $n_e(\eta)$ as follows: 1) two Boltzmann distributions and 2) a Boltzmann distribution and a beam.

1. TWO BOLTZMANN DISTRIBUTIONS

In this case Eq. (2) becomes

$$\left(\frac{M}{2T_1}\right)^{1/2}\int\limits_0^{\eta}\frac{g(u)\,du}{\frac{du}{ds}(\eta-u)^{1/2}}=n_{0e}\left[(1-\lambda)e^{-\eta}+\lambda e^{-\beta\eta}\right], \tag{3}$$

where $\beta = T_1/T_2$ and n_{0e} and λ are, respectively, the total electron density and the relative portion of electrons with temperature T_2 at the coordinate origin ($\eta = 0$).

Applying the Laplace transform[10] to Eq. (3), we obtain the following differential equation for the potential:

$$g(\eta)\frac{dz}{d\eta}=\left(\frac{2T_1}{M}\right)^{1/2}\frac{n_{0e}}{\pi}\left[\frac{1}{\sqrt{\eta}}-(1-\lambda)\,2e^{-\eta}D(\sqrt{\eta})-2\lambda\sqrt{\beta}\,e^{-\beta\eta}D(\sqrt{\beta\eta})\right], \tag{4}$$

where $e^{-\eta}D(\sqrt{\eta}) = e^{-\eta}\int\limits_0^{\sqrt{\eta}} e^{x^2}dx$ is a tabulated function.[11]

We first use Eq. (4) to determine the potential at the boundary at which there is a transition from plasma to a space-charge electrode sheath.

Since the electric field in the sheath is much larger than in the plasma, Tonks and Langmuir,[1] as well as the authors of refs. 2-6, define the plasma boundary by formally assuming the electric field at the boundary to be infinite. Thus, equating the right-hand side of Eq. (4) to zero, we obtain a relationship between the boundary potential η_a and the parameters of the electron distribution, λ and β, [for an arbitrary ion generation distribution $g(\eta)$]:

$$\frac{\lambda}{1-\lambda}=\frac{2\sqrt{\eta_a}e^{-\eta_a}D(\sqrt{\eta_a})-1}{1-2\sqrt{\beta\eta_a}e^{-\beta\eta_a}D(\sqrt{\beta\eta_a})}. \tag{5}$$

For a single Boltzmann distribution η_a is defined from Eq. (5) as a special case with $\lambda = 0$ (absence of electrons with temperature T_2) or with $\lambda = 1$ (absence of electrons with temperature T_1). In these cases Eq. (5) breaks up into two equations

$$\left.\begin{aligned}2\sqrt{\eta_a}e^{-\eta_a}D(\sqrt{\eta_a})&=1,\\2\sqrt{\beta\eta_a}\,e^{-\beta\eta_a}D(\sqrt{\beta\eta_a})&=1,\end{aligned}\right\} \tag{6}$$

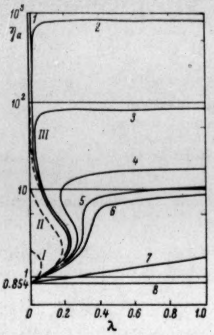

Fig. 1. Dependence of the boundary potential η_a on the parameters of the electron distribution λ, β, and γ. The solid curves refer to the case of two Maxwellian distributions. β: 1) 0; 2) 10^{-3}; 3) 10^{-2}; 4) $5\cdot10^{-2}$; 5) $8.5\cdot10^{-2}$; 6) 10^{-1}; 7) 0.5; 8) 1. Dotted curves refer to the case of a Maxwellian distribution with a beam. γ: I) 2; II) 10; III) 10^2.

to which correspond[3] the known solutions $\eta_a = 0.854$ and $\eta_a = 0.854/\beta$.

The dependence of η_a on arbitrary λ and $\beta \leq 1$ is shown in Fig. 1 (solid curves) and is characterized by the following properties.

1. For variation of λ and β within the limits $0 \leq \lambda \leq 1$ and $0 \leq \beta \leq 1$ the boundary potential η_a may assume any value within $0.854 \leq \eta_a \leq 0.854/\beta$.

2. For $\beta \leq 0.085$ there is a definite minimum $\lambda_1(\beta)$ such that for $\lambda < \lambda_1(\beta)$ the potential of the exterior boundary of the plasma is approximately established at the lower temperature T_1, and for $\lambda > \lambda_1(\beta)$ at the higher temperature T_2. $\lambda_1(\beta)$ decreases with decreasing β, being ~ 0.3 for $\beta = 0.085$ and ~ 0.035 for $\beta = 10^{-2}$. For $\beta > 0.085$ the boundary potential increases monotonically with λ.

3. For $\lambda_1 < \lambda < 0.3$ and $0 \leq \beta < 0.085$ there are three successively increasing values of η_a. The first two correspond to the boundaries of a space-charge double layer which arises in the plasma volume due to a mismatch in the ion and electron densities. The third value of η_a corresponds to the exterior boundary of the plasma adjacent to the electrode positive sheath.

4. If $\lambda > 0.3$ or $\beta > 0.085$, the interior sheath and potential jump are not formed inside the plasma. The boundary potential has a unique value in this case and corresponds to the exterior plasma boundary.

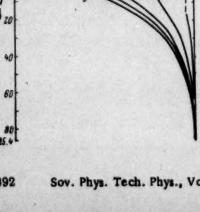

Fig. 2. Potential distributions, η. Here and in Fig. 3 the high-energy electrons have Maxwellian velocity distributions. $\beta = 10^{-2}$, $\alpha = 0$. λ: 1) 0.03; 2) 0.05; 3) 0.1; 4) 0.2; 5) 0.3; 6) 1.

In order to determine the potential distribution it is necessary to prescribe the neutral gas distribution $n_0(z)$ or $n_0(\eta)$ in Eq. (4). In this case only a numerical solution is possible. Thus, we prescribe the ion generation distribution, for example, in the form of the function $g(z) = g_0e^{\alpha z}$, which can always be accomplished by appropriate choice of the (neutral) gas distribution. In this case Eq. (4) has the integral

$$\left.\begin{aligned} &z=\frac{1}{\alpha}\ln[1+\alpha F(\eta)];\\ &F(\eta)=\left|\begin{aligned}&\frac{2I_0}{g_0}\left\{(1-\lambda)e^{-\eta}D(\sqrt{\eta})+\frac{\lambda}{\sqrt{\beta}}e^{-\beta\eta}D(\sqrt{\beta\eta})\right\} \quad \text{for} \quad \eta\leqslant\eta_1,\\ &F(\eta_1)+\frac{2I_0}{g_0}\left\{(1-\lambda)[e^{-\eta}D(\sqrt{\eta})-e^{-\eta_2}D(\sqrt{\eta_2})]\right.\\ &\left.+\frac{\lambda}{\sqrt{\beta}}[e^{-\beta\eta}D\sqrt{\beta\eta})-e^{-\beta\eta_2}D(\sqrt{\beta\eta_2})]\right\} \quad \text{for} \quad \eta_2\leqslant\eta\leqslant\eta_3,\end{aligned}\right.\end{aligned}\right\} \quad (7)$$

where $I_0 = n_{0_e}(2T/M)^{1/2}/\pi$; and η_1, η_2, η_3 are the values of the boundary potential as determined from Eq. (7) or Fig. 1. The quantity $F(\eta)$ is calculated neglecting the thickness of the inner space-charge sheath (if it exists); hence, when $\eta > \eta_2$ the z coordinate is determined using Eq. (7) to an accuracy of the order of the sheath thickness (with a reduction of the value). Calculation of the sheath thickness requires the solution of Eq. (1).

Taking this remark into account, the potential distribution between the origin (of the coordinates) and the exterior plasma boundary, whose coordinate we denote by L, can be written in the form

$$\frac{z}{L}=\frac{\ln[1+\alpha F(\eta)]}{\ln[1+\alpha F(\eta_a)]}, \quad (8)$$

where $\eta_a = \eta_3$, if there is an interior sheath, and $\eta_a = \eta_1$, if there is no interior sheath. This distribution is shown in Fig. 2 for $\alpha = 0$ (uniform ion generation), $\beta = 10^{-2}$, and several values of λ. From the figure it is clear that for sufficiently high densities of hot (T_2) electrons the potential distribution is monotonic with a boundary potential of the order of the temperature T_2. With a reduction in λ a discontinuity in the potential (a space-charge double layer), which divides the plasma into two parts, arises within the plasma volume: an anode part with low potential (on the order of T_1) and a cathode part with a high boundary potential (on the order of T_2). Depending on the reduction in λ the interior sheath is shifted in the direction of the exterior boundary of the plasma. For very small λ (e.g., $\lambda = 0.03$) the interior sheath and the cathode plasma do not develop. For $\beta > 0.085$ the potential distribution is monotonic for any λ.

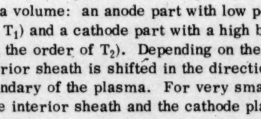

Fig. 3. Density distribution. λ: 1) 0.05; 2) 0.1; 3) 0.2; 4) 0.3; 5) 0.4; 6) 0.5; 7) 0.6; 8) 0.8; 9) 1.

In Fig. 3 the spatial electron density distribution is shown as calculated using Eq. (8) and the known function $n_e(\eta)$ for the case $\alpha = 0$. For $\alpha > 0$ (ion generation increases with z) the curves for the potential and density distributions will lie above the curves for $\alpha = 0$; while for $\alpha < 0$ (generation decreases with z) they will lie below these curves.

We now find the local ion current density

$$I(\eta) = \int_0^{\sqrt{\frac{2T_1}{M}\eta}} v_i f_i(v_i)\, dv_i.$$

Here, $f_i(v_i)$ is the ion velocity distribution and $v_i = (2T_1/M)^{1/2} \cdot (\eta - u)^{1/2}$ is the velocity of ions with energies $W = T_1(\eta - u)$ (in the z direction). Assuming that $f_i(v_i)dv_i$ corresponds to the expression under the integral of Eq. (1), we obtain

$$I(\eta) = \int_0^{\eta} g(u) \frac{dz}{du}\, du = g_0 F(\eta), \tag{9}$$

where $F(\eta)$ is defined in Eq. (7). Thus the ion current density at any point is independent of the ion generation distribution and is completely determined by the electron density distribution. In the case of a single Boltzmann distribution ($\lambda = 0$) the ion current density at the plasma boundary ($\eta = \eta_1$) is obtained from Eqs. (9) and (7),[3]

$$I(\eta_1) = \frac{2n_{0e}}{\pi}\left(\frac{2T}{M}\right)^{1/2} e^{-\eta_1} D(\sqrt{\eta_1}) = 0.344 n_{0e} \left(\frac{2T}{M}\right)^{1/2}. \tag{10}$$

As λ increases the ion current at the exterior boundary increases monotonically from the minimum given in Eq. (10) for $\lambda = 0$ to a maximum value of

$$I(\eta_3) = 0.344 \frac{n_{0e}}{\sqrt{3}} \left(\frac{2T_1}{M}\right)^{1/2}.$$

For fixed λ and β the function $I(\eta)$ is the integrated distribution of ion current over energy (the current of ions with energies from $W = 0$ to $T_1\eta$). Expressions for the differential current distribution and density of the ions at the point with potential η follow from Eq. (9):

$$\left.\begin{aligned} \frac{dI(W)}{dW} &= \frac{1}{T_1} g\left(\eta - \frac{W}{T_1}\right) \frac{dz}{d\eta}\left(\eta - \frac{W}{T_1}\right), \\ \frac{dn_i(W)}{dW} &= \frac{1}{T_1}\left(\frac{M}{2W}\right)^{1/2} g\left(\eta - \frac{W}{T_1}\right) \frac{dz}{d\eta}\left(\eta - \frac{W}{T_1}\right), \end{aligned}\right\} \tag{11}$$

where

$$g\left(\eta - \frac{W}{T_1}\right) \frac{dz}{d\eta}\left(\eta - \frac{W}{T_1}\right)$$

is defined by Eq. (4).

2. BOLTZMANN DISTRIBUTION AND MONOENERGETIC BEAM

In this case Eq. (2) has the form

$$\left(\frac{M}{2T}\right)^{1/2} \int_0^{\eta} \frac{g(\gamma)\, du}{\frac{du}{dz}(\eta - u)^{1/2}} = n_{0e}\left[(1-\lambda)e^{-\eta} + \frac{\lambda\sqrt{\gamma}}{(\gamma - \eta)^{1/2}}\right]. \tag{12}$$

Here, $\gamma = W_e/T$ and λ and W_e are the relative density and energy of the electron beam at $\eta = 0$. For $0 \le \eta \le \gamma$ Eq. (12) has a solution analogous to Eq. (4):

$$g(\eta)\frac{dz}{d\eta} = \frac{n_{0e}}{\pi}\left(\frac{2T}{M}\right)^{1/2}\left[\frac{1}{\sqrt{\eta}} - (1-\lambda)\, 2e^{-\eta} D(\sqrt{\eta}) + \lambda \frac{\sqrt{\eta}}{\gamma - \eta}\right]. \tag{13}$$

From Eq. (13) there follows an equation for the boundary potential η_a:

$$\frac{\lambda}{1-\lambda} = \frac{2\sqrt{\eta_a}\, e^{-\eta_a} D(\sqrt{\eta_a}) - 1}{1 + \frac{\eta_a}{\gamma - \eta_a}}. \tag{14}$$

The dependence of η_a on the parameters of the electron distributions, γ and λ, is shown in the dotted curves of Fig. 1. As in the preceding case, for relative electron beam densities below some critical value $\lambda_1(\gamma)$ an internal space-charge sheath is formed in the plasma whose boundary potentials are η_1 and η_2. For $\lambda > 0.22$ the interior sheath is not formed. A feature of this case is the absence of a solution for a third value of the boundary potential for arbitrary λ and γ.

The potential distribution between the origin of the coordinates and the point $z = L$ with a fixed potential $\eta_L < \gamma$ for the above generation distribution has the form

$$\frac{z}{L} = \frac{\ln|1 + \alpha F_1(\eta)|}{\ln|1 + \alpha F_1(\eta_1)|}; \tag{15}$$

where

$$F_1(\eta) = \left|\begin{aligned} &\frac{I_0}{g_0}\left\{2(1-\lambda)e^{-\eta} D(\sqrt{\eta}) + \lambda\sqrt{\gamma}\ln\left(\frac{\sqrt{\gamma}+\sqrt{\eta}}{\sqrt{\gamma}-\sqrt{\eta}}\right)\right\} \quad \text{for} \quad \eta \leqslant \eta_1, \\ &F_1(\eta_1) + \frac{I_0}{g_0}\left\{2(1-\lambda)\left[e^{-\eta} D(\sqrt{\eta}) - e^{-\eta_2} D(\sqrt{\eta_2})\right]\right. \\ &\left. + \lambda\sqrt{\gamma}\ln\frac{(\sqrt{\gamma}+\sqrt{\eta})(\sqrt{\gamma}-\sqrt{\eta_2})}{(\sqrt{\gamma}-\sqrt{\eta})(\sqrt{\gamma}+\sqrt{\eta_2})}\right\} \quad \text{for} \quad \eta_2 \leqslant \eta \leqslant \eta_L. \end{aligned}\right.$$

This distribution is shown in Fig. 4 for the case $\alpha = 0$, $\gamma = 10^2$ and several values of λ and η_L. The ion current density at the point with potential η is determined by Eq. (9) upon substitution of $F_1(\eta)$ for $F(\eta)$. The distributions of ion current and density (as functions of energy) are determined by Eqs. (11), where

$$g\left(\eta - \frac{W}{T_1}\right) \frac{dz}{d\eta}\left(\eta - \frac{W}{T_1}\right)$$

is determined by Eq. (13).

3. STABILITY OF THE ION CURRENT

It has been assumed above that the potential η increases monotonically from the origin of coordinates to the plasma boundary. In this case there are no trapped

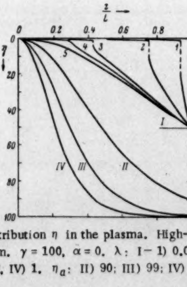

Fig. 4. Potential distribution η in the plasma. High-energy electrons in the form of a beam. γ = 100, α = 0. λ: I – 1) 0.02, 2) 0.05, 3) 0.15, 4) 0.23, 5) 1; II, III, IV) 1. η_a: II) 90; III) 99; IV) 99.9.

ions and all the ions which are generated move to the exterior boundary. The conditions for monotonic variation of the potential as found from Eq. (1) in the linear approximation are

$$\left\langle \frac{1}{W} \right\rangle_{\eta} \leqslant \left(\frac{2}{T_1}\right) \frac{n_{0e}\left[(1-\lambda)e^{-\eta}+\lambda\beta e^{-\beta\eta}\right]+\left(\frac{M}{2T_1}\right)^{1/2} g(\eta)\frac{dz}{d\eta}\frac{1}{\sqrt{\eta}}}{n_{0e}\left[(1-\lambda)e^{-\eta}+\lambda e^{-\beta\eta}\right]} \tag{16}$$

for two Boltzmann electron distributions and

$$\left\langle \frac{1}{W} \right\rangle_{\eta} \leqslant \left(\frac{2}{T}\right) \frac{n_{0e}\left[(1-\lambda)e^{-\eta}-\frac{\lambda\sqrt{\gamma}}{2(\gamma-\eta)^{3/2}}\right]+\left(\frac{M}{2T}\right)^{1/2} g(\eta)\frac{dz}{d\eta}\frac{1}{\sqrt{\eta}}}{n_{0e}\left[(1-\lambda)e^{-\eta}+\frac{\lambda\sqrt{\gamma}}{(\gamma-\eta)^{1/2}}\right]} \tag{16a}$$

for a Boltzmann distribution and a beam, where $\langle 1/W \rangle_{\eta}$ is the mean value of the reciprocal of the ion energy at an arbitrary point $\eta > 0$. These conditions are clearly satisfied for any $\eta < \eta_a$ if they are satisfied on the plasma boundary ($dz/d\eta \to 0$):

$$\left\langle \frac{1}{W} \right\rangle_{\eta_a} \leqslant \left(\frac{2}{T_1}\right) \frac{(1-\lambda)e^{-\eta_a}+\lambda\beta e^{-\beta\eta_a}}{(1-\lambda)e^{-\eta_a}+\lambda e^{-\beta\eta_a}}, \tag{17}$$

and

$$\left\langle \frac{1}{W} \right\rangle_{\eta_a} \leqslant \left(\frac{2}{T}\right) \frac{(1-\lambda)e^{-\eta_a}-\frac{\lambda\sqrt{\gamma}}{2(\gamma-\eta_a)^{3/2}}}{(1-\lambda)e^{-\eta_a}+\frac{\lambda\sqrt{\gamma}}{(\gamma-\eta_a)^{1/2}}}. \tag{17a}$$

Thus, the inequalities in Eq. (17) represent a condition for a monotonic potential distribution as a whole, including the plasma boundary. For $\lambda = 0$ the well-known "instability criterion" follows from Eq. (17) for the case of a single Boltzmann distribution:[3]

$$\left\langle \frac{1}{W} \right\rangle_{\eta_a} \leqslant \frac{2}{T}. \tag{18}$$

The inequalities (17) must be supplemented by conditions for the existence of solutions to Eq. (1) which satisfy the boundary values $\eta(0) = 0$ and $(d\eta/dz)_{z=0} = 0$. These additional conditions are obtained from the expression for the first integral of Eq. (1) in the range from $\eta = 0$ to arbitrary η and may be written in the form

$$\langle W(\eta) \rangle \geqslant \frac{T_1}{2} \frac{(1-\lambda)(1-e^{-\eta})+\frac{\lambda}{\beta}(1-e^{-\beta\eta})}{(1-\lambda)e^{-\eta}+\lambda e^{-\beta\eta}} \tag{19}$$

for two Boltzmann electron distributions and

$$\langle W(\eta) \rangle \geqslant \frac{T}{2} \frac{(1-\lambda)(1-e^{-\eta})+\lambda\gamma 2\left[\left(1-\frac{\eta}{\gamma}\right)^{1/2}-1\right]}{(1-\lambda)e^{-\eta}+\frac{\lambda\sqrt{\gamma}}{(\gamma-\eta)^{1/2}}} \tag{19a}$$

for a Boltzmann distribution and a beam, where $\langle W(\eta) \rangle$ is the mean energy of the ions at the point η. Equalities in Eqs. (17) and (19) correspond to solutions of Eq. (2).

The conditions Eqs. (17) and (19) are necessary for the existence of the preceding stationary solutions (but not sufficient). If either of them is not satisfied there is either no solution for Eq. (1) and the given boundary conditions, or the potential distribution is oscillatory. In the latter case, due to buildup of the generated ions in potential wells the positive charge increases with time for constant electron density and a stationary solution becomes impossible.

CONCLUSION

It follows from the above solutions that the presence of a group of high-energy electrons with a Maxwellian velocity distribution or in the form of a beam, and with a relative density higher than a few percent, leads to a drop in the plasma potential of the order of the temperature of these electrons. Depending on the relative densities and energies of the high- and low-energy electrons the potential distribution may either be continuous or undergo jumps corresponding to the formation of a space-charge double layer. The current and energy spectrum of the ions at any point of the discharge are determined only by the electron velocity distribution, being independent of the potential distribution and the ion generation distribution in the plasma.

These results explain the mechanism by which ions are accelerated to high energies in discharges which have high-energy electrons.[7,12] More accurate solutions require that the initial ion velocities, the spread in velocity of the electron beam, and the recombination of ions with neutral atoms be taken into account.

Stabilization of the major radius of toroidal pinch by a feedback system

V. V. Arsenin

(Submitted June 4, 1973)
Zh. Tekh. Fiz., 44, 1432-1436 (July 1974)

The stabilization of the major radius of a toroidal current-carrying pinch by a feedback system is considered. The case in which the control field is homogeneous over the torus has been studied earlier. In the present work the more general case of an inhomogeneous winding density is considered. In particular, the winding can be local. A dispersion equation of the oscillations is obtained taking account of the mode coupling resulting from the breakdown of axial symmetry. When the frequency (growth rate) of oscillations of the major radius in the absence of stabilization is much less than the frequencies of the helical modes the coupling is weak. In the stable state the control field appears in the form of an average taken over a circuit around the torus.

The elongation of a toroidal current-carrying pinch can be balanced by a Lorentz force due to a magnetic field perpendicular to the plane of the torus. Such a field arises, for example, if the plasma is surrounded by a metal wall.[1] Stable equilibrium in the absence of a wall can be attained by using a feedback system, which controls the value of the transverse field. The efficiency of such a system has been demonstrated in experiments on a Tokamak[2]. In these experiments the control field generated by a special winding is constant over the torus (the case considered theoretically in ref. 3). This kind of stabilizing field corresponds to the perturbation which it is desired to quench. However, it is convenient to achieve stabilization of the major radius using an inhomogeneous control winding (such a system simplifies access to the plasma for diagnostics). In the present work we analyze a stabilizing system of the type of ref. 2 with an inhomogeneous winding density. We obtain a dispersion equation taking account of the mode coupling arising as a result of the breakdown in axial symmetry. When the frequency (growth rate) of the oscillations of the major radius in the absence of stabilization is much lower than the frequencies of the helical modes, the coupling is weak (the pinch is not deflected). The oscillations of the major radius prove to be affected only by the value of the control field averaged over the torus.

We consider a toroidal pinch of an ideally conducting incompressible fluid of density ρ with longitudinal current J uniformly distributed over the cross section in a longitudinal field $B_{\parallel}$. Let the major radius of the pinch be R, and the minor radius be a. We introduce a radial coordinate r, measured from the circular axis, and two angular coordinates: θ – along the small circuit, and φ – along the large circuit. We consider the stability of a pinch with respect to displacements

$$\xi_r = \sum_{m,n} \xi_{m,n} \exp(im\theta - in\varphi - i\omega t),$$

where $m = \pm 1$, $n \ll R/a$. In the absence of external ("stabilizing") currents, the oscillations of particular harmonics m and n are independent (neglecting weak toroidal effects).

We assume that the longitudinal field $B_{\parallel}$ is much greater than the field of the current $B_J = 2J/(ca)$, so that $q = aB_{\parallel}/(RB_J) > 1$, and perturbations with $n \neq 0$ (helical modes), satisfying (neglecting toroidal effects) the equations

$$\xi_{m,n} + \omega^2_{m,n}\xi_{m,n} = 0, \tag{1}$$

where

$$\omega^2_{m,n} = 2\Omega_A^2[(m - nq)^2 - m(m - nq)], \quad \Omega_A = \frac{B_J}{\sqrt{4\pi\rho}\, a}$$

is the Alfvén frequency, are stable.

We assume that the pinch is unstable (with growth rate γ) with respect to variations in the major radius ($n = 0$, $\xi_{1,0} = \xi_{-1,0}$), and the oscillations are described by the equation

$$\xi_{\pm 1,0} - \gamma^2\xi_{\pm 1,0} = 0. \tag{2}$$

These perturbations can be stabilized by applying to the fluid perpendicular to the plane of the torus a magnetic field B_Z, proportional to the displacement δR, $B_Z = \alpha \cdot (ca^2)^{-1}[J \cdot \delta R]$. Taking account of the force $(1/c)[JB_Z]$, we have

$$\xi_{\pm 1,0} - \gamma^2\xi_{\pm 1,0} + \alpha\Omega_A^2\xi_{\pm 1,0} = 0. \tag{3}$$

For stability it is sufficient that

$$\alpha > \left(\frac{\gamma}{\Omega_A}\right)^2. \tag{4}$$

The required field B_Z is produced by the winding $r = d$, $a < d \ll R$, which is homogeneous with respect to φ. The current excited in the winding by the "primary" magnetic perturbation field (i.e., the field that would exist outside the plasma in the absence of the winding), and the coefficient α, depend on the impedance of the winding and the spatial structure of the primary field. Because of the φ homogeneity the winding affects only the perturbation field, as averaged over the torus. Thus, a homogeneous winding automatically acts on spatial modes for which $n = 0$.

The problem of finding the frequency spectrum of the plasma + winding system is complicated in the case of interest to us, in which the current in the winding depends on φ. The eigenfunctions are not the separate Fourier harmonics $\exp(in\varphi)$, but are coupled. Below we introduce the dispersion equation for this case.

We represent the density of the surface current $j_\varphi = j(\varphi)\cos\theta\exp(-i\omega t)$, $\operatorname{div} \mathbf{j} = 0$, produced by the winding $r = d$, by the Fourier series

$$\left.\begin{aligned} j_\varphi &= \sum_{m=\pm 1}\sum_n j_{m,n}\exp(im\theta - in\varphi), \\ j_{m,n} &= \frac{1}{4\pi}\int_0^{2\pi} j(\varphi)\exp(in\varphi)\,d\varphi. \end{aligned}\right\} \tag{5}$$

The constant component of current (n = 0) produces in the region r < d a homogeneous (neglecting the toroidality) magnetic field $B_z = (2\pi/c)(j_{1,0} + j_{-1,0})$. Thus, the equation of oscillations of the major radius of the pinch is

$$(\omega^2 + \gamma^2)\xi_{\pm 1,0} + 2\pi\Omega_A^2 \frac{j_{\pm 1,0}a^2}{J} = 0. \tag{6}$$

The harmonics n ≠ 0 in the expansion of the current affect the helical modes. These modes are described by the equation

$$(\omega^2 - \omega_{m,n}^2)\xi_{m,n} + 2\pi m(m - nq)\Omega_A^2 \frac{j_{m,n}a^2}{J} = 0. \tag{7}$$

For j = 0, Eqs. (6) and (7) are transformed, respectively, into (2) and (1).

The density of the current induced in the winding, which appears in Eqs. (6) and (7), depends, in turn, on the displacement of the pinch. We find this density under the assumption that the winding consists of N series-connected loops with angular dimensions $\Delta\theta \ll 1$ and $\Delta\varphi$ (see Fig. 1), the centers of which are distributed over the surface r = d with angular density $(N/4)\, n(\varphi) \sin\theta$ (the variation in sign indicates a difference in orientation). The $n(\varphi)$ distribution is normalized to unity. The flux of the perturbation magnetic field $B_r' = \sum_{m,n} B_{m,n} \exp(im\theta - in\varphi)$, in terms of a single loop, is

$$\Phi = Rd\Delta\theta \sum_n \frac{2}{n} \sin\frac{n\Delta\varphi}{2} \sum_m B_{m,n} \exp(im\theta_0 - in\varphi_0), \tag{8}$$

where θ_0 and φ_0 are the angular coordinates of the center of the loop. The flux through the entire winding is

$$\Phi = i\frac{\pi}{4} NRd\Delta\theta \sum_n \frac{2}{n} \sin\frac{n\Delta\varphi}{2} C_n \sum_{m=\pm 1} mB_{m,n}, \tag{9}$$

where

$$C_n = \frac{1}{2\pi}\int_0^{2\pi} n(\varphi) \exp(-in\varphi)\, d\varphi \tag{10}$$

(for the assumed normalization, $C_0 = 1$).

A current

$$I = -\frac{i\omega}{cZ}\Phi \tag{11}$$

is excited in the winding, where Z is the impedance of the winding. If the inductive component of the impedance is calculated[1] under the assumption that the volume of the plasma is occupied by a solid ideal conductor, then the $B_{m,n}$ in (9) are the harmonics of the primary perturbation field

$$B_{m,n} = i(m - nq) B_J \frac{\xi_{m,n}}{d} \tag{12}$$

(see, e.g., ref. 4).

As a result we have

$$I = \frac{i\omega\pi NR\Delta\theta B_J}{4cZ} \sum_n \frac{2}{n} \sin\frac{n\Delta\varphi}{2} C_n \sum_{m=\pm 1} m(m - nq)\xi_{m,n}. \tag{13}$$

We calculate the surface current density. The density produced by a single winding is

$$j_\varphi = \frac{I}{d} f(\varphi - \varphi_0)\left[\delta\left(\theta - \theta_0 - \frac{\Delta\theta}{2}\right) - \delta\left(\theta - \theta_0 + \frac{\Delta\theta}{2}\right)\right], \tag{14}$$

where

$$f = \begin{cases} 1, & |\varphi - \varphi_0| < \frac{\Delta\varphi}{2}, \\ 0, & |\varphi - \varphi_0| > \frac{\Delta\varphi}{2}. \end{cases}$$

The total current density is obtained by integrating (14) over θ_0, φ_0 with weight factor $(N/4) \sin\theta_0 n(\varphi_0)$. The Fourier harmonics of the current density of interest to us will be (since $\Delta\theta \ll 1$)

$$j_{m,n} = \frac{IN\Delta\theta}{8d} \frac{2}{n} \sin\frac{n\Delta\varphi}{2} C_n^* \tag{15}$$

(the asterisk denotes the complex conjugate).

In order to obtain the dispersion equation we express $\xi_{m,n}$ from (6), (7), and (15) in terms of I, and we substitute in (13). We obtain

$$1 = -\frac{i\omega}{c^2 Z}(\pi N\Delta\theta)^2 \frac{Ra}{d} \Omega_A^2 \left[\frac{(\Delta\varphi)^2}{\omega^2 + \gamma^2} + \frac{1}{2}\sum_{n\neq 0}\left(\frac{2}{n}\sin\frac{n\Delta\varphi}{2}\right)^2 |C_n|^2 \sum_{m=\pm 1} \frac{(m - nq)^2}{\omega^2 + \omega_{m,n}^2}\right]. \tag{16}$$

For $N\Delta\theta \to 0$ or $\Delta\varphi = 0$ this equation breaks up into an equation for the separate harmonics (1) and (2). When one loop occupies the entire major circumference of the torus ($\Delta\varphi = 2\pi$), Eq. (16) contains only the term with the mean field

$$1 = -\frac{i\omega}{c^2 Z}(2\pi^2 N\Delta\theta)^2 \frac{Ra}{d} \frac{\Omega_A^2}{\omega^2 + \gamma^2}. \tag{17}$$

The helical modes also drop out of Eq. (16) when the loops (with arbitrary $\Delta\varphi$) are distributed uniformly over the large circuit of the torus ($C_n = 0$ for n ≠ 0).

In the absence of current in the winding ($|Z| \to \infty$), Eq. (17) has the unstable root $\omega = i\gamma$. Stabilization holds if the impedance Z is purely inductive ($Z = -i\omega L/c^2$) and

$$0 < L < (2\pi^2 N\Delta\theta)^2 \frac{Ra}{d} \frac{\Omega_A^2}{\gamma^2}. \tag{18}$$

The required impedance with small inductance is

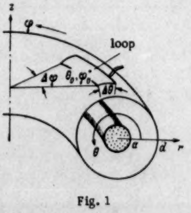

Fig. 1

achieved by connecting the winding to an external two-terminal network with negative resistance, which compensates the resistance of the winding, and a negative inductance.[3]

For $\Delta\varphi < 2\pi$ and arbitrary density of the winding, the dispersion equation (16) is unwieldy. We consider the interesting case in which the instability growth rate of the major radius γ is much smaller than the frequencies of the helical modes $\omega_{m,n}$ (order of the Alfvén frequency Ω_A). In the frequency region $|\omega| \lesssim \gamma$ the sum of terms with $n \neq 0$ in (16) is small. The equation of the low-frequency oscillations takes the form

$$1 = \frac{i\omega}{c^2 Z} (\pi N \Delta\theta\Delta\varphi)^2 \frac{Ra}{d} \frac{\Omega_A^2}{\omega^2 + \gamma^2}, \tag{19}$$

and the stability condition for inductive impedance is

$$0 < L < (\pi N \Delta\theta\Delta\varphi)^2 \frac{Ra}{d} \frac{\Omega_A^2}{\gamma^2}. \tag{20}$$

As can be seen from (19), for given $\Delta\varphi$, $\Delta\Theta$ the motion of the pinch depends on the total number of loops N. The distribution of loops over the surface $r = d$ appears in (19) only in terms of the inductance of the winding. For a given N the total impedance Z is fixed (by the choice of the inductance of the external two-terminal network); the motion of the pinch does not depend, in particular, on whether or not the loops are distributed about the torus uniformly, or the winding is local.

The terms with $n \neq 0$ in (16) are important for $\omega \approx \omega_{m,n}$. If the inductance L is not too small, so that $(\pi N \Delta\theta\Delta\varphi)^2 (Ra/d) \sim \gamma^2/\Omega_A^2$, they give stable natural oscillations with frequencies close to the frequencies of the helical modes $\omega_{m,n}$ in the absence of feedback.

We give an expression for the variation in major radius when the given current I(t) is fed into the control winding for a time much less than $1/\gamma$ (programmed control by the position of the pinch)

$$\delta R = \frac{\pi}{2} N \Delta\theta\Delta\varphi \frac{a^2}{d} \Omega_A^2 \int_0^t d\tau \int_0^\tau \frac{I(\alpha)}{J} d\alpha. \tag{21}$$

High-frequency discharge in a mercury – helium mixture

S. D. Vagner, Yu. M. Kagan, A. I. Konstantinov, and I. S. Niskonen

Karelskii Pedagogical Institute, Petrozavodsk

(Submitted September 21, 1973)
Zh. Tekh. Fiz., 44, 1437-1441 (July 1974)

The radial electron distribution function, the ion densities, the densities of atoms in the lower excited levels, and the absolute intensities of certain helium and mercury lines are measured in a high-frequency discharge. The spatial characteristics of the helium and mercury line intensities and the densities of atomic mercury are calculated, allowing for the radial densities of electrons and mercury atoms, and the densities of atoms in the lower excited states.

INTRODUCTION

The properties of discharges in gas – vapor mixtures are closely related to the phenomenon of electrophoresis.[1] Spatial separation of the components of the mixture can occur in both the longitudinal and radial directions. There is essentially no experimental literature on radial electrophoresis, although this phenomenon is of considerable interest in regard to the development of gas discharges in mixtures. Radial electrophoresis and related phenomena can be studied most conveniently in the central part of a high-frequency discharge in which there is no constant longitudinal electric field. Longitudinal electrophoresis does not occur under these conditions.

In the present paper the electrical and optical properties of a high-frequency discharge are investigated in the central part of a cylindrical tube. The radial characteristics of the electron distribution function, the ion densities, the densities of atoms in the lower excited states, and the absolute intensities of some helium and mercury lines are measured.

The measured electron distribution functions and the densities of atoms in the lower excited states are used to calculate the radial densities of the mercury atoms and mercury ions, and the radial characteristics of helium and mercury line intensities. The calculated characteristics are compared with the experimental data.

EXPERIMENTAL TECHNIQUE

The measurements are performed in a tube 34 mm in diameter and 300 mm long. The discharge is excited by a high-frequency oscillator with a balanced output at 28 MHz by means of cylindrical electrodes. The discharge current is measured by two T-22 thermoelectric milliammeters connected directly to the electrodes.

A cylindrical probe 5 mm long and 0.03 mm in radius is placed in the center of the tube and is perpendicular to the tube axis. The probe is moved in the radial direction by means of a magnetic system. Two nickel counterprobes, with an area of 7.6 cm^2 each, are placed symmetrically on the walls. The procedure described in refs. 2 and 3 is used to measure the electron distribution function by the second derivative method.

The ends of the discharge tube contain glass windows, and end-on measurements are made of the radial emission distribution. A micrometer screw is used for radial scans of the discharge tube. The optical system includes a DMR-4 monochromator with a photoelectric recorder. The densities of atoms in the lower excited levels were determined by the reabsorption method with the aid of a planar mirror.[4] The absolute line intensities are obtained from an SI-300 temperature-calibrated lamp.

The basic measurements are carried out at a current of 200 mA, a helium pressure of 0.5 torr, and a mercury vapor pressure of $2 \cdot 10^{-4}$ torr. The mercury vapor pressure is determined by a temperature sidearm with mercury mounted at the center of the tube.

EXPERIMENTAL RESULTS

In Fig. 1, the electron energy distribution function, normalized for the same area, is given for three points along the radius. The shape of the distribution does not vary along the radius and differs from a Maxwellian distribution for potentials larger than the mercury ionization potential. The radial electron density shown in Fig. 2 differs negligibly from the Bessel function. The electron density is determined from the electron current at the space potential. The space potential is taken to be the potential at which the second derivative of the probe current is zero. The average electron velocity is determined from the measured electron distribution function. Figure 2 also gives the radial distributions of the total population of the lower excited mercury levels 6^1P_1 and 6^3P_{012} and the lower excited helium levels 2^3S_1, 2^3P_{012}, 2^1S_0, and 2^1P_1. In interpreting the results it is assumed that the line profiles have a Doppler shape corresponding to room temperature, 300°K. At the $k_0 l$ values occurring in our experiments the fine structure and edge effects can be neglected. It can be seen that the density of atoms in the lower excited states declines more slowly along the radius for mercury than for helium. The distribution of the latter coincides with the Bessel function. The ion parts of the probe characteristic curves are determined simultaneously with the second derivative of the probe current. The simultaneous use of the electron and ion parts of the characteristic curves, as shown in ref. 5, allows the ion densities of the components in the case of a binary mixture to be estimated. The experimental values of the mercury ion density are shown in Fig. 3.

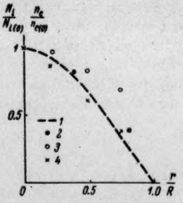

Fig. 2. Radial distribution of electron density and densities of mercury and helium atoms in lower excited levels. 1) Bessel function; 2) distribution of electron density $n_e(0) = 3.4 \cdot 10^{10}\ \mathrm{cm}^{-3}$; 3) distribution of the total population of mercury levels 6^1P_1 and 6^3P_{012}, $N_i(O) = 1.1 \cdot 10^{11}\ \mathrm{cm}^{-3}$; 4) distribution of the total population of helium levels 2^1S_0, 2^1P_1, 2^3S_1, 2^3P_{012}, $N_i(O) = 6 \cdot 10^{11}\ \mathrm{cm}^{-3}$.

The absolute values of the measured parameters at the tube axis are given under the captions to the figures.

The radial distribution of mercury neutrals and ions can be estimated by solving the balance equations for the neutral and charged particles[6,7]

$$\operatorname{div}\left(-D_a \frac{dn}{dr}\right) = (z_1 + z_2) n_e + \alpha, \tag{1}$$

$$-D_a \frac{dn}{dr} = D \frac{dN}{dr}, \tag{2}$$

where n_e, n, and N are the densities of the electrons, mercury ions, and neutral mercury atoms, respectively, z_1 and z_2 are the frequencies of direct and cascade ionization, α is the number of ionizations per unit volume per unit time due to the Penning effect, D_a is the ambipolar diffusion coefficient of mercury ions, and D is the diffusion coefficient of neutral mercury atoms. The flux of metastable mercury atoms can be neglected in Eq. (2) since the diffusion coefficient of metastable mercury atoms is much smaller than the ambipolar diffusion coefficient of mercury ions, and the density gradients of these particles differ negligibly (see Figs. 2 and 3). After substitution of (2) into (1), in the case of cylindrical geometry for the radial component, Eq. (1) transforms to

$$\frac{d^2N}{dr^2} + \frac{1}{r}\frac{dN}{dr} = \frac{z_1 + z_2}{D} n_e + \frac{\alpha}{D}. \tag{3}$$

The radial density N is approximated by

$$N(r) = N(R) - \Delta N J_0\left(2.4 \frac{r}{R}\right), \tag{4}$$

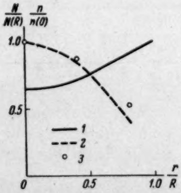

Fig. 3. Radial distribution of densities of neutral mercury atoms and ions. 1) Calculated density of neutral mercury atoms $N(O) = 4.5 \cdot 10^{12}\ \mathrm{cm}^{-3}$; 2) calculated density of mercury ions; 3) experimental values of mercury ion density $n(0) = 1.9 \cdot 10^{10}\ \mathrm{cm}^{-3}$.

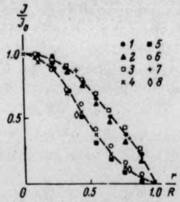

Fig. 4. Radial distribution of radiation intensity of mercury and helium. Mercury: 1) 4047; 2) 4358; 3) 5461 Å; 7) calculated excitation of the 7^3S_1 level. Helium: 4) 5015; 5) 5876; 6) 3888 Å; 8) calculated excitation of 3^1P_1 level.

where N(R) is the density of atomic mercury at the wall determined from the mercury temperature in the sidearm, ΔN is the difference in the densities of atomic mercury at the wall and at the axis of the tube, and $J_0\,(2.4\ r/R)$ is the zeroth-order Bessel function. Substitution of (4) into (3) gives for r = 0

$$\Delta N = \frac{R^2}{5.8}\left[\frac{(z_1 + z_2) n_e + \alpha}{D}\right]. \tag{5}$$

Thus, if the values of z_1, z_2, α, n_e, and D are known at the center of the tube, the value of ΔN can be estimated.

The first calculation of z_1 and α does not allow for the decreased density of atomic mercury at the axis of the tube. Then, the method of successive approximations is used to refine the values of z_1 and α, and thus of ΔN.

The ionization rates of z_1 and z_2 are calculated from the measured electron distribution functions. To calculate direct ionization the experimental value of the cross section of the process is used.[8] Cascade ionization is calculated from the experimental values of the populations of the lower excited levels. The cross section of this process is approximated by an expression taken from ref. 9.

The value of the diffusion coefficient of atomic mercury and helium is not known to us. The data[10] indicate that the diffusion coefficients for atoms of different elements in helium, in the cases where they are known, are close to the corresponding values for the diffusion coefficients in hydrogen. To estimate ΔN, therefore, D was taken to be the value of the diffusion coefficient of atomic mercury in hydrogen given in ref. 10.

The density of atomic mercury obtained is shown in Fig. 3. The density at the axis is roughly 35% smaller than at the wall.

The corresponding calculation for helium gives a value of the order of 0.02%. The possible radial gradients of the gas temperature produce effects that considerably exceed the indicated value. Therefore, a calculation of the radial density of atomic helium must allow for the gas temperature gradient.

Using Eqs. (2) and (4), and the relationship between the fluxes and the corresponding diffusion coefficients, the following expression can be obtained for the radial distribution of atomic mercury:

$$n(r) = n(0) - \frac{D\Delta N}{D_a}\left[1 - J_0\left(2.4 \frac{r}{R}\right)\right]. \tag{6}$$

To calculate D_a the mobility of mercury ions in helium is used.[8] An equation similar to (6) is not used to calculate the radial distribution of helium ions due to the lack of sufficiently precise values for the difference between the densities of atomic helium at the axis and the wall of the tube.

Figure 3 gives the radial density of mercury ions calculated from Eq. (6). Good agreement with experiment is shown.

The measured radial radiation intensities of some helium and mercury lines are shown in Fig. 4. This figure also gives the calculated excitation frequencies of the emitting levels for mercury at 4046, 4358, and 5461 Å and for helium at 5015 Å. The excitation calculations for mercury include both direct and cascade processes. The Fabrikant approximation and experimental values of the cross sections[12] are used to calculate direct excitation. Cascade excitation is calculated using the cross section approximation given in ref. 9. Only cascade processes are included in the calculation of helium excitation, which employs the tables given in ref. 13.

The agreement between the experimental and calculated values makes it possible to conclude that the assumptions as to the nature of the excitation processes are valid.

Thus, the differences in the radial distribution of emission by helium and mercury lines are due to the difference in the excitation processes, the radial densities of lower excited atoms of helium and mercury, and to the decrease in the density of normal mercury atoms at the axis of the tube resulting from electrophoresis.

Effect of ionization and excitation on the penetration of an electromagnetic wave into a weakly ionized plasma

A. G. Boev and A. V. Prokopov
Institute of Radiophysics and Electronics,
Academy of Sciences of the Ukrainian SSR, Khar'kov
(Submitted July 17, 1973)
Zh. Tekh. Fiz., 44, 1442-1447 (July 1974)

The effect of excitation and ionization on the spatial structure of a low-frequency electromagnetic field ($\omega \ll \nu$) in a plasma is analyzed. It is shown that consideration of these processes leads to a qualitatively different dependence of skin depth (a decrease rather than an increase) on the amplitude of the incident field as compared with the case in which only elastic processes are considered. Calculated results for the skin depth and the dependence on amplitude are given for a discharge in argon excited by an electromagnetic field with λ = 10 cm.

Although the electron temperature and density are important characteristics in the case of a discharge excited by an electromagnetic field, the depth of penetration is also very important, as is its dependence on field strength. These quantities figure in practical problems such as the determination of the volume of a plasma chemical microwave reactor,[1] the selection of channel diameter for a magnetohydrodynamic generator with microwave ionization,[2] the calculation of the specific power dissipated in a discharge, etc.

The calculation of the depth of field penetration into a plasma (skin depth) is based on solutions of the self-consistent boundary value problem for Maxwell's equations and the balance equations for temperature and density with consideration of such inelastic atomic processes as excitation and ionization being necessary from the very definition of a self-sustaining discharge.

The problem of field penetration into plasma including only elastic atomic processes has been considered;[3,4] the problem has also been considered[5,6] with ionization taken into account (atomic excitation was not considered) with the dependence of the ionization rate ν_i on the electron temperature T_e being taken as

$$\nu_i \sim \exp\left(-\frac{I}{\varkappa T_e}\right). \qquad (1)$$

In calculating the parameters of a microwave discharge in which the electron–neutral collision frequency is much greater than the field frequency, $\nu \gg \omega$, one can exploit the analogy between a microwave discharge and a dc discharge; in the latter the ionization rate is

$$\nu_i = \alpha\left(\frac{E}{p}\right)(\mu p)\frac{E}{p}, \qquad (2)$$

where α(E/p) is the first Townsend coefficient, μ is the electron mobility, and p is pressure.

In this connection, in the present work the effect of excitation and ionization on the spatial structure of a low-frequency electromagnetic field $\omega \ll \nu$ in a plasma is carried out below using the dc description.

1. Consider a half-space x ≥ 0 filled with an atomic gas at pressure p. On the boundary of this half-space there is incident along the normal to the surface a plane, linearly polarized electromagnetic wave

$$E = E_0 e^{i(kx-\omega t)}$$

with amplitude E_0 sufficient to ionize the gas.

The behavior of this wave in the plasma is described by the equation

$$\frac{d^2E}{dx^2} + k^2\varepsilon' E = 0 \qquad (1.1)$$

with the boundary conditions

$$E_{x=+0} = E_{x=-0}, \quad \left.\frac{dE}{dx}\right|_{x=+0} = \left.\frac{dE}{dx}\right|_{x=-0}, \qquad (1.2)$$

which express the continuity of the tangential components of the electric and magnetic fields at the plasma boundary. We assume that the plasma is weakly ionized and neglect electron–electron collisions.

The complex dielectric constant

$$\varepsilon' = 1 - \frac{\omega_0^2}{\omega^2+\nu^2}\left(1 + i\frac{\nu}{\omega}\right) \qquad (1.3)$$

is related to the electron density n through the plasma frequency $\omega_0 = (4\pi e^2 n m^{-1})^{1/2}$ and to the electron temperature T_e through the electron–neutral collision frequency[3]

$$\nu = \nu_0\left(\frac{T_e}{T}\right)^{1/2} \qquad (1.4)$$

(T is the gas temperature). Because of this, Eq. (1.1) must be solved simultaneously with the balance equations for electron temperature

$$\frac{e^2|E|^2}{m(\omega^2+\nu^2)} = 3\varkappa\delta(T_e - T) \qquad (1.5)$$

and electron density

$$\rho n = \nu_i(|E|), \qquad (1.6)$$

where ν_i is the ionization rate, ρ is the coefficient of volume recombination, δ is the average fractional energy transferred to an atom by an electron in a single collision, and $\varkappa$ is the Boltzmann constant.

Equations (1.5) and (1.6) do not contain terms with spatial derivatives and consequently do not take account of such processes as thermal conductivity, diffusion, and redistribution of electron density because of plasma heating in a nonuniform field, i.e., they determine the local dependence of temperature and density on the field. Thus, they are valid only when

$$l\delta^{-1/2} \ll L, \quad \left(\frac{D_a}{\rho n}\right)^{1/2} \ll L, \qquad (1.7)$$

where l is the mean free path, D_a is the coefficient of ambipolar diffusion, and L is the characteristic scale length

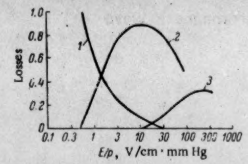

Fig. 1. Distribution of energy losses in an argon discharge.[9]

for field variation in the plasma.

In the following we shall be interested in the behavior of an electromagnetic wave with a frequency ω satisfying the inequality

$$\omega \ll \nu \leqslant \omega_0,$$

which is equivalent to the consideration of a highly damped wave.

2. Consideration of inelastic collisions in the equation for temperature balance (1.5) can be achieved by the introduction of a certain effective parameter

$$\delta = \delta_e + \delta_{in}, \tag{2.1}$$

which can characterize the average fractional electron energy transferred to a heavy neutral[3] in both elastic collisions, δ_e, and inelastic collisions, δ_{in}. The calculation of δ implies a knowledge of the detailed picture of the distribution of the energy supplied to the discharge among the various processes (elastic and inelastic) and generally requires the solution of the kinetic equation.

The energy distribution per unit volume among the various processes was determined by Druyvestyn and Penning[9] as a function of electric field for a dc discharge in certain gases (Ar, Ne, N_2). Figure 1 shows a diagram of the energy distribution for a discharge in argon. Curve 1 characterizes energy losses in elastic collisions, curve 2 losses in excitation, and curve 3 losses in ionization of atoms. The presence of maxima in curves 2 and 3 is associated with the existence of maxima in the cross sections for atomic excitation and ionization.

A picture similar to that shown in Fig. 1 occurs for any atomic gas; the effect of the kind of gas and of the electron energy distribution function appears only in the height and width of the maxima and in a shift of the excitation and ionization regions along the E/p axis.

According to the dc analogy,[8] this feature is also true of a discharge excited by a varying electromagnetic field with frequency ω below the collision frequency ν, with the sole difference that the quantity $E_* = E/\sqrt{2}$ now plays the part of the field E.

Using these results we can approximate the effective parameter δ in the region where the losses in elastic collisions are nonzero by the equation

$$\delta = \delta_e \left\{ 1 + \left(\frac{E_*}{pV_m} \right)^q \right\}, \tag{2.2}$$

where $\delta_e = 2m/M$ is twice the ratio of electron mass to atomic mass; the quantity $V_m = (E_*/p)_m$ characterizes the minimum electron energy for which the losses in inelastic collisions are comparable to the losses in elastic collisions. This quantity and the exponent q depend on the kind of gas.

Since the role of inelastic processes increases as the field increases, the average fractional energy δ transferred to an atom by an electron must also rise, and therefore the exponent q must be positive:

$$q > 0. \tag{2.3}$$

A solution of Eq. (1.5) can easily be found with δ from Eq. (2.2); for the case $E \gg pV_m$, the electron temperature is a power function of the electric field

$$T_e = A \, |E|^{1-q/2}, \tag{2.4}$$

where

$$A = \left[\frac{e^2 T (\sqrt{2} p V_m)^q}{3 \varkappa \delta_e m \nu_0^2} \right]^{1/2}.$$

As is well known,[3] the electron temperature for the case $\omega \ll \nu$ with only elastic collisions considered increases linearly as the electric field increases, $T_e \sim |E|$. As expected, consideration of inelastic collisions leads to a slower rise in temperature $T_e \sim |E|^{1-q/2}$.

3. The electron density n must be determined from Eq. (1.6) for a given ionization rate ν_i and recombination coefficient ρ:

$$n = \frac{\nu_i(|E|)}{\rho}. \tag{3.1}$$

Generally speaking, the recombination coefficient ρ depends on the value of the field E; however, following refs. 5 and 6, we shall assume it to be constant in the subsequent development; to determine the dependence of ionization coefficient on field amplitude we use the analogy of a low frequency discharge with $\omega \ll \nu$ to a dc discharge.

In the theory of a dc discharge the following equation is used for the ionization rate:[9]

$$\nu_i = \alpha \left(\frac{|E|}{p} \right) (\mu p) \frac{|E|}{p}, \tag{3.2}$$

where $\alpha(|E|/p)$ is the so-called first Townsend ionization coefficient and μ is the electron mobility. Experimental measurements[10] of ν_i and theoretical calculations[11] make it possible to represent the ionization coefficient in the form of a power function:

$$\nu_i = B \left(\frac{|E|}{p} \right)^r, \tag{3.3}$$

where B and the exponent r depend on the kind of gas.

The dependence of the Townsend coefficient α on field is determined by the dependence of the ionization cross section on electron energy and is an increasing function of E/p in the region of all achievable electric fields. When $\omega \ll \nu$ the electron mobility cannot decrease more rapidly than $E^{-1/2}$ as the field increases. This means that the exponent r in Eq. (3.3) is greater than 1/2:

$$r > \frac{1}{2}. \tag{3.4}$$

Thus the dependence of density on electric field, which we shall use subsequently, can be written in the form

$$n = \frac{B}{\rho}\left(\frac{|E|}{\sqrt{2}\,p}\right)^r. \qquad (3.5)$$

4. Using Eq. (2.4) for the electron temperature and Eq. (3.5) for the electron density, the equation for the determination of the electric field in the plasma can be brought to the following form:

$$\frac{d^2E}{dx^2} - iQ\,|E|^{\gamma} E = 0, \qquad (4.1)$$

where $\gamma = r-(1/2) + (q/4)$,

$$Q = \frac{4\pi k e^2 B}{mc\rho\,(\sqrt{2}\,p)^r}\left\{\frac{e^2\nu_0^2\,(\sqrt{2}\,p\,V_m)^q}{3\varkappa\delta_y mT}\right\}^{-1/4}.$$

A nonlinear equation of this type has been investigated;[4] its solution can be written in the form

$$E(x) = E(0)\left(1+\frac{x}{L}\right)^{-(\alpha+i\beta)}, \qquad (4.2)$$

where E(0) is the value of the field at the point x = + 0. By substituting Eq. (4.2) into Eq. (4.1), equating powers of 1 + (x/L), and then eliminating α, β, and L, the value of E(0) is determined by the boundary conditions (1.2). In our case, the dependence of the electric field on the coordinate has the form

$$E(x)| = 2|\zeta|\,E_0\left\{1+\frac{\gamma}{[8+2\gamma]^{1/2}}\frac{\omega}{\quad}x\right\}^{-2/\gamma}, \qquad (4.3)$$

where

$$L = E_0^{-\frac{\gamma}{2+\gamma}}\,\frac{[8+2\gamma]^{1/2}}{\gamma k}\left\{\frac{k^2}{2^{\gamma}Q}\left[1+\frac{\gamma}{2}\right]^{1/2}\right\}^{\frac{1}{2+\gamma}} \qquad (4.4)$$

is a typical scale factor for the variation of field amplitude in the plasma, and

$$|\zeta| = E_0^{-\frac{\gamma}{2+\gamma}}\left\{\frac{k^2}{2^{\gamma}Q}\left[1+\frac{\gamma}{2}\right]^{1/2}\right\}^{\frac{1}{2+\gamma}}$$

is the absolute value of the surface impedance ζ. The region of applicability of solutions of the form (4.2) is discussed in ref. 4.

It is clear from Eqs. (4.3) and (4.4) that the change in plasma properties under the influence of the field leads to qualitatively new results in comparison with linear theory: a slower fall-off of the field within the plasma and of a dependence of the penetration depth L on the amplitude of the incident field E_0. Furthermore, the sign of the derivative dL/dE_0, which characterizes the variation of the depth of penetration with amplitude of the incident field E_0, is determined by the value of the exponent γ.

To clarify the role of inelastic atomic processes on the nature of field penetration into a plasma we discuss Eqs. (4.3) and (4.4) for the following cases.

a) Plasma properties determined by elastic collisions only. In this case

$$\gamma = -\frac{1}{2}, \quad Q = \frac{4\pi k e^2 n}{mc}\left\{\frac{3\varkappa\delta_y mT}{\nu_0^2 e^2}\right\}^{1/4}$$

and

$$|E(x)| \sim E_0^{1/3}\left(1-\frac{x}{|L|}\right)^4, \quad L \sim E_0^{1/3},$$

which agrees with previous results[4] for strong damping. In this case, an increase in the amplitude of the incident field leads to a reduction in plasma conductivity and consequently to an increase in the depth of field penetration $[dL/(dE_0) > 0]$.

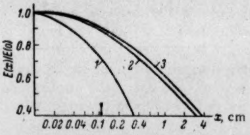

Fig. 2. Spatial distribution of field in plasma.

b) Plasma properties determined by both elastic and inelastic atomic processes.

According to Eqs. (2.3) and (3.4), q > 0 and r > ½ and consequently $\gamma > 0$. Thus, consideration of inelastic processes leads to a change in the sign of the derivative

$$\frac{\partial L}{\partial E_0} < 0$$

and consequently not to an increase as in a) but to a decrease in the depth of penetration L with increasing E_0.

5. We can carry out a further analysis of the effect of inelastic collisions on the nature of electromagnetic field penetration into a plasma by considering a discharge in argon excited by an electromagnetic field with λ = 10 cm and a field E_0 = 500 V/cm, which corresponds to an input power W ~ 3 kW.

The recombination rate is taken to be

$$\rho = 10^{-13}\ \mathrm{cm}^{-3}\cdot\mathrm{sec}^{-1},$$

which is typical for collisional radiative recombination at an electron temperature characteristic of a microwave discharge.[12] For definiteness we assume a gas temperature $T = 10^3$ °K and a pressure of 100 mm Hg. The value of the electron density created by the incident field at the plasma boundary is $n = 10^{13}$ cm^{-3}. Under these conditions, all the assumptions made above are satisfied, as is easily verified.

The dependence of the electric field amplitude normalized to E(0) on the coordinate x measured into the plasma is shown in Fig. 2 for elastic atomic processes only (curve 1), for ionization and elastic processes (curve 2), and for ionization, excitation, and elastic processes (curve 3). The coordinates of the points at which the curves intersect the x axis characterize the distances at which the field amplitude decreases by a factor of e. The arrow on the x axis indicates the depth of the skin layer calculated from linear theory for a constant electron density and temperature $T_e = T$.

It is clear that the failure to consider the effect of in-

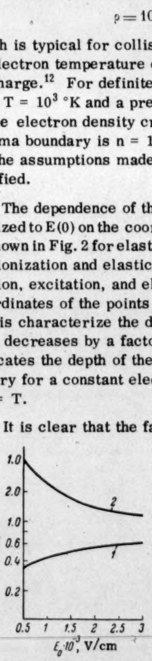

Fig. 3. Depth of field penetration into plasma as a function of incident field amplitude.

elastic processes leads to an error of an order of magnitude in the estimate of the depth of the skin layer; complete neglect of the effect of the field on plasma properties leads to an error of almost two orders of magnitude. At the same time, neglect of the effect of excitation with ionization taken into account is completely valid; this is due to the large difference of the exponents r and $q/4$ (for argon $r = 4.5$ and $q = 1.4$). Physically, this means that atomic excitation influences the optical properties of a discharge rather than the electrical properties. The error in the estimate of skin depth when ionization is not included is due to the neglect of the large drop in conductivity within the plasma.

Figure 3 illustrates the dependence of depth of penetration on E_0 for electron heating alone (curve 1) and for electron heating plus atomic excitation and ionization (curve 2). The difference in the curves is due to the difference in the effect of collision frequency and electron density on plasma conductivity.

The authors thank A. P. Motornenko and Yu. G. Gurevich for discussion and F. G. Bass for his interest.

Optical investigation of a turbulent plasma

Ya. F. Volkov, V. G. Dyatlov, and N. I. Mitina

(Submitted September 24, 1973)
Zh. Tekh. Fiz., 44, 1448-1454 (July 1974)

Θ-pinch plasma is investigated. For a density $n \geq 5 \cdot 10^{14}$ cm^{-3} and ion temperature $T_i \sim 30$ eV there are intense oscillations with electric fields up to 25 kV/cm. These are low-frequency ($\omega \gg \omega_{pe}$) oscillations with vector directed predominantly along the azimuthal plasma current. The plasma turbulence level is of the order of 10^{-3}.

There is a good deal of interest in plasma systems in which a closed confinement magnetic field depends on the plasma currents. These systems are like Tokamaks, in a certain sense but have special features.

One such system is the Θ pinch with a superimposed azimuthal magnetic field and a reverse axial field. This system has been investigated by several authors (refs. 1, 2), from the viewpoint of plasma heating and confinement. A high-power facility (~ 1 MJ) was used in ref. 2 to investigate a dense plasma ($n \sim 10^{16}$ cm^{-3}) formed at initial gas pressures $P \geq 0.1$ torr.

The same authors had investigated a discharge with initial pressure $P \leq 0.01$ torr. For these conditions ($n \sim 10^{14}$ cm^{-3}) the induction electric field generates directed velocities of the order of electron and ion thermal velocities. In this case the plasma can contain runaway electrons which can be accelerated to large energies (ref. 3) when the magnetic configuration favors containment. The interaction of the electron beam with the plasma can excite various instabilities, leading to turbulent heating if the fluctuations are large enough. A turbulent plasma has an anomalously large resistance, leading to accelerated diffusion of the fields into the plasma. This can limit the lifetime of the Θ pinch with an aximuthal magnetic field, since these require that the plasma ring contain a trapped axial field opposite to the external field. The present paper discusses turbulent heating and certain plasma containment processes in such systems in which the plasma parameters are measured by optical methods.

APPARATUS AND METHODS OF MEASUREMENT

The experiments are carried out on an apparatus which differs in size from those described in refs. 1 and 3 (discharge tube diameter D = 22 cm, distance between coils 20 cm) and in the capacitor bank energy (c = 65 μF, V = 20 kV; T = 33 μsec). The discharge is in flowing helium at pressure $P = 5 \cdot 10^{-4}$ to 10^{-2} torr. The optical measurements are similar to those described in refs. 4 and 5. An image of the plasma volume to be investigated is projected on the entrance slit of a type ISP-51 spectrograph employing a five-stage image-converter tube operating in the continuous scan mode. When the system induces a Fabry–Perot etalon the latter is mounted behind the collimating objective of the spectrograph.

The plasma density is measured using the cutoff of a microwave signal at λ = 2, 4, and 8 mm.

The radial electron and ion distributions are determined at different times by taking integral transforms of high-speed scans of the discharge in continuum light or in light from ion lines. The continuum is studied in the wavelength region 4980 Å with a bandwidth of ± 10 Å. There are no spectral lines in this region. The relative ion density distribution is investigated by measuring the light in the He II 4686 Å and C II 4627 Å lines. Since the plasma electron temperature is high ($T_e > 100$ eV), one can assume that the intensities of the continuum and of the C II and He II spectral lines depend only slightly on T_e. In reducing the data of the high-speed scans in continuum light we assume that multiply charged impurity ions have the same distribution as He^{++} ions, i.e., that the effective ion charge is independent of the radius. Then more than 90% of the positively charged plasma component consists of He^{++} ions.

The electron temperature is evaluated from the absorption of the soft x radiation in beryllium. Under the conditions of greatest interest, from the viewpoint of interaction of the electron flux with the plasma ($P \leq 7 \cdot 10^{-3}$ torr), the hard x radiation makes it impossible to measure T_e.

The ion temperature is measured from the Doppler broadening of the C II and O II lines. The instrumental width of the system does not exceed 0.25 Å for the He II 4886 Å and 0.35 Å for C II and O II 4103 Å lines. The instrumental line shape is close to a Lorentzian; therefore the Doppler width of the C II and O II lines is computed from tables for the Voigt profile.

The mean intensity of the turbulent electric fields is calculated from the width of the He II 4686 Å line. This line profile is the sum of the instrumental and Doppler profiles and that due to Stark broadening in the turbulent electric fields. The Stark broadening due to the Coulomb fields of the electrons and ions is negligibly small for $n < 10^{15}$ cm^{-3}. The total width due to instrumental and Doppler broadening is calculated from tables for the Voigt profile. Assuming that the turbulent field intensity distribution is Gaussian, and that the Doppler broadening is much greater than the instrumental width, we compute the linewidth due to the turbulent fields to be

$$\Delta\lambda_s = (\Delta\lambda^2_{\text{mea}} - \Delta\lambda^2_{\text{d.i.}})^{1/2},$$

where $\Delta\lambda_{\text{meas}}$ is the measured linewidth; $\Delta\lambda_{\text{d.i.}}$ is the linewidth due to the Doppler effect and the instrument. With this assumption the width of the He II 468.6 nm line is related to the mean turbulent field intensity $\overline{E}$, according to ref. 6, by the expression $\Delta\lambda_s = 4 \cdot 10^{-2}\,\overline{E}$ (Å, kV/cm).

One probable cause of the appearance of turbulent fields is the ion-acoustic instability. The electrical field of these waves is predominantly directed along the current created by the instability. In the experiment an attempt is made to determine the degree of anisotropy of the electric fields by the method described in ref. 7. The most suitable line for this purpose is Hα, used by the authors of ref. 7. However, in our discharge this hydrogen line does not emit at the times of interest to us, because of the high electron temperature. We therefore use the He II 4686 Å line to evaluate the degree of anisotropy of the fields. Computed values of the σ- and π-component intensities of this line are taken from ref. 8, and difference profiles for the He II line are constructed for two positions of the polaroid filter; 1) with the polaroid transmission axis along the facility axis (y polarization), and 2) with the polaroid axis in a plane perpendicular to the facility axis (z polarization). The degree of anisotropy is given by the ratio E_z/E_y. A series of computed curves is constructed for different values of E_z/E_y and for the specific value of E_z found from the linewidth $\Delta\lambda_s$.

It turns out there is a noticeable difference in the profiles even for an insignificant degree of anisotropy. However, we have not found an accurate value of the anisotropy when the Doppler width of each component is more than 0.5 Å. In our case, therefore, ($\Delta\lambda_{Dop} \sim 1$ Å) we can only indicate the presence of anisotropy.

We have also determined the density of the azimuthal plasma current by magnetic probe measurements.

RESULTS AND DISCUSSION

All the measured results presented here refer to the third half-cycle of the discharge. In this half-cycle closed magnetic configurations and beams of accelerated electrons appear for pressures $5 \cdot 10^{-4}$ torr $\leq P \leq 6 \cdot 10^{-3}$ torr.

Figure 1a shows the dependence of maximum plasma density on the initial gas pressure, obtained with different discharge tube volumes [D_1 = 11 cm (ref. 3), and D_2 = 22 cm] at essentially the same magnetic field parameters. It can be seen that the density is greater by a factor of 3 or 4, in the larger facility, which can be explained as follows. The minimum, i.e., limiting size of the plasma tube, is determined mainly by the ratio between the trapped opposed magnetic field and the external compression field. Since the field intensities are the same, the limiting size of the plasma tube will not differ in the two cases, when the gas-kinetic pressure of the plasma is less than the magnetic pressure ($\beta < 1$). When the "snowplow" model holds, as it does in most Θ pinch cases, the limiting density increases with the volume from which the plasma is collected.

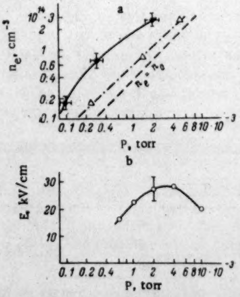

Fig. 1. a) Plasma density as a function of initial pressure: solid line – in an apparatus of tube diameter 22 cm; dot-dash line – in an apparatus whose linear dimensions are less by a factor of 2; broken line – for a plasma density equal to the initial density of the neutral gas ($n_e = n_0$). (b) Turbulent electric field as a function of pressure.

Intense hard γ radiation is observed in ref. 3, due to the flux of accelerated electrons for initial gas pressures $P \leq 3 \cdot 10^{-3}$ torr, which corresponds to a maximum plasma density of $n \leq 1 \cdot 10^{14}$ cm^{-3}. It is interesting that this radiation is observed in the present system at pressures $P \leq 6 \cdot 10^{-13}$ torr, when the density can reach $6 \cdot 10^{14}$ cm^{-3}, although the induction electric field remains the same. This is evidence that a particularly important requisite for the existence of beams of accelerated electrons is that runaway conditions prevail for some of the plasma electrons in the initial phases of the discharge. Following preliminary acceleration at the very beginning of the compression phase, when the plasma density favors runaway, the electrons becomes less sensitive to increased density at later times, i.e., they possess enough initial velocity to escape, even at high densities. Thus, a larger system makes it possible to have large beams of relativistic electrons in a high-density plasma.

When the electron temperature is high enough ($T_e >$ 100 eV) the intensity of the He II line can be expressed as $I_{He\,II} \sim n_e n^+_{He}$, where $n_e n^+_{He}$ are the density of electrons and singly charged ions, respectively, and the continuum intensity can be expressed as $I_c \sim n_e^2$. Then the radial distribution of I_c can be used to determine the radial distribution of the electron density, and the ratio $I_{He\,II}/\sqrt{I_c}$ can be used to determine the radial density distribution of the He$^+$ ions since $I_{He\,II}/\sqrt{I_c} \sim n^+_{He}$. Figure 2 shows the experimental radial distributions of n_e and n^+_{He} at various times during the discharge. Evidently the maximum of the He$^+$ ion density is displaced relative to the maximum electron density. A possible reason is that the ions are formed in the plasma ring from neutrals which come in from the periphery and are heated as they penetrate more into the plasma ring.

Measurements show that the ion temperature depends very little on the neutral gas pressure in this range (0.5 to $10 \cdot 10^{-3}$ torr). After a time $\tau \sim \mu$sec, the ion temperature increases to 30 eV, and then remains essentially constant during the time in which the containment field exists. After the collapse of the magnetic configuration the temperature falls rapidly.

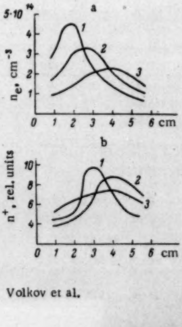

Fig. 2. Radial density distributions for electrons (a) and He$^+$ ions (b). t is in μsec; 1) 1.5 after the start of the magnetic field subperiod; 2 and 3) 3 to 5.

One can attribute the heating of the ions both to adiabatic compression and to turbulent heating. It can be seen from the high-speed scans of the discharge that the first stage of compression down to a radius of ~ 4 cm occurs in approximately 1 μsec; then there is a slow compression down to a radius of 2 to 2.5 cm in a time of 4 to 5 μsec.

The large intensity of the turbulent electric fields in the plasma indicates turbulent heating. The electric field (Fig. 1b) increases with pressure up to $P \sim 1 \cdot 10^{-3}$ torr, reaching a value of 25 kV/cm; it then remains almost constant for pressures up to 5 to $6 \cdot 10^{-3}$ torr. It is difficult to measure the electric field for higher initial pressures because of line broadening due to Holtsmark fields. The observed level of the electric oscillations (25 kV/cm) is reached in a time $\tau \sim 1$ μsec, and remains essentially constant until the breakdown of the plasma formation, for initial pressure $P > 10^{-3}$ torr. For $P < 10^{-3}$ torr the linewidth (which means the electric field also) increases monotonically from the beginning of the half-cycle until the decay of the plasma. Figure 3 shows image-converter tube pictures of the He II line shape for three values of pressure; and these bear out the analysis above.

From the nature and magnitude of the spectral line broadening one can evaluate the frequency range of the electric fluctuations which excite the broadening. A current-carrying plasma containing beams of accelerated electrons can show instabilities at frequencies in the region of the electron frequencies ω_{pe} and the ion plasma frequency ω_{pi}. If we assume that the line broadening results from high-frequency fields (ω_{pe}), then the linewidth $\Delta\lambda_{hf}$ at the maximum plasma density cannot exceed 0.5 Å since $\Delta\lambda_{hf} = \lambda^2(\omega_{pe}/2\pi c)$ (where λ is the wavelength of the spectral line), while the observed widths are as large as 1 Å. This is evidence that strong low-frequency fluctuations are present and, that if there are high-frequency fluctuations, their contribution is small. Moreover, broadening in a field of frequency of the order of ω_{pe} is similar to shock broadening; therefore the radiated light is not polarized. In low-frequency fields, e.g., ion-acoustic fields, the broadening resembles that in a static field, and the light wave is polarized. It is known that the electric vector in ion-acoustic oscillations is directed along the current which has caused the oscillations. The He II 4686 Å line profile radiation in polarized light (Fig. 4) confirms the presence of anisotropy in the electric fluctuations of the plasma in that the electric vector has a predominant direction coinciding with that of the plasma current. This once again confirms the presence of low-frequency oscillations.

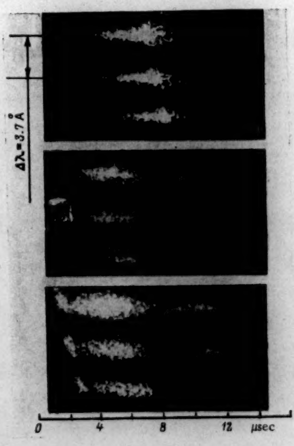

Fig. 3. Image-converter tube photographs of the 4686 Å He II line for different pressures. P, torr: 1) $6 \cdot 10^{-4}$; 2) 10^{-3}; 3) $4 \cdot 10^{-3}$.

The discharge has all the conditions necessary for the excitation of an ion-acoustic instability. Estimates of the current velocity from the measured plasma density ($n \approx 6 \cdot 10^{14}$ cm^{-3}) and the azimuthal current density ($j \approx 10$ kA/cm^2 give

$$u = \frac{j}{en} \approx 10^8 \text{ cm/sec}.$$

Here the thermal velocity of the ions and electrons in $4 \cdot 10^6$ cm/sec, and $V_{Te} \geq 6 \cdot 10^8$ cm/sec, while the acoustic velocity $C_s = 10^7$ cm/sec.

Estimates of the plasma conductivity $\sigma = j/E_\varphi$, where E_φ is the strength of the vortical electric field, give $\sigma \approx 2 \cdot 10^2/\Omega^{-1} \cdot \text{cm}^{-1}$, which corresponds to an effective collision frequency of $\nu_{eff} = 8 \cdot 10^8$ sec^{-1}. We note that this is two orders higher than the Coulomb collision frequency. From the well-known relation (ref. 9) $\nu_{eff} = \alpha\omega_{pe}(w/nT)$, where w is the energy density of the fluctuations, α is a coefficient, and $\alpha \sim 1$, we can find the turbulence level of the fluctuations:

$$\frac{w}{nT} = \frac{\nu_{eff}}{\alpha\omega_{pe}} \approx 6 \cdot 10^{-4}.$$

A comparison of the energy density of the fluctuations $\overline{E}^2/8\pi$ ($\overline{E}^2$ was obtained from the optical measurements) with the density of thermal energy in the plasma gives a turbulence level of $3 \cdot 10^{-3}$. Bearing in mind the tentative nature of the calculations, one can conclude that the agreement is satisfactory.

Thus, the plasma investigated is highly turbulent. The conductivity of such a plasma can be much smaller than the classical value. Therefore, because of the accelerated penetration of the magnetic field into the plasma, the life-

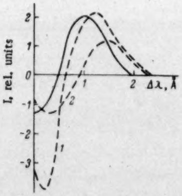

Fig. 4. Difference in the He II λ = 4686 Å line shape with z and y polarization. The solid curve is experimental; the broken lines are theoretical, for $E_z = 30$ kV/cm and level of anisotropy E_z/E_y = 1) 5; 2) 1.5. In the calculations the shape of each individual component is assumed to be gaussian, with $\Delta\lambda_{1/2} = 1$ Å.

time of the trapped magnetic field and, therefore, the lifetime of the closed magnetic configurations in a Θ-pinch system with an azimuthal magnetic field cannot exceed 25 μsec in our case. The fact is that the turbulence produces rapid heating, leading to the undesired limtation on the lifetime of the confinement configuration. It is known that the conductivity of a turbulent plasma increases with density; therefore one can increase the lifetime of the containment configuration by increasing the density. But if we increase the density by increasing the initial gas pressure, it is difficult to obtain a turbulent discharge regime, because of the lighter electric fields that are required. It is therefore desirable to increase the final density by increasing the size of the system. It is then easy to reach critical velocities with a comparatively small electron density, and some of the electrons, being accelerated, can remain runaway electrons during the subsequent density increase due to compression. In this way one can reach the requisite degree of turbulence when the plasma conductivity is large enough.

CONCLUSIONS

It has been shown that in a plasma with density $n \geq 5 \cdot 10^{14}$ cm^{-3} and ion temperature $T_i \sim 30$ eV there are intense fluctuations with electric fields, up to 25 kV/cm. These fluctuations are low-frequency ($\omega \ll \omega_{pe}$), and their electric vector has a predominant direction along the plasma azimuthal current. The plasma level of turbulence is 10^{-3}. Because of the anomalously high resistance of a turbulent plasma, which limits the lifetime of the closed magnetic configurations, it is proposed to increase the plasma conductivity by increasing the density without changing the conditions for excitation of instability; this can be done by increasing the discharge volume.

Electron temperature in a high-frequency helium discharge

V. S. Voitsenya, A. Yu. Voloshko, V. G. Konovalov, and S. I. Solodovchenko

(Submitted September 24, 1973; resubmitted December 20, 1973)
Zh. Tekh. Fiz., 44, 1455-1457 (July 1974)

Spectroscopic measurements of the electron temperature in a high-frequency discharge plasma ($T_e \sim 10$ eV, $n_e \sim 2 \cdot 10^{11}$ cm^{-3}) in a toroidal stellarator are described. As the density of neutrals in the discharge increases one must take account of radiation trapping resonance lines.

The "helium thermometer" method is widely used for nocontact measurement of the electron temperature of a plasma. Many theoretical and experimental papers have been published on the possibilities and the conditions for application of this method. It has been shown (refs. 1, 2) that although the method is experimentally simple, there are serious limitations on its applicability. The experimental conditions in a plasma very often do not admit of the simplest model for level populations, i.e., the corona model, and one must take account of processes which give additional populations (e.g., multistage excitation, cascade, transitions, etc.). The almost complete absence of experimental level excitation cross sections requires rather complex calculations when the corona model cannot be applied.

In addition, in the case of incomplete helium ionization (and in the corresponding pressure range) the population of some levels can be appreciably affected by absorption of radiation in resonance lines.

The present paper compares experimental results of measurement of T_e from various pairs of singlet and triplet helium lines in a weakly ionized high-frequency discharge.

The discharge is produced in the metal chamber of the "Saturn" toroidal stellarator (ref. 3) using the electron cyclotron resonance. The microwave power at f = 10 GHz is 12 W. The helium pressure in the chamber is varied from $3 \cdot 10^{-5}$ to $6 \cdot 10^{-4}$ torr. The major and minor radii of the vacuum chamber are R = 36 and r = 8.7 cm, and the plasma volume is a little more than 20 liters.

The plasma parameters are investigated by means of single and double electrostatic probes, a microwave interferometer (λ = 8 mm and λ = 16 mm), and a type MDR-2 monochromator with an FÉU-39 photomultiplier.

The monochromator is used to determine the ratio of intensities of the following pairs of neutral helium lines: 4713 and 4922 Å, 5016 and 4713 Å, 5047 and 4713 Å. In determining the electron temperature we use the results of calculations of refs. 4-6, based on the corona model.

An error estimate of the intensity determination, (taking account of the spectral sensitivity of the photomultiplier) gives ±15%, which corresponds to a relative error in the T_e measurement below ±25% for all pairs of lines.

Measurement shows that the plasma density (an average through the plasma cylinder with radius r_{pl} = 6 cm) is $\sim 2 \cdot 10^{11}$ cm^{-3} and varies very little as the helium pressure is varied.

Figure 1 shows the dependence of electron temperature on pressure. As expected (ref. 7), at increased pressures the electron temperature, determined from the I_{5016}/I_{4713} ratio, is appreciably higher than values found for the other line pairs and by means of the electrostatic probes. The observed difference can be accounted for numerically in a satisfactory manner if one takes account of the additional increase of 3^1P level population due to absorption of radiation by the resonance line He I at λ = 537 Å.

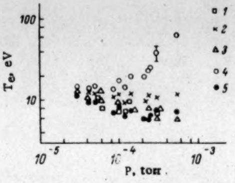

Fig. 1. Pressure dependence of the electron temperature as measured by probes (1) and from the intensity ratios of He I lines. 2) I_{4713}/I_{4922}; 3) I_{5047}/I_{4713}; 4) I_{5016}/I_{4713} without accounting for absorption at λ = 537 Å; 5) I_{5016}/I_{4713} allowing for absorption at λ = 537 Å.

Figure 2 shows the results of calculations of the effective excitation cross section for the 5016 Å line from ref. 7, taking the vacuum chamber radius (8.7 cm) to be the radius of the absorbing region. It follows from this relation that in these experiments (10^{12} cm$^{-3} \le n_0 \le 1.9 \cdot 10^{13}$ cm^{-3}) the value of Q_{eff}^{5016} can differ by roughly a factor of 10 from the value for the fully ionized plasma.

Figure 1 also shows the electron temperature, determined from the I_{5016}/I_{4713} ratio, taking account of the results of ref. 7. There is good agreement between the results from the 5016 and 4713 Å pairs, the probe measurements, and the I_{5047}/I_{4713} ratio results. The difference does not exceed 20% over the entire range of pressure variation. However, the electron temperature, determined from the intensity ratio for the 4922 and 4713 Å lines, is systematically higher than the values from the other methods. A possible cause of this discrepancy is the additional popu-

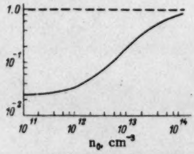

Fig. 2. Calculated dependence of the effective cross section for excitation of the He I 5016 Å line on helium atom density in the discharge. The broken line shows the total absorption of the λ = 537 Å line.

lation of the upper level of the 4922 Å line (4^1D), not accounted for in ref. 4, due to absorption at the resonance line 522 Å (1s−4p transition) and to collisional transitions between 4p−4d levels.

Thus, the present paper has shown that for plasma density ~ $2 \cdot 10^{11}$ cm^{-3} and higher a comparatively wide range of neutral helium density (10^{12} cm$^{-3} \leq n_0 \leq 1.9 \cdot 10^{13}$ cm^{-3}), the helium thermometer method gives results in good agreement when one uses the line pairs 5016 and 4713 Å, and 5047 and 4713 Å.

In conclusion the authors thank V. I. Kononenko, I. Yu. Adamov, and V. L. Berezhnyi for the microwave measurements, and O. S. Pavlichenko for useful discussion.

Effect of molecular hydrogen on a cesium discharge. I

N. D. Morgulis and V. I. Klapchenko

T. G. Shevchenko Kiev University

(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 1458-1462 (July 1974)

The effect of neutral molecular hydrogen at pressures of 0.003–0.2 mm Hg on a cesium discharge at 0.01 0.1 mm Hg is considered. It is shown that the addition of such a gas causes: 1) a marked increase in both the electric field E in the plasma and in the energy $\omega = jE$ needed to maintain it, and 2) a deficit of electrons with energies $\gtrsim$ 1 eV in the Maxwellian distribution. The reason is that under these conditions additional energy losses occur due to: a) impact excitation of the rotational–vibrational spectrum of molecular hydrogen, and b) partial quenching by these molecules of the resonance excitation of atomic cesium which is important for generation of the plasma. Experimental results are compared with the conclusions following from a) and b), and good agreement is found.

Cesium discharges, either pure or in a mixture with neutral inert gases, have been subjected to detailed analysis in recent years. The basic stimulus for this interest comes from the importance of such systems in energy conversion – in thermionic converters and closed-cycle MHD generators. At the present time, new applications have been found for cesium plasmas – but of a different type, in mixtures with different molecular gases – primarily in the physics of open-cycle MHD generators, high-power gas lasers, etc. Undoubtedly, the molecular gas, even in neutral form, can have a considerable effect on the properties and parameters of the cesium plasma, causing for example: 1) appreciable impact deexcitation quenching of the cesium atoms[1] in the 6P resonance level, which is very important for ionization–recombination processes;[2] 2) additional marked energy losses due to impact excitation of the rotational–vibrational spectrum in this mixture;[3] 3) numerous ion–molecular processes that are much more complicated and diverse than in a pure cesium plasma;[4] etc. The experimental material on this interesting problem is very limited,[5–7] basically involving a general description of the phenomena without a detailed analysis of the elementary processes and parameters of the plasma. This situation makes it very difficult to analyze the processes occurring in such plasmas,[8,9] and is the reason that the present work has been undertaken.

In the first part of this paper, pure molecular hydrogen is used as the neutral and passive un-ionized gas added to the cesium discharge plasma with a comparatively low electron temperature. The hydrogen is easily and conveniently admitted to the experimental apparatus using the familiar titanium leak. The useful nature of the gas is also seen from the fact that the usually bright Hγ line at $\lambda = 4340$ Å is difficult to observe in the background of the cesium recombination spectrum. In this sense, our work differs considerably from, for example, ref. 10, in which a sodium–hydrogen pulsed discharge laser is investigated.

A schematic diagram of the apparatus is shown in Fig. 1, where the middle plasma section has a radius R = 1 cm and a length l = 12 cm ≫ R. In addition to a hot cathode 1, an anode 2, two axial probes 3, and a sidearm with the cesium 4, which are conventional, the apparatus also has a hydrogen source 5 and a thermocouple manometer 6 to measure the pressure P. The probes are used to determine the axial temperature T_e and density n_e of the plasma electrons, their energy distribution function $f(v_e)$, and the electric field E in the plasma. The function $f(v_e)$ is determined by double differentiation of the probe characteristic curve. In certain cases the T_e is also determined from the cesium recombination spectrum. Other required quantities are: 1) the axial density of cesium atoms n_a^* excited to the 6P resonance level, which is determined from the reversal temperature in a similar device with end windows, and 2) the axial current density j_0, which is roughly determined from the discharge current I_d and the radial distribution of the radiation intensity of the plasma column Q = f(r), which is determined using an antinomy–cesium photoelectric sensor with a subsequent Abel inversion procedure.

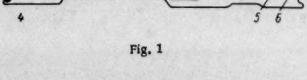

Fig. 1

In the initial stage the hydrogen source is not connected to the apparatus, and control measurements are performed in the pure cesium plasma. Then the connection between them is broken; the hydrogen flows into the apparatus until the required pressure P is reached, and the corresponding measurements are made largely at only one cesium pressure p = 0.1 mm Hg and at one n_e value $n_e = 2.5 \cdot 10^{13}$ cm^{-3}. The latter condition (n_e = const) greatly facilitates the subsequent analysis of the experimental data. We note also that when the hydrogen is admitted into the apparatus a sharp increase occurs in both the potential drop and in the discharge current necessary to maintain n_e = const, i.e., in the power required by the apparatus; simultaneously, a marked contraction of the plasma column occurs.

Thus, the standard we use is a pure cesium plasma (P = 0) with the following axial parameters: T_e = 2700°K, $n_e = 2.5 \cdot 10^{13}$ cm^{-3}, E = 0.3 V/cm, $n_a^* \approx 3 \cdot 10^{12}$ cm^{-3}, conductivity $\sigma_0 = j_0/E = 1.8\ \Omega^{-1} \cdot$ cm^{-1} and power $\omega_0 = j_0 E$ = 0.16 W/cm^3 with a purely Maxwellian electron energy distribution $f(v_e)$ and the usual radial distribution of the electron density, similar to the curve Q = f(r). With the subsequent admission of the hydrogen gas, p and n_e remain constant, but all the other parameters can change. This feature is shown in Figs. 2 and 3 on a semilogarithmic scale for the point P = 0, and then for P = 0.003-0.2 mm Hg, where the following quantities are given: T_e(I), E(II), σ (III), and ω (IV). Examination of the figures leads to the following conclusions.

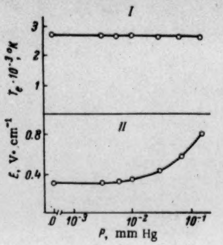

Fig. 2

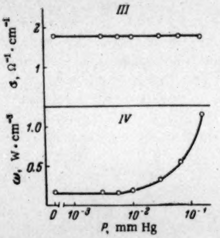

Fig. 3

1. We find n_e = const, and T_e remains constant and independent of P. This means that n_a^* remains constant along with the equilibrium ionization rate of the cesium $dn_e/dt = f(T_e) = n_e/\tau_p$, i.e., the charge recombination rate in the plasma $1/\tau_p$. Consequently, the introduction of the hydrogen gas (up to P = 0.2 mm Hg) does not change the existing significant volume recombination in the plasma, which is very sensitive to a change in plasma density. Thus, there are no new phenomena in the plasma due to the hydrogen: This results from the fairly high critical potentials for a plasma with T_e = 2700°K and to their low effective cross sections.[3]

2. The conductivity $\sigma = e\mu_e n_e$, i.e., the electron mobility $\mu_e = e/mu_e\,\Sigma nq$, is constant in our case, along with n_e and T_e. This indicates that the additional scattering of plasma electrons by hydrogen molecules ($q_1 \approx 1\cdot10^{-15}\,cm^2$) is significantly smaller than the total scattering by cesium atoms ($q_a \approx 2\cdot10^{-14}\,cm^2$) and the Coulomb scattering ($q_k \approx 5\cdot10^{-12}\,cm^2$ at T_e = 2700°K). This same situation (μ_e = const) can also be observed in Fig. 4, I, which shows the variation with increasing P of n_e and σ under different conditions, where a constant discharge current $I_d \sim \sigma E$ = const is maintained and where an increase in energy losses leads inevitably to an increase in E, i.e., to a decrease in σ.

3. The values of E and ω exhibit a very strong increase, especially starting near P > 0.01 mm Hg and above. The reason for the increase is the necessity for compensation of the additional energy losses $\Delta\omega = (\omega - \omega_0)$ primarily due to 1) excitation of the rotational–vibrational spectrum of molecular hydrogen due to electron impact, and 2) partial quenching of the 6P resonance level of the cesium atoms through collisions with these same molecules; for example, when P = 0.2 mm Hg, we obtain $\Delta\omega/\omega_0 \approx 6$.

Actually, for $\Delta\omega = (\Delta\omega_1 + \Delta\omega_2)$ we can write

$$\Delta\omega = q_1 u_e n_e n_{H_2} \alpha \mathcal{E}_e + q_2 u_a n_a^* n_{H_2} \mathcal{E}_a^*$$

or

$$\beta = \frac{d\Delta\omega}{dn_{H_2}} = q_1 u_e n_e \alpha \mathcal{E}_e + q_2 u_a n_a^* \mathcal{E}_a^* = \beta_1 + \beta_2.$$

To check this expression and the estimates of the contributions of $\Delta\omega_1$ and $\Delta\omega_2$ to the additional energy losses due to the hydrogen gas. Fig. 4, II, gives $\Delta\omega = f(n_{H_2})$ replotted from the data of Fig. 3, IV, for P > 0.01 mm Hg. This dependence actually has a linear character, with slope $\beta = 3.6\cdot10^{-16}$ W. On the other hand, reliable values[11] of q_2, which are the same for the $6P_{3/2}$ and $6P_{1/2}$ cesium sublevels ($8\cdot10^{-16}\,cm^2$ on the average), make it possible to obtain a reliable estimate $\beta_2 = 1.2\cdot10^{-16}$ W; thus $\beta_1 = (\beta - \beta_2) = 2.4\cdot10^{-16}$ W, i.e., $\beta_1/\beta_2 \approx 2$. The latter estimate for β_1 also gives – for our electrons at T_e = 2700°K, i.e., $\mathcal{E}_e$ = 0.35 eV, and with a rough use of the not very reliable value given in the literature[3] for the transport cross section $q_1 \approx 1\cdot10^{-15}\,cm^2$ – the effective accommodation coefficient $\alpha = 5\cdot10^{-3}$. For comparison, we point out that the calculated value for molecular hydrogen is $\alpha_0 = 2m/M = 5.5\cdot10^{-4}$, i.e., a loss coefficient $\delta = \alpha/\alpha_0 = 10$. These values for α and δ are in good agreement with those in the literature,[3] i.e., there is a good correlation between the experimental data given here and the general picture of the physical processes occurring in the plasma. We note also that the two-way transitions between the cesium sublevels $6P_{3/2}-6P_{1/2}$, which often occur along with the quenching, have little effect on the energy balance in the plasma.

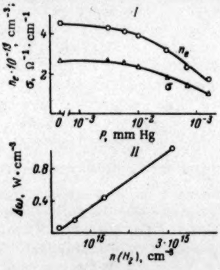

Fig. 4

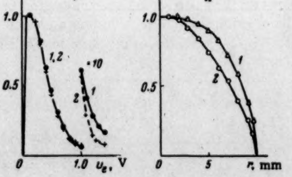

Fig. 5

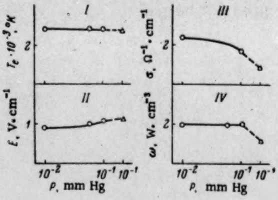

Fig. 6

The effect of the hydrogen gas on the energy spectrum of the plasma electrons $f(v_e)$ is shown in Fig. 5, I, for the following two cases: 1) P = 0, and 2) P = 0.2 mm Hg. In this figure: a) The origin is at the maximum of the second derivative of the probe characteristic curve, and b) the tail of this curve is shown on a 10× scale for clarity. It can be seen from the figure that in the first case $f(v_e)$ always has a purely Maxwellian shape at $T_e = 2700$°K (solid curve). In the second case with the gas present, it retains this shape only for $0 < v_e < 1$ eV; then, a certain deficit of fast ($v_e \gtrsim 1$ eV) electrons occurs. The reason is obviously that in this range there is a sharp increase in the effective cross section for impact excitation of the vibrational spectrum of molecular hydrogen.[3] Thus, the rate of decay of the Maxwellian distribution under these conditions is comparable to its rate of regeneration by the Coulomb interaction.

On the other hand, Fig. 5, II, gives the curves after Abel inversion of the radial distribution of radiation intensity $Q = f(r)$ for these same two cases, and it can be seen that the introduction of the hydrogen gas produces a marked contraction of the cesium plasma column.

Finally, we point out that, as mentioned above, some measurements have been performed for I_d = const and the same pressure p = 0.1 mm Hg. The data obtained in this case for n_e and σ are shown in Fig. 4, I. The general pattern of results obtained in this case is similar to those obtained in the first case n_e = const; therefore, they have not been subjected to additional quantitative analysis.

Up to this point, we have considered the case $P \leq p$. It is therefore of interest to include some preliminary data for the inverse case $p \leq P$ but with the same conditions of a cesium plasma with neutral hydrogen. For example, we consider the case P = 0.2 mm Hg = constant and a range of cesium vapor pressures p = 0.01–0.1 mm Hg, but a somewhat larger electron density $n_e = 5 \cdot 10^{13}$ cm^{-3}. The results obtained are shown in Fig. 6 for T_e (I), E (II), σ (III), and ω (IV); for comparison, the points on the extreme right give the values of these parameters for the previous case: P = 0.2, p = 0.1 mm Hg, and $n_e = 2.5 \cdot 10^{13}$ cm^{-3}. It can be seen from the figure that variation in p for the given limits has a comparatively small effect on these parameters, about equal to its effect on $f(v_e)$, which continues to exhibit the above-mentioned small deficit of fast electrons. Nevertheless, the variations in these parameters (dashed curve) between the new and old n_e values looks reasonable. These data are limited and require further analysis.

In conclusion, the authors thank A. M. Przhonskii for his help.

Mass and energy analysis of ions in the cathode of an anomalous glow discharge. II. Binary gas mixtures Ne + Ar and N_2 + Ar

A. V. Bondarenko
M. V. Lomonosov Moscow State University

(Submitted June 26, 1973)
Zh. Tekh. Fiz., 44, 1463-1471 (July 1974)

Detailed mass-energy spectra have been obtained with a double-focusing mass spectrometer for the ions from discharges in various mixtures. The transformation of the energy spectra and the change in the total relative abundances of the various ion species are studied as a function of the mixture composition. For the mixture N_2 + Ar the production of nitrogen ions (N_2^+ and N^+) and argon ions obeys an additivity rule. The N^+ ions are produced predominantly in the cathode fall as a result of secondary processes involving N_2^+ ions which drift away from the negative glow. The most probable elementary processes resulting in the production of N^+ ions are discussed. For the Ne + Ar mixture the additivity rule is not obeyed in the production of the principal ions of the components, perhaps because of a difference between the cross sections for ionization by electrons and because of the supplementary ionization of Ar due to the Penning effects. The transformation of the Ne^+ and Ar^+ spectra resulting from a change in the mixture composition is interpreted on the basis of secondary processes. It is concluded that the point near the cathode at which the ions are produced depends on the nature of the medium and can vary as a function of the mixture composition.

On the basis of general considerations, the energy spectra of the various ion species in the cathode fall of a glow discharge should be governed by the electric field distribution, the distribution and intensity of the primary ion production, and the efficiency of secondary processes of energy and charge exchange between particles in the cathode fall.[2] As is shown in the first part of this work,[1] the majority of the principal ions (Ne^+, Ar^+, N_2^+, etc.) in an anomalous discharge in an individual gas form in the negative glow; as they move through the cathode fall they undergo a rapid charge exchange and acquire an exponential energy spectrum. The nature of the low-energy peak in the experimental spectrum requires special study.[1]

An elementary theory for the energy spectrum of the ions near the cathode is proposed in ref. 3 on the basis of simplified arguments regarding the linearity of the field in the cathode fall; it is assumed that all the ions are produced in the glow and that the predominant interaction of these ions with neutrals is charge exchange, for which the cross section is not a function of the energy. Analysis of the experimental data on slightly anomalous discharges in various gases has given the charge-exchange cross sections for He, Ne, Ar, and hydrogen ions for charge exchange with neutrals of the same atomic species.[3]

In a discharge in a gaseous mixture the situation is complicated because of the additional interactions between the various particles. Nevertheless, the corresponding experimental results can be used to evaluate the relative importance of a particular elementary process in a gas discharge.

There are well-known cases in the development and application of gas-discharge devices in which a slight impurity has a strong effect on the operation and in the characteristics of these devices. There has been essentially no study of the effect of the composition of the medium on the mass-energy spectra. Cumme[4] has reported, along with the mass-energy spectra of the principal ions from anomalous discharges in He and Ne, data on the ion distribution for mixtures of Ne with small amounts of He and Ar of fixed compositions. Bashirova[5] reported the mass spectra of channeled ions in a narrow energy range (near the high-energy peak) from discharges in binary mixtures of Ne + Ar, N_2 + Ar, O_2 + Ar, and N_2 + O_2 of various compositions. Obviously, these results do not give a complete picture of the situation, since the high-energy peak contains only a negligibly small fraction of the ions of the principal gases.[1]

TABLE 1

Mixture comp., %		Pressure p, torr	Current I_r, mA	Ion abundance in beam, %	
Ne	Ar			Ne^+	Ar^+
99	1	0.07	0.2	85	15
95	5	0.7	0.6	54	46
80	20	0.7	0.6	31	69
50	50	0.7	1.2	15	85
20	80	0.7	2.9	5.6	94.4
10	90	0.1	7.0	3.3	96.7

We have now obtained and analyzed detailed mass-energy spectra for the principal channeled ions from anomalous low-pressure glow discharges in mixtures of Ne + Ar and N_2 + Ar for various ratios of the components.

EXPERIMENTAL PROCEDURE

The mass-energy analysis of the channeled ions is carried out in the experimental apparatus described in detail previously,[1] under the following conditions: a voltage of V_r = 3000 V (±1%) across the electrodes and a pressure of p = 0.05-0.1 torr (±10%) in the gas-discharge medium. A thermocouple gauge calibrated for air is used to measure the pressures of Ne, Ar, and their mixtures; conversion coefficients are used for this purpose.[6] The reduced current density j/p^2 is $(5-80) \cdot 10^{-3}$ A/(cm^2 · torr^2), corresponding to the anomalous regime of the glow discharge.

The functional dependence of the photomultiplier gain

TABLE 2

Mixture comp., %		Pressure p, torr	Current I_r, mA	Ion abundance in beam, %

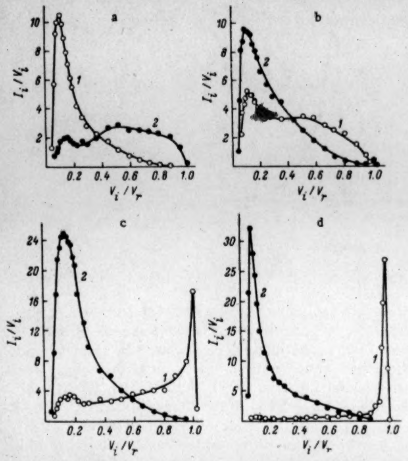

Fig. 1. Discharge in a mixture of neon with argon; energy spectra of the principal ions. a: 99% Ne + 1% Ar. 1) Ne^+; 2) Ar^+ (×5). b: 50% Ne + 50% Ar. 1) Ne^+ (×5); 2) Ar^+. c: 20% Ne + 80% Ar. 1) Ne^+ (×10); 2) Ar^+. d: 10% Ne + 90% Ar. 1) Ne^+ (×10); 2) Ar^+. Here and in Fig. 2 the "×" indicates that the ordinates of these curves are multiplied by the corresponding number.

on the mass and nature of the ion species is incorporated in the analysis of the results.[1] For this purpose the argon-ion current is multiplied by a factor of 1.4 (with respect to Ne^+). In the case of the N_2 + Ar mixture the ion currents are normalized to the N^+ current, i.e., the N_2^+ current is divided by 1.2, while the current of Ar^+ and Ar^{2+} ions is multiplied by 1.7. For each of the mixtures, differential energy spectra are plotted for the current of the principal ions,[1] and the contribution of ions of each species to the total ion current is determined graphically. For the N_2 + Ar mixtures the ratio between the currents of N_2^+ and N^+ ions is also calculated.

EXPERIMENTAL RESULTS

We have studied six different Ne + Ar mixtures and five different N_2 + Ar mixtures; the results for the individual components are reported in ref. 1. The mixture composition, the experimental conditions, and certain results are shown in Tables 1 and 2.

The mixture Ne + Ar. As the amount of Ar in this mixture is increased the total discharge current I_r increases along a hyperbolic curve. The principal ions of the channeled beam are $^{40}Ar^+$, $^{20}Ne^+$, and $^{22}Ne^+$. At energies near eV_r we detect a few (1%-3%) foreign ions,[1] not included in the overall balance. The hydride ions NeH^+ and ArH^+, whose numbers are about 1% and 2%-3%, respectively, of the numbers of the numbers of Ne^+ and Ar^+ ions, are added to the total current of principal ions. Doubly charged Ne^{2+} ions (amounting to about 2% of the number of Ne^+ ions) and Ar^{2+} ions (up to 3% of the number of Ar^+ ions) are taken into account in a similar manner. Appreciable numbers of these additional components are found in the case of Ne only in mixtures containing 80% or more Ne; for the case of Ar, these amounts are appreciable when there is only 5% Ar.

Direct measurement of the $^{40}Ar^{2+}$ current in the Ne + Ar mixtures is complicated by the circumstance that the mass line of this ion coincides with the $^{20}Ne^+$ line. We deal with this difficulty by multiplying the measured $^{22}Ne^+$ current by 9.3, corresponding to the natural abundance of neon isotopes.[1] In the same manner we determine the correct current of $^{20}Ne^+$ ions and attribute its difference from the current measured for m = 20 to $^{40}Ar^{2+}$.

Figure 1 shows the most characteristic energy spectra of the principal ions in several Ne + Ar mixtures. For Ne the total current of the ions of the isotopes is shown. The Ne^+ and Ar^+ spectra for a mixture of a given composition are markedly different in shape. As the composition is changed, these spectra undergo a gradual transformation, which can be described qualitatively as follows: The low-energy peak on the Ne^+ curve for (0.11-0.12) eV_r broadens slightly and fades rapidly. A step appears on the monotonically decaying branch of the curve at about 80% Ne; this step is clearly defined for the mixture with 50% Ne. The curvature of the subsequent part of this curve changes (Fig. 1b). As the amount of Ne in the mixture is reduced further, the low-energy peak is flattened out almost completely; at higher energies the amount of Ne^+ does not fall off, but instead gradually increases. For the mixture with 10% Ne most of the Ne^+ ions have energies in the range (0.9-1.0)eV_r, i.e., form a sharp high-energy peak (Fig. 1d).

The Ar^+ curve, with a low-energy peak at (0.08-0.12) eV_r, retains its shape as the amount of Ar in the mixture is reduced to 50% and below; only at 20% Ar does the descending branch display a step and a change in the nature of the curvature. Subsequently (at 5% and 1% Ar) a broad peak forms in the center of the energy range, and the low-energy peak fades markedly. The relative number of high-energy Ar^+ ions increases, as in the case of Ne. However, the mixture components do not behave in a completely symmetric manner: Down to 1% Ar, the Ar^+ ions are distributed more uniformly over the energy range, and the high-energy peak at V_r is not found in this case. A further deviation from the symmetry is evident in the circumstance that even a slight addition of argon (1%-5%) to the Ne leads to a disproportionately high yield of Ar^+ ions and a rapid decrease in the number of Ne^+ ions, while the addition of up to 20% neon to the Ar has little effect on the abundance of Ar^+ ions.

The mixture N_2 + Ar. As the amount of Ar in this mixture is increased, the discharge current increases nearly linearly. The principal channeled ions in this case are $^{40}Ar^+$, N_2^+, and N^+. In the nitrogen-rich mixtures, some N_2^{2+} ions can form; their mass line coincides with that of N^+ (ref. 1). In the argon-rich mixtures (80% and 95% Ar), there are an appreciable number of Ar^{2+} ions (amounting to about 3% of the number of Ar^+ ions) as well as ArH^+ ions. In the overall calculations, the number of these ions was combined with that of Ar^+ ions.

Figure 2 shows the energy spectrum of the principal ions for several N_2 + Ar mixtures. The shape of the curves for the Ar^+ and N_2^+ ions is essentially unaffected by the mixture composition, remaining similar to the

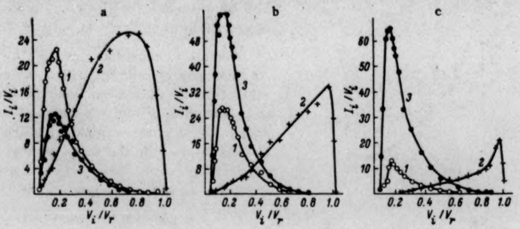

Fig. 2. Discharge in mixtures of nitrogen with argon; energy spectra of the principal ions. a: 95% N_2 + 5% Ar. 1) N_2^+; 2) N^+ (×2); 3) Ar^+ (×5). b: 20% N_2 + 80% Ar. 1) N_2^+ (×10); 2) N^+ (×10); 3) Ar^+. c: 5% N_2 + 95% Ar. 1) N_2^+ (×20); 2) N^+ (×10); 3) Ar^+.

curves for the individual gases.[1] The height of the peaks and the relative ion abundances are functions of the composition. The Ar^+ abundance is essentially proportional to the Ar concentration, while the N_2^+ abundance falls off slightly more rapidly than the amount of neutral N_2 in the mixture.

The curves for N^+ undergo an appreciable transformation as the composition is changed. The broad peak characteristic of a discharge in pure nitrogen[1] gradually vanishes as the amount of N_2 is reduced, the relative abundance of low-energy ions decreases, and a sharp peak forms at high energies. For the mixture with 5% N_2 an appreciable fraction of the N^+ ions have energies approximately equal to eV_r. In contrast with the case of N_2^+, the relative abundance of N^+ ions falls off more slowly than the concentration of neutral N_2.

The results are summarized in Fig. 3, which shows the total relative contribution of the principal ions as a function of the mixture composition. For the N_2 + Ar system we analyzed the contribution of the Ar^+ ions and the nitrogen ions, $N_2^+ + N^+$. In Fig. 3, points 1 show the abundance of argon ions, while the straight line corresponds to the additive rule for the production of ions of both components of the mixture. The positions of the experimental points show that argon ions and, correspondingly, nitrogen ions are produced and exist in a number proportional to the abundance of the neutral components. However, the relative abundances of the different nitrogen-ion species do not display the same functional dependence on the mixture composition. Points 2 in Fig. 3 show the N^+ contribution to the total current of nitrogen ions. The tendency for the relative N^+ abundance to increase approximately linearly (and, correspondingly, for the relative N_2^+ abundance to decrease approximately linearly) as a function of the argon concentration is evidence that argon affects the production of both molecular and atomic nitrogen ions.

Curve 3 in Fig. 3 shows the Ar^+ contribution to the total ion current for the Ne + Ar mixture. The hyperbolic shape of this curve implies a nonadditive production of ions in this mixture.

DISCUSSION OF RESULTS

The immediate problem of a study of binary mixtures is to determine the reasons for the change in the total relative abundance of the ions of the various species and in the shape of their spectral curves as functions of the composition. An analysis of the experimental results should incorporate: 1) the difference between the cross sections for ionization of the mixture components by electrons, 2) the difference between the cross sections for charge exchange of the component ions with their own neutrals, 3) the functional dependence of the charge-exchange efficiency on the partial pressures of the components, 4) the functional dependence of this efficiency on the length of the cathode fall, which is itself a function of the composition, and 5) cross interactions of ions and neutrals of different atomic species, taking account of the cross sections, partial abundances, etc.

When we take these circumstances into account we find that the nonadditive nature of the functional dependence of the relative ion abundance on the composition of the Ne + Ar mixture (Fig. 3) is due largely to the difference between the ionization cross sections of the mixture components. The ratio of the cross sections σ_{Ar} and σ_{Ne} for electron energies of 300-3000 eV is 3-4. When we take account of ionization by secondary electrons, which have lower energies and thus higher cross sections, we conclude that the value 4 is preferable. Calculation of the relative Ar^+ abundance on the basis of this assumption yields hyperbolic curve 4 (Fig. 3), which approximately coincides with the experimental curve for mixtures having > 50% Ar. In mixtures with less Ar, the measured fractions of Ar ions are much higher than the calculated fractions, apparently because of an additional mechanism for the production of Ar^+ ions. As this additional mechanism we can suggest the secondary charge exchange

$$Ne^+ + Ar \rightarrow Ne + Ar^+, \tag{1}$$

whose cross section over the energy range 20-200 eV is 7-8 cm^2/cm^3 (ref. 7) or five to six times lower than the cross section for charge exchange of Ne^+ with Ne known for this energy range.[8] In neon-rich mixtures the contribution of process (1) would be appreciable. However, it is necessary to keep in mind the opposing process,

$$Ar^+ + Ne \rightarrow Ar + Ne^+, \tag{2}$$

for which the cross section is one third that for process (1) (ref. 7). Nevertheless, a straightforward calculation shows that in a mixture of any composition the contributions of processes (1) and (2) essentially cancel out because of the simultaneous changes in the ratio of both the neutral components and the abundance of both ion species, although these contributions are also functions of the absolute composition.

Another mechanism leading to the formation of more Ar^+ ions is the Penning effect:

$$Ne^* + Ar \rightarrow Ne + Ar^+ + e, \qquad (3)$$

where Ne^* is metastably excited neon (16.5 V). The reverse process does not occur. The cross section for process (3) is approximately equal to the gas-kinetic cross section, i.e., can exceed the cross section for ionization of Ar by electrons. Also assuming that the additional contribution of process (3) is proportional to the product of the Ne and Ar abundances, we can show that the Ar^+ abundance due to this process in neon-rich mixtures increases significantly, approaching the experimental values.

Rapid charge exchange of one or another of the ion species produced does not affect the number of these ions but does strongly affect the shape of the spectral curves. Then we can offer a qualitative explanation for the transformation of the experimental curves which occurs as the composition of the Ne + Ar mixture is changed. In the mixture 10% Ne + 90% Ar (Fig. 1d) the efficiency of the resonance Ne^+ charge exchange is low because of the low abundance of Ne. A large fraction of the Ne^+ (~50%) from the negative glow pass through the cathode fall without losing energy, explaining the high-energy neon peak (Fig. 1d). The decaying branch of the curve to the left of the peak is characteristic of inefficient charge exchange.[3] Charge exchange of Ar^+ with Ar is much more efficient because the cross section for this process is higher (by a factor of ~ 3) than for Ne^+ and because of the large Ar abundance. Therefore, the Ar^+ spectrum is an exponential branch at low energies. As the abundance of Ne in the mixture is increased to (20%), the probability for charge exchange of Ne^+ increases, so that the high-energy peak fades and a low-energy branch of the curve begins to form (Fig. 1c). Nonresonance charge-exchange processes (1) and (2), although they do not alter the total abundance of the various ion species, do affect the shapes of the curves. For example, a calculation shows that process (2) in neon-poor mixtures produces Ne^+ in an amount comparable to that formed in the primary process. The subsequent fate of the ions produced in both processes is the same: charge exchange at a relatively low efficiency. However, since process (2) is distributed along the cathode fall, the resulting Ne^+ ions begin their motion from different energy levels and produce a continuous "background" in the cathode fall. As the mixture is enriched with neon this background intensifies, to the point at which a convex region appears in the curve for 50% Ne (Fig. 1b). Process (1) which produces Ar^+ ions, simply offsets their loss due to process (2) and does not affect the shape of the curve for Ar^+ because of the intense charge exchange of Ar^+ with Ar. An increase in the Ne abundance to 80% leads to a situation in which the efficiency of the resonance charge exchange of Ne^+ becomes higher than that of Ar^+. The Ne^+ ions produced in process (2) reach the low-energy region more rapidly than the Ar^+ ions, and the distribution of the latter ions becomes distorted by process (1). The curve for Ne^+ converts into an exponential branch in the low-energy region, and a step is observed on the decaying curve for Ar^+, i.e., these curves in a sense begin to interchange.

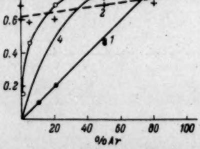

Fig. 3. Relative contributions of various ions as functions of the amount of Ar in the mixture. 1) Fraction of argon ions in the total ion current of the discharge in N_2 + Ar; 2) fraction of N^+ ions in the total current of nitrogen ions; 3) fraction of argon ions in the total current for Ne + Ar; 4) fraction of Ar^+ ions in the total current (the difference between the Ne and Ar ionization cross sections is taken into account).

A further reduction of the Ar concentration causes a further reduction in the efficiency of the Ar^+ charge exchange, leads to an increasingly pronounced accumulation of Ar^+ at intermediate energies because of processes (1) and (3), and leads to convex areas on the curves for the mixtures with 5% and 1% Ar (Fig. 1a). Although we cannot expect a completely analogous behavior of the mixture components, we do not understand why the argon-poor mixtures do not display a high-energy Ar^+ peak analogous to the Ne^+ peak (Fig. 1d). It may be that this peak appears at an even lower Ar content, on the order of some tenths of 1%, at which the efficiency of the charge exchange of Ar^+ with Ar is extremely low. It should also be noted that the relative number of high-energy Ar^+ $[E \geq 0.5\ (V_i/V_r)]$ in the Ar-poor mixtures is much higher (amounting to 10% of the total ion current) than the relative number of such Ne^+ (~2%) in the mixture with 10% Ne.

These results should be examined in light of the known separation of a gaseous mixture in a discharge, which results in the concentration of the component having the lower ionization potential (Ar) near the cathode. As a result of this separation, the current of Ar^+ ions might increase disproportionately. However, as is shown in ref. 9, this separation is observed only at pressures of ~ 0.4 torr and above, at discharge currents mA, and at a length-to-diameter ratio of > 20 for the discharge tube. In our experiments these conditions are not satisfied, so that this separation can not have affected our results.

In the other gaseous system, N_2 + Ar, the experiments revealed a simple proportionality between the relative Ar^+ contribution and the total number of ionized nitrogen particles, on the one hand, and the abundance of the corresponding neutral components, on the other. This result is primarily a consequence of the circumstance that the cross sections for the ionization of N_2 and Ar are essentially equal in the energy range 300–3000 eV. The cross sections for the resonance charge exchange of Ar^+ with Ar and of N_2^+ with N_2 are large and also approximately equal.[8–10] Finally, the cross sections for the cross charge-exchange processes

$$Ar^+ \text{ with } N_2 \qquad (4)$$

and

$$N_2^+ \text{ with} Ar \qquad (5)$$

are not very small and apparently only slightly different, i.e., these processes cancel each other out. These circumstances also furnish an explanation for the fact that the shapes of the N_2^+ and Ar^+ distributions are essentially independent of the composition, and the exponential shapes of these curves at low energies imply a high efficiency for resonance and cross charge exchange and the absence of a distorting effect of the latter process, as in the case of Ne + Ar.

This simplification of the situation in the $N_2 + Ar$ case permits an almost trivial interpretation of the results, except for the question regarding the production and behavior of the N^+ ions, which display an unusual distribution. The N^+ ions can be produced in the primary ionization and dissociation of N_2

$$N_2 + e \rightarrow N^+ + N + 2e, \tag{6}$$

as well as in certain secondary processes. Lacking reliable data on the cross section for process (6) for electrons having energies on the order of 1 keV, we cannot determine how this contribution compares with that of ordinary ionization of N_2. However, direct mass-spectrum observations of ions in the negative glow of discharges in N_2 (ref. 12) show that in this case the number of N^+ ions is much lower than the number of N_2^+ ions. The distribution of N^+ ions (Fig. 2) shows that most of them have high energies [above $0.6\,(V_iV_T)$], so that they move from the part of the cathode fall nearer the negative glow, where apparently most of them are produced. In interactions with neutrals,

$$N^+ + N_2 \rightarrow N_2^+ + N, \tag{7}$$

$$N^+ + Ar \rightarrow Ar^+ + N \tag{8}$$

some of the N^+ ions can be consumed. The cross section for process (7), however, is known to be low:[13] 2-3 $cm^2 \cdot cm^{-3}$. The cross section for process (8) is not known, but we would believe that it is inefficient because in Ar-rich mixtures there are a large number of high-energy N^+ ions, which would be consumed if the efficiency for this process were high. The same can be said of process (7) in N_2-rich mixtures.

Accordingly, the low-energy descending branch of the curve for N^+ ions must primarily reflect a decrease in the production of these ions. Since the additivity rule for the numbers of Ar^+ and nitrogen ions holds only for the total number of N_2^+ + N particles, it is extremely likely that N^+ is produced primarily in the cathode fall in secondary processes involving N_2^+ ions which have drifted from the negative glow. In pure nitrogen this could be the process

$$N_2^+ + N_2 \rightarrow N^+ + N + N_2, \tag{9}$$

postulated in ref. 14. In a mixture with Ar we could also have

$$N_2^+ + Ar \rightarrow N^+ + Ar + N \tag{10}$$

or

$$Ar^+ + N_2 \rightarrow N^+ + N + Ar. \tag{11}$$

Processes (10) and (11) are variants of processes (5) and (4) and must compete with them. Process (9) competes with the resonance charge exchange of N_2^+.

The cross section for process (9) at ion energies ~ 50 eV has been found[15] to be on the order of 3 cm^2/cm^3 or 30-40 times smaller than the cross section for charge exchange of N_2^+ with N_2. Accordingly, charge exchange must be predominant here. The same conclusion can apparently be drawn regarding processes (10) and (11), i.e., all these processes together could not produce the high relative abundance of N^+ ions in the cathode fall which is observed experimentally. However, it should be kept in mind that the cross section for process (9) can be a function of the excitation state of the N_2^+ ions. There are several known excited electronic and vibrational states $(N_2^+)^*$, e.g., $A^2\Pi_u$, having excitation energies of a few electron volts and lifetimes of 10^{-6}-10^{-7} sec (ref. 15). The cross sections for processes (9) and (10) involving $(N_2^+)^*$ states can be much larger than 3 cm^2/cm^3. The appearance of such N_2^+ states in the negative glow is quite possible. The mean free path for resonance charge exchange of N_2^+ is approximately equal to the gas-kinetic value, while the time between collisions of N_2^+ with neutrals under our experimental conditions is on the same order of magnitude as the $(N_2^+)^*$ lifetime. Accordingly, processes (9) and (10) can compete with resonance charge exchange to such a degree that the abundances of N^+ and N_2^+ in the cathode fall and become comparable. The reduced production of N^+ ions at a point far from the negative glow can be attributed to the circumstance that most of the excited N_2^+ ions have vanished by the time this point is reached.

According to this scheme, when there is a change in the relative concentration of N_2 in the mixture the ratio of the abundances of N^+ and N_2^+ should remain constant, since we have $N^+ \sim (N_2)^* \sim N_2$ and $N_2^+ \sim N_2$. Actually, the ratio between the N^+ and N_2^+ abundances changes slightly, with an increase in the N^+ abundance and a decrease in the N_2^+ abundance, as argon is added (curve 2 in Fig. 3). Processes (10) and (11) may be responsible for a similar effect in the case of Ar.

On the whole, the experimental results with binary mixtures confirm the conclusion[1] that the point at which the ions are predominantly produced in the cathode region of an anomalous discharge is a function of the nature of the gas-discharge medium and can be different not only for ions of different species, but also for ions of a given species for different ratios of the mixture components.

Yu. A. Lamakin and E. V. Ilyukin participated in these experiments.

Electromagnetic fields outside a synthesized plasma jet

(Submitted July 11, 1973)
Zh. Tekh. Fiz., 44, 1472-1476 (July 1974)

An experimental study is made of the high-frequency oscillations of argon plasma in a synthesized jet in the range 20-200 MHz at distances $r \leq \lambda$ from the axis of the jet. At distances $r/\lambda < 0.3$ the field from the jet is similar to the field in the near-field region of a dipole. The possibility of increasing the radiation from the jet by inserting a conductor in the jet or placing a dielectric plate across it is demonstrated experimentally. The coefficient for conversion of the longitudinal wave into an electromagnetic wave is estimated for the case of an immersed conductor-antenna. The increase in the radiation in the case of the dielectric plate is due mainly to an increase in the amplitude of the field of the high-frequency oscillations in the jet as the result of a reflected electron stream.

Oscillations at the characteristic electron frequencies of plasma have been observed in a synthesized plasma in the presence of streams of fast electrons.[1-3] In a previous paper[4] study was made of the spatial distribution of the amplitude of the high-frequency oscillations in a synthesized argon plasma and the relation of the intensity and spectrum of the oscillations to the parameters of the jet was investigated. The paresent paper is a continuation of ref. 4. It is devoted to a study of characteristic oscillations in the range 20-200 MHz and to methods of increasing the radiated intensity of these oscillations outside the jet.

A schematic diagram of the experimental arrangement is shown in Fig. 1. The synthesized plasma is produced by the source described previously.[4] The fields of the jet outside the experimental volume (at plasma densities 10^8-10^9, electron-beam energies 80-250 eV, electron-beam currents 150-250 mA) are investigated by means of a ferrite antenna and P5-1 and P5-2 receivers.

The experiments have established the following.

1. The magnitude of the alternating magnetic field and its spatial distribution outside the jet are determined by the motion of the fast electrons, which interact with the plasma, since a forced distortion of the electron trajectories by a dc magnetic field of the order of a few gauss results in a change in the magnitude and orientation of the alternating magnetic field. The motion of the ions is perturbed weakly since the ion Larmor radius is much greater than the dimensions of the jet.

As the distance increases from the experimental volume in a direction perpendicular to the axis, the alternating magnetic field varies with radius approximately as $1/r^2$ for distances r such that $r/\lambda < 0.3$, indicating the similarity of the field distribution outside the jet to the near field of a dipole (Fig. 2).

It has been shown previously[4] that in a synthesized plasma jet the intensity of the high-frequency oscillations is strongest at a short distance (a few retarded wavelengths) from the source, the intensity thereafter decreasing as a result of the divergence of the jet. Since the radial dimensions of the jet are finite, one can assume that some of the force lines induced by the alternating space charge close, from the region in which its density is greatest, on the source and on the metal part of the experimental volume. The field configuration is then similar to that of a dipole.

As expected, for $r/\lambda > 0.3$ the magnetic field varies with radius less sharply than $1/r^2$. One should keep in mind, however, that under laboratory conditions the field distribution can be distorted by metal objects even at these distances from the jet, and more so when $r/\lambda > 1$, as the field of the jet becomes comparable with the fringing field.

The electric field at 103 MHz is 60 mV/m for $r \simeq \lambda$.

2. The field outside the jet can be increased by placing a dielectric plate in the jet. The field enhancement in this case is due mainly to an increase in the intensity of the oscillations of the jet as a result of the formation of a counterstreaming electron beam which is reflected from the plate.

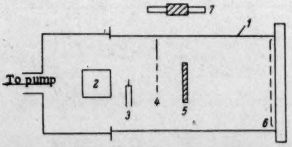

Fig. 1. Schematic diagram of the experimental arrangement. 1) Cavity with ceramic walls; 2) plasma source; 3) high-frequency probe; 4) conductor-antenna; 5) dielectric plate; 6) collector; 7) ferrite antenna.

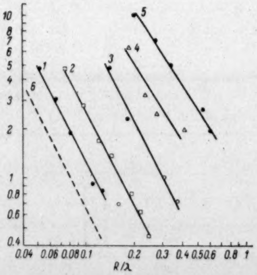

Fig. 2. Experimental plots of alternating magnetic field as a function of radius (relative units) for various frequencies. ω, MHz: 1) 24, 2) 36, 3) 68.5, 4) 80.5, 5) 103, 6) $1/R^2$.

Conversion of longitudinal waves reflected from the dielectric plate into electromagnetic radiation can occur at the plasma–dielectric boundary. The conversion efficiency depends strongly on the angle at which the longitudinal wave is incident upon this boundary.[5] Under the experimental conditions it is difficult to achieve the conditions required for efficient conversion, as the electron flow in the jet is an unfocused divergent flow and the plasma boundary near the dielectric can have an arbitrary curvature because of the inhomogeneity of the charge distribution over the dielectric surface.

Placing a plate of mica across the stream (dimensions of mica plate 20 × 30 cm) increases the amplitude of the oscillations in the stream by a factor of 5-7 (f = 150-200 MHz), and a capacitive probe picks up oscillations in the second-harmonic range of frequencies (300-400 MHz), indicating the nonlinear character of the interaction of the plasma and the electron stream. The amplitude of the oscillations detected in the frequency range 150-200 MHz by an antenna located 2 m from the experimental volume increases by a factor of 4-5 when the mica plate is introduced. The optimum orientation of the mica plate in the jet is perpendicular to the axis in the region of maximum oscillation intensity.

3. Experiments have shown that the field outside the jet can be increased by partially immersing a conductor (conductor–antenna) in the jet in a plane perpendicular to the direction of propagation of the longitudinal wave. In the jet a layer of positive space charge is formed around the insulated conductor. The boundary of the plasma and the surface of the conductor constitute a capacitor; as a result an alternating charge is induced on the conductor by the longutidinal waves of the jet. Clearly, when the conductor is oriented along the direction of propagation of the longitudinal wave and the length of the conductor extends over a few retarded wavelengths, the total induced charge will not be large.

In the first approximation the alternating electromagnetic fields near the part of the conductor–antenna jutting out from the plasma are distributed like the fields of an asymmetric dipole.

The longitudinal wave incident upon the surface of the plasma–conductor layer can be regarded as a certain line with distributed parameters loaded by a complex impedance determined by the parameters of the conductor and the plasma. The equivalent circuit of the load is shown in Fig. 3.

The power flux for a plane wave is $P_n = \varepsilon_0 k^2 U_0 v_g$ is the wave number, ω_p is the electron plasma frequency, U_0 is the potential of the longitudinal wave, S is the cross-sectional area of the flux, v_g is the group velocity of the wave, close to the velocity of the electron stream v_e, and ε_0 is the dielectric constant. We represent the power flux in the form $P_n = (1/2)(U_0^2/\rho)$ and regard $\rho = 2/(\varepsilon_0 k^2 S v_g)$ as a certain equivalent wave impedance of the longitudinal wave.

The power radiated by the conductor–antenna can be expressed as

$$P_r = \frac{1}{2}\frac{(1-p)^2 U_0^2 R_r}{\rho^2},$$

where

$$p = \sqrt{\frac{(R_{in}-\rho)^2 + \left(X + \frac{1}{\omega C}\right)^2}{(R_{in}+\rho)^2 + \left(X + \frac{1}{\omega C}\right)^2}}$$

is the reflection coefficient,

$$R_{in} = \frac{R_r}{\sin^2\frac{2\pi l}{\lambda}}.$$

If the reflected wave is assumed to have no effect on the processes in the plasma, the conversion coefficient is given by

$$\frac{P_r}{P_n} = \frac{(1-p)^2 R_r}{\rho}.$$

By suitably choosing the length of the external radiating portion of the conductor–antenna l it is possible to balance out the capacitive reactance of a layer for $0.25 < l/\lambda < 0.5$. The required length l is found from the relationship

$$-60\left(\ln\frac{l}{r_1} - 1\right)\operatorname{ctg}\frac{2\pi l}{\lambda} = \frac{1}{\omega_p C}$$

where r_1 is the radius of the conductor. The results of a calculation of the conversion coefficient as a function of ρ for zero load reactance are shown in Fig. 4 along with the values of l/λ required to achieve this condition. In the calculations the thickness of the plasma–conductor layer is estimated through the equation for a planar layer near an electrode having a negative potential relative to the plasma, the space charge of the fast electron beam being ignored. In this approximation

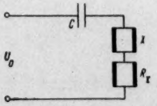

Fig. 3. Equivalent circuit of radiating conductor. U_0) Amplitude of potential of longitudinal wave; C) capacitance of conductor–plasma layer; R_r) radiation resistance of asymmetric dipole; X) reactance of asymmetric dipole.

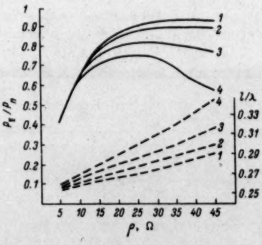

Fig. 4. Coefficient of conversion of longitudinal wave into electromagnetic wave by conductor–antenna (solid curves) and l/λ (dashed curves) vs equivalent wave impedance of longitudinal wave under condition $1/\omega_p C + X = 0$. U/T_e: 1) 50, 2) 150, 3) 500, 4) 1500.

$$\frac{\frac{1}{\omega_p C}}{\rho} = 0.37\sqrt[4]{\frac{U}{T_e}},$$

where U is the potential determining the energy of the fast electron beam and T_e is the temperature of the plasma electrons (in eV).

Figure 5 shows plots of conversion coefficient vs ρ for $l/\lambda = 0.25$ and $X = 0$, $R_r = 36.5\ \Omega$.

The conversion coefficient is somewhat lower here on account of the large reflection coefficient. Since

$$\rho = \frac{12 \cdot 10^3 U^{1/2}}{\varepsilon_0 \omega_p^2 S},$$

we can use Figs. 4 and 5 to determine the optimum geometrical dimensions of the radiative part of the conductor–antenna and the part of it immersed in the plasma.

It is found experimentally that a molybdenum wire 1 mm in diameter and 30 cm long immersed to one half its length in a plasma jet in the transverse direction to the jet in the region where the oscillations are most intense gives a fivefold increase in the intrinsic noise at 170 MHz. The receiving antenna is located 2 m from the experimental volume. Replacing the wire with a grid of dimensions 15×15 cm and cell size 1.5×1.5 mm increases the field amplitude by a further factor of 20.

Estimates imply that this corresponds to an increase in the surface area of the layer by a factor of 10-15. The ratio of the amplitude for the grid to the amplitude for the wire calculated allowing for the experimental parameters of the jet amounts to 15-22, in good agreement with experiment.

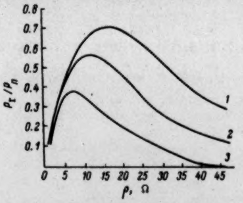

Fig. 5. Coefficient of conversion of longitudinal wave into electromagnetic wave by conductor–antenna vs equivalent wave impedance of longitudinal wave under condition $l/\lambda = 0.25$. U/T_e: 1) 15, 2) 150, 3) 1500.

Accelerators

Efficiency of internal targets in the accelerator at the Institute of High-Energy Physics

V. I. Gridasov, K. P. Myznikov, and V. N. Chepegin

(Submitted September 18, 1973)
Zh. Tekh. Fiz., 44, 1477-1483 (July 1974)

The accelerator at the Institute of High-Energy Physics has been studied in an attempt to maximize the efficiency of the beam—target interaction. An efficiency higher than 90% can be achieved if the beam is brought onto the target slowly; an efficiency of 30%-50% can still be achieved if the beam is brought onto the target rapidly, in a time as short as 1 msec.

Most of the physical experiments carried out with the accelerator at the Institute of High-Energy Physics use particle beams produced on internal targets. Methods for producing these secondary-particle beams have been described elsewhere.[1,2] The target position in the accelerator chamber is chosen so that the desired secondary-particle species at the desired momentum can be extracted from the accelerator at a very small angle. Intense beams can be extracted in this manner. On the other hand, since it is desirable to extract beams as intense as possible containing particles with various momenta in a specified direction, it is necessary to vary the radial and azimuthal positions of the target. Figure 1 shows a cross section of the vacuum chamber in the radial-focusing unit and the extreme radial positions of the target. The proton beam is held at the central orbit throughout the acceleration cycle. With the beam in this position, a dynamic gradient-correction system provides conditions such that the working point as far as synchrotron-oscillation frequencies are concerned is far from any nonlinear-resonance lines.[3] This measure makes it possible to avoid anomalous beam broadening; the beam dimensions at the end of the acceleration cycle do not exceed 10 mm horizontally and 7 mm vertically in the focusing unit. The practical range of target radial positions is ± 4 cm from the central orbit. In the vertical direction the center of the target coincides with that of the accelerated beam at the given azimuth. The target is brought to the specified position by an actuating mechanism which positions the target in both the outer and inner parts of the chamber with respect to the beam. The beam is brought onto the target by systems which excite a local distortion of the orbit at the target position. Long secondary-particle pulses (up to 2 sec long) are produced by slowly increasing this local distortion.[4] When the beam is shifted to the target rapidly a rapidly increasing perturbation results.[5]

The structural elements of the internal target are shown at the top of Fig. 1. The target proper, i.e., the part which interacts with the beam, is attached to the target holder by a brace. The holder is quite massive, since it supplies the rigidity for the structure. The brace length is limited by the operating conditions within the radial-focusing units, in which the vertical dimension of the gap at the edge of the open part is 80 mm (Fig. 1). The brace itself is limited to a length of 15 mm. The target dimensions are governed largely by the operating conditions in the channel which guides the extracted beam to the experimental apparatus. The transverse dimensions of the target must satisfy the conditions imposed by the specified momentum resolution and the specified dimensions of the particle beam incident on the experimental apparatus; in most cases the target diameter cannot exceed 3 mm. The mass of the target along the beam direction must be much larger than that of the brace and holder so that the latter do not make important contributions to the secondary beam. The brace and the part of the holder near the target are therefore as light as possible. The material and maximum dimension of the target are chosen to maximize the efficiency of the beam-target interaction, i.e., to maximize the fraction of the accelerated particles which undergo nuclear interactions in the target itself. Below we report work carried out to determine the conditions maximizing this efficiency for operation of internal targets in the accelerator at the Institute of High-Energy Physics at an accelerator energy of 70 GeV.

Numerical calculations have been carried out on a BÉSM-6 computer to study the mechanism for the beam—target interaction. In these calculations the beam of accelerated protons is described as a set of particles differing in initial amplitudes and phases of synchrotron oscillation. The calculation procedure itself is described in detail elsewhere.[6] We have modified this procedure by calculating the trajectory of each particle through an integration of the equations of motion (not linearized) in the magnetic field, determined from magnetic measurements, taking nonlinear terms up to the fifth power, inclusively, into account.[1] In several cases it is possible to incorporate the effects of the nonlinearities of the accelerator magnetic field. The instantaneous coordinates of the particle trajectory near the target are compared with the specified coordinates of the volumes occupied by the target, brace, and holder for each orbit. When a particle with specified initial conditions is incident on

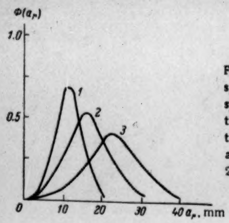

Fig. 2. Particle distribution with respect to the amplitudes of the radial synchrotron oscillations after 80% of the particles initially incident on the target have undergone nuclear interactions with it. 1) Beryllium target; 2) aluminum; 3) copper.

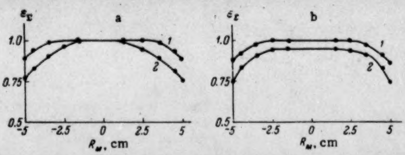

Fig. 3. Relative efficiencies of beryllium (1) and aluminum (2) targets as functions of the radial position of the target in the radial-focusing (a) and radial-defocusing (b) units of the accelerator.

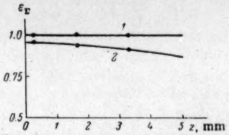

Fig. 4. Relative efficiencies of beryllium (1) and aluminum (2) targets in the radial-defocusing unit as functions of the amplitude of the vertical orbit distortion.

one of these volumes the relative number of particles which undergo nuclear interactions with the absorber is calculated; the particle energy is modified by the magnitude of the ionization loss; the multiple-scattering angle is calculated by a standard random-number program. A definite intensity is assigned to particles with specified initial conditions and the calculation is continued until all the particles undergo nuclear interactions with the target, the supporting structures, or the walls of the vacuum chamber. The choice of initial conditions incorporates the experimental distributions of the beam particles with respect to free-oscillation amplitudes.[7]

Figure 2 shows the particle distributions with respect to oscillation amplitude for multiple interactions of the beam with copper, aluminum, and beryllium targets according to numerical calculations carried out for 100 particles with various initial conditions. The beam dimensions increase rapidly with the number of passes through the target; this increase is more pronounced, the heavier the target material. Calculations of this type show that the interaction efficiency for heavy targets is reduced significantly by particles which strike the chamber walls. The interactions with the walls can be avoided when beryllium and aluminum targets are used in a restricted radial interval.

In practice, the amplitudes of the synchrotron oscillations can also increase because of resonances as well as multiple scattering. Experiments have been carried out to determine the relative efficiency of the beam–target interaction as a function of the radial position of the target. In these experiments a scintillation detector monitoring the target measures a signal proportional to the integrated number of particles which have interacted with the target. The resultant effect due to interactions with the target, brace, and holder is recorded in this manner. To reduce the spread in working-point positions on the diagram of synchrotron-oscillation frequencies, as the radial target position is varied the beam is brought onto the target through a local distortion of the orbit; this procedure minimizes the frequency shift which occurs as the distortion amplitude is raised.[1] For changes of ± 5 cm in the radial position of the target, the frequency shift is about ± 0.02. Figure 3a shows the measured relative efficiency for various positions of beryllium and aluminum targets with respect to the central orbit in the radial-focusing unit; the analogous curves for the radial-defocusing unit are shown in Fig. 3b. The efficiency falls off considerably more rapidly for aluminum targets than for beryllium targets as the target is withdrawn from the center of the chamber. The reason for this efficiency reduction is the incidence of the beam on the chamber walls, which occurs because of the increase in the beam dimensions due to the interaction with the target. Since the dimensions of the part of the beam in a strong-focusing accelerator which interacts with the target are functions of the azimuthal position of the target, these functional dependences of the efficiency on the target position are quite different for the focusing and defocusing units.

We carry out additional measurements to study this question in more detail. With the target in the radial-defocusing unit, corresponding to the maximum vertical dimension of the beam envelope, we cause an artificial vertical distortion of the orbit; the peak of this distortion also coincides with the defocusing unit. Figure 4 shows the relative efficiences of Al and Be targets as functions of the amplitude of this vertical distortion. We see that when a Be target is used there is a gap between the edge of the beam and the vertical chamber wall, but there is no such gap in the case of an Al target; in this latter case the beam strikes the vertical walls even when the target is near the center of the chamber (Fig. 3b). When the target is in the radial-focusing unit there is no beam loss at the vertical walls, so that the curves in Fig. 3a for Al and Be coincide for the central part of the chamber.

The horizontal dimensions of the beam interacting with the target are determined with probe targets. For this purpose the beam is brought onto the target slowly. Two targets, used as probes, are placed in the accelerator unit through which the beam passes before it reaches the unit under study. One of these probes is inserted from the outer chamber wall, and the other is inserted from the inner wall. A detector monitoring the probe records the coordinate at which the probe becomes tangent to the edge of the beam. The positions of the inner and outer edges of the beam interacting with the target are determined. From these results and from the previously measured position of the beam, unperturbed by the target, the amplitude of the envelope of horizontal

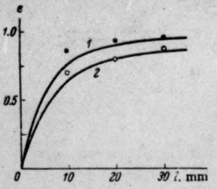

Fig. 5. Absolute efficiences of beryllium (1) and aluminum (2) targets as functions of their length.

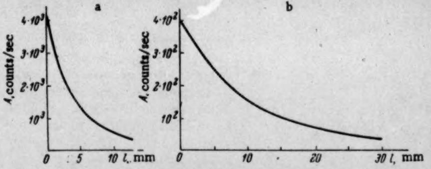

Fig. 6. Induced activity along the length of the brace (a) and along the length of the holder (b).

synchrotron oscillation, a_r, and the maximum momentum spread of the particles after interacting with the target, $(\Delta p/p)_{max}$, are determined. Table 1 shows the results for Be and Al targets 30 mm long and 3 mm in diameter, corresponding to a 95% efficiency.

We can explain the curves in Fig. 3 on the basis of these results. When an Al target is in the radial-focusing unit, with the beam envelope at a maximum, the efficiency reduction due to particle loss at the walls occurs relatively rapidly as the target is withdrawn from the center of the chamber. There is a corresponding contraction of the range of radial target positions in which the efficiency is a maximum.

When the beam is prevented from reaching the chamber walls, and the efficiency is a maximum, the particles can undergo nuclear interaction only with the target holder and brace in addition to the target proper. Numerical calculations show that the fraction of particles interacting with the target increases directly as the target volume is increased (Fig. 5). In an experimental check of these results, aluminum and beryllium targets of various length, all 3 mm in diameter, are irradiated by a 70-GeV proton beam. This irradiation is carried out in a radial-focusing unit with the target 12 mm outside the equilibrium orbit, at a position at which the efficiency is a maximum for Be and Al targets (Fig. 3). In each irradiation care is taken to prevent the beam from striking the chamber walls. The holder and brace are made of aluminum. In the case of the aluminum targets the fraction of particles undergoing nuclear interactions with the target, brace, and holder is determined through relative measurements of the activity of Na^{22} nuclei formed in these structural elements. In the irradiation of the Be targets, an absolute measurement is made of the number of Na^{22} nuclei formed in the holder and brace. The relative number of particles undergoing nuclear interactions with the beryllium target is determined from the results of the measurements and the measured intensity of protons incident on the target. The experimental points are shown along with the calculated curves in Fig. 5. Figure 6 shows the measured distributions of induced activity over the lengths of the holder and brace for the irradiation of a beryllium target 3 mm in diameter and 30 mm long. Using these results, we select a length for the irradiated part of the target holder.

Comparing the calculated and experimental results we conclude that under the optimum working conditions of the accelerator at the Institute of High-Energy Physics, with the beam brought onto the internal targets slowly, the efficiency of these targets can exceed 90%. Beryllium is the best target material. When beryllium is used the efficiency reaches a maximum over the entire range of radial target positions, within ± 40 mm from the central orbit. Measurements have shown that the effects of nonlinear resonances can cause an additional broadening of the beam during its interaction with targets and can significantly reduce the efficiency. The corresponding results will be published and discussed in a separate paper; here we simply note that the results given here correspond to the case in which the effects of these nonlinear resonances are minimized.

TABLE 1

Target position	Target material	Δr_{max}, mm	$\left(\frac{\Delta p}{p}\right)_{max}$
Radial-focusing unit	Be	50	$5\cdot10^{-3}$
	Al	74	$7\cdot10^{-3}$
Radial-defocusing unit	Be	32	$5\cdot10^{-3}$
	Al	55	$7\cdot10^{-3}$

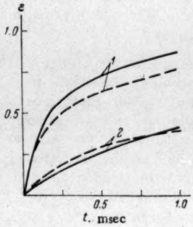

Fig. 7. Efficiency as a function of the duration of the interaction of the beam with Be targets having volumes of 180 mm³ (1) and 1000 mm³ (2). The dashed curves are the analogous curves for Al.

The efficiency is significantly reduced when the accelerated beam is brought onto the target rapidly, due to the reduction in the number of times the particles pass throught the target over the interaction time. Nevertheless in certain physics experiments it is important to hold the beam–target interaction time to a few hundred microseconds, and the efficiency must be maximized under this constraint. Numerical calculations show that if the beam–target interaction is not deliberately interrupted the particles which are incident on the target and undergo repeated interactions with it can continue to interact with the target for some tens of milliseconds, the precise duration depending on the target material, size, and shape and on the method used to bring the beam onto the target. The upper limit on the efficiency can be found

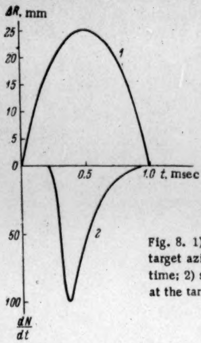

Fig. 8. 1) Distortion of the orbit at the target azimuth as a function of the time; 2) shape of the particle pulse at the target.

by instantaneously shifting the beam to the target, holding it there for a specified time, and then instantaneously removing it. From the curves calculated for this situation (Fig. 7) we see the functional dependence of the efficiency on the beam−target interaction time for targets of various materials and volumes. For maximum efficiency at a limited interaction time the target should be made of a light material and should have as large a volume as possible.

In practice it is extremely difficult to move the beam onto the target "instantaneously," so we have carried out calculations for the fast-deflection system used in the accelerator at the Institute of High-Energy Physics.[5] Figure 8 shows the orbital deflection at the target azimuth as a function of the time for this system. We calculated the efficiency for the interaction with a beryllium target under 50 sets of initial conditions. Figure 8 shows the shape of the particle pulse (current pulse) incident on a beryllium target 3 × 3 × 30 mm in size. The efficiency varies from 0.3 to 0.5 for this target, depending on the initial conditions.

In conclusion the authors thank Yu. S. Fedotov for assistance in the calculations, and G. I. Britvich and V. S. Lukanin for participating in measurements of the absolute target efficiency.

Phase motion of particles in an accelerator with an azimuthally varying electric field

M. F. Vorogushin and V. I. Petrunin

(Submitted May 22, 1973; resubmitted October 19, 1973)
Zh. Tekh. Fiz., 44, 1484-1489 (July 1974)

The slow phase motion of particles in an accelerator with an azimuthally varying electric field is analyzed by averaging the dynamic equations. Phase focusing is caused by the rf field components.

In the elementary analysis of an accelerator with an azimuthally varying electric field[1] the nonrelativistic dynamic equations are used for a quasistatic approximation of the single-harmonic field in the gap.

In this note we give the complete system of dynamic equations in the electromagnetic fields of a resonator with azimuthally varying gap;[2] in this system of equations it is possible to incorporate the irregularities in the particle motion due to the high acceleration rate. We also analyze slow phase motion.

We use the Lorentz equation

$$\frac{d\mathbf{V}}{dt}=\frac{e}{m}\left[\mathbf{E}+\mathbf{V}\times\mathbf{B}-\frac{1}{c^2}\mathbf{V}(\mathbf{VE})\right], \tag{1}$$

where **V** and c are the particle velocity and the speed of light, **E** and **B** are the electric field and the magnetic field, and e and $m = m_0/\sqrt{1-(V/c)^2}$ are the charge and relativistic mass of the particle.

The last term in the brackets is due to the mass change during acceleration:

$$\frac{e}{c^2}\mathbf{V}(\mathbf{VE})=e\mathbf{V}\frac{dm}{dt}.$$

Denoting the particle gyrofrequency by $\omega_0 = -eB_0/m_0$, in the usual manner, and denoting the decay rate of the isochronous magnetic field by

$$n_n=-\frac{\omega_0^2r^2}{c^2}, \tag{2}$$

we write the static and rf components of the magnetic field in the cylindrical coordinate system r, φ, z as follows

$$\left.\begin{aligned}B_z&=B_0\left(1+\frac{\omega_0^2r^2}{2c^2}\right)+B_z(t),\\B_r&=B_0\frac{\omega_0^2rz}{c^2}+B_r(t),\\B_\varphi&=B_{\varphi\,\mathrm{st}}+B_\varphi(t).\end{aligned}\right\} \tag{3}$$

Substituting (3) and

$$(\bar{V}E)=\omega_0(r'E_r+r\varphi'E_\varphi+z'E_z) \tag{4}$$

into (1), and transforming to the new variable $\theta = \omega_0 t$, we find a system of equations for all fields in the accelerating structure:

$$\begin{aligned}r''=r\varphi'\left(\varphi'-\frac{\omega}{\omega_0}\right)+\frac{e}{m_0\gamma\omega_0^2}\Big[&E_r\left(1-\frac{\omega_0^2r'^2}{c^2}\right)-\omega_0z'\left(B_\varphi+\frac{\omega_0r'}{c^2}E_z\right)\\&-\frac{\omega_0^2rr'\varphi'}{c^2}E_\varphi+\omega_0r\varphi'B_z(t)\Big],\end{aligned} \tag{5}$$

$$\begin{aligned}\varphi''=-\frac{r'}{r}\left(2\varphi'-\frac{\omega}{\omega_0}\right)+\frac{e}{m_0\gamma\omega_0^2r}\Big[&E_\varphi\left(1-\frac{\omega_0^2r^2\varphi'^2}{c^2}\right)\\&+\omega_0z'\left(B_r-\frac{\omega_0r\varphi'}{c^2}E_z\right)-\frac{\omega_0^2rr'}{c^2}E_r-\omega_0r'B_z(t)\Big],\end{aligned} \tag{6}$$

$$\begin{aligned}z''=\frac{e}{m_0\gamma\omega_0^2}\Big[&E_z\left(1-\frac{\omega_0^2z'^2}{c^2}\right)+\omega_0r'\left(B_\varphi-\frac{\omega_0z'}{c^2}E_r\right)\\&-\omega_0r\varphi'\left(B_r+\frac{\omega_0z'}{c^2}E_\varphi\right)\Big],\end{aligned} \tag{7}$$

where

$$\frac{\omega}{\omega_0}=\frac{1}{\gamma}\left(1+\frac{\omega_0^2r^2}{2c^2}\right),$$

and $\gamma \cong 1+\omega_0^2r^2\varphi'^2/2c^2$ is the relativistic factor.

The field components in Eqs. (5)-(7) were determined previously[2] for an accelerating structure with azimuthally varying boundaries. Using these components, we can integrate the dynamic equations on a computer.

In an analytic approach we evaluate the terms in Eqs. (5)-(7) using several characteristic parameters, usually known in order of magnitude:[1] the energy increment per revolution and the kinetic energy of the particle (both in volts),

$$U_{\mathrm{rv}}=\frac{\pi}{2}U_0\delta\nu f(r)\cos\psi_\theta=|U_{\mathrm{rv}}|\cos\psi_\theta, \tag{8}$$

$$U_m=\frac{m\omega_0^2r^2}{2e}; \tag{9}$$

the electric-focusing index,

$$n_{\mathrm{el}}=\frac{U_0\nu^2\delta f(r)}{8U_m}\sin\psi_\theta=|n_{\mathrm{el}}|\sin\psi_\theta; \tag{10}$$

and the instantaneous particle phase,

$$\psi_\theta=\psi-\nu(\varphi-\theta).$$

Here

$$\delta=\left(1-\frac{2z_0}{d}\right)\frac{\mathrm{ch}\,\frac{\nu z}{r}}{\mathrm{ch}\,\frac{\nu z_0}{r}}.$$

Let us consider the equation for the vertical motion, Eq. (7). Using the obvious inequalities $r\varphi' \gg r'$, $r\varphi' \gg z'$ we simplify Eq. (4)

$$(\bar{V}E)\cong r\varphi'E_\varphi\omega_0. \tag{11}$$

Then, using (8)-(11) and the approximation $r' \cong [e/(m_0\cdot\omega_0^2)]E_\varphi$ of ref. 1, and averaging the terms of the equation over the period of the structure $(2\pi/\nu)$, we find the following equation, which holds near the median plane $(z < z_0)$:

$$z''+\frac{U_{\mathrm{rv}}\delta^2}{4\pi U_m}z'+\left[n_{\mathrm{el}}+n_n-\frac{df}{dr}\frac{|U_{\mathrm{rv}}|^2r\cos 2\psi_\theta}{(4\pi U_m)^2 2f}\right]z=0. \tag{12}$$

This equation, with slowly varying coefficients, has an oscillatory solution with a damping constant

$$\sigma=\frac{U_{\mathrm{rv}}\delta^2}{8\pi U_m}=\omega_0\frac{m'}{m},$$

which is negligibly small – a typical situation for a cyclotron.[3] The frequency of the vertical oscillations of a particle is governed by the three terms in the coefficient of z; the first is related to E_z, a component of the rf electric field;[1)] the second is due to the defocusing effect of the isochronous magnetic field; and the third is due to the interaction of r' and B_φ, a component of the rf magnetic field. This last term is defocusing in the case $\cos 2\psi_0 > 0$ and focusing in the case $df/dr > 0$, but in practice it is difficult to use it because it is small in comparison with the preceding terms.

Taking these assumptions into account, we write the averaged equation of the vertical oscillations in the standard form,[4]

$$z'' + (n_{el} + n_M) z = 0. \tag{13}$$

In our case, however, in contrast with the case of slit focusing, the vertical stability of a particle is governed by the aperture coefficient δ, which incorporates the electric field configuration in the median plane, and the function $f(r)$, which governs the radial distribution of the rf field. In addition, the quantity n_{el} is typically a quadratic function of the number of azimuthal field cycles. In particular, for a two-dee accelerating structure $\nu = 1$, $f(r) \equiv 1$, $\delta = 1$ and the equations for n_{el} are the same.

We now consider the radial-phase motion. In accelerating structures in which the electric field varies in the azimuthal direction the rapid acceleration rate causes the term r" to become important. This term causes both the "fast" radial-phase oscillations, which (in contrast with synchrotron oscillations) are related to energy oscillations, and a "slow" phase drift. Since the characteristic times for these types of motion are of different orders of magnitude, a separate analysis is possible.

Equation (13) is solved by the WKB method[1] for the slow phase motion ($\varphi' \cong 1$; $r\varphi'' \ll r'$), and Eqs. (5) and (6) can be solved jointly. In this case, with an isochronous magnetic field ($\omega/\omega_0 \cong 1$), the quantity $2\varphi' - \omega/\omega_0$ is approximately equal to unity; thus, neglecting the term containing the product of small quantities zz' in Eq. (6), we find

$$r' = \frac{eE_\varphi}{m_0\gamma\omega_0^2\left[1 + \frac{2|n_{el}|rf'_r}{\nu^2 f}\sin\nu\varphi\cos(\nu\theta + \psi)\right]}.$$

An estimate of the last term in brackets by averaging shows that the effect of the H_z component of the rf magnetic field on the radial motion is negligible $[n_{el}\, rf'_r \cdot (\nu^2 f)^{-1} \ll 1]$:

$$r' \cong \frac{eE_\varphi}{m_0\gamma\omega_0^2}. \tag{14}$$

Evaluating the total derivative

$$r'' = \frac{e}{m\omega_0^2}\left(\frac{\partial E_\varphi}{\partial\theta} + r'\frac{\partial E_\varphi}{\partial r} + \varphi'\frac{\partial E_\varphi}{\partial\varphi}\right) \tag{15}$$

and substituting into Eq. (5), we average this equation over the period of the structure, using Eqs. (8) and (10):

$$\varphi' = \frac{1 - n_{el} - \frac{n_{el}z_0}{\nu r}\operatorname{th}\frac{\nu z_0}{r} + \frac{e^2U_0^2 ff'_r}{2m^2\omega_0^4\nu^2 d^2 r} + \frac{|n_{el}|^2}{\nu^2}\left[\frac{rf'_r}{f} - 1 - \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right]\left(\frac{1}{2} + \cos^2\psi_\theta\right)}{1 - n_{el} - \frac{rf'_r}{\nu^2 f}n_{el} - \frac{\omega_0^2 r^2}{\nu^2 c^2}|n_{el}|^2\left(\frac{1}{2} + \cos^2\psi_\theta\right)}.$$

Differentiating the equation for the instantaneous phase $\psi'_\theta = -\nu(\varphi' - 1)$ and substituting into (16), we find

$$\psi'_\theta = -\frac{1}{\nu}\,\frac{|n_{el}|^2\left[\frac{rf'_r}{f} - 1 + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right]\left(\frac{1}{2} + \cos^2\psi_\theta\right) + n_{el}\left(\frac{rf'_r}{f} + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right)}{1 - n_{el} - n_{el}\frac{rf'_r}{\nu^2 f} - |n_{el}|^2\frac{\omega_0^2 r^2}{\nu^2 c^2}\left(\frac{1}{2} + \cos^2\psi_\theta\right)}. \tag{17}$$

The smallness of the quantities $(\omega_0 r/c)^2 \ll 1$ and $2 \cdot (2r/\delta d\nu^2)^2 \ll 1$, is taken into account here; physically, this smallness means that the contribution of the azimuthal component of the rf magnetic field and of scalar product (4) to the phase motion of the particles is negligible.

Accordingly, in this case the dynamics of the particles in an accelerator with an azimuthally varying electric field is described by the system of averaged equations (13), (14), (17).

For estimate purposes we neglect the terms small in comparison with one in the denominator in (17); it can be shown that this simplification has only a quantitative effect and does not alter the nature of the phase motion. Then, using $\psi'_\theta = (d\psi_\theta/dr)r'$, we convert Eq. (17) to a Riccati equation through the substitution $y = \sin\psi_\theta$:

$$\frac{dy}{dr} = \frac{|n_{el}|}{r}\left(\frac{rf'_r}{f} - 1 + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right)\left(y^2 - \frac{3}{2}\right) - y\left(\frac{f'_r}{f} + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right) \tag{18}$$

For phases satisfying $\sin^2\psi_\theta \ll 3/2$ the solution can be found by quadratures:

$$y = \frac{\operatorname{ch}\frac{\nu z_0}{r}}{f}\left[C - \frac{3}{2}\int\frac{|n_{el}|f}{r\operatorname{ch}\frac{\nu z_0}{r}}\left(\frac{rf'_r}{f} + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right)dr\right].$$

Using (10) and the initial conditions at $\theta = 0$,

$$f = f(0),\ |n_{el}| = |n_{el}(0)|,\ \psi_\theta = \psi,$$

we can evaluate the integral:

$$\sin\psi_\theta = \sin\psi\,\frac{f(0)}{f}\,\frac{\operatorname{ch}\frac{\nu z_0}{r}}{\operatorname{ch}\frac{\nu z_0}{r(0)}} - \frac{3}{4}|n_{el}|\left[1 - \left(\frac{rf(0)\operatorname{ch}\frac{\nu z_0}{r}}{r(0)f\operatorname{ch}\frac{\nu z_0}{r(0)}}\right)^2\right]. \tag{19}$$

The slow phase motion is governed by two terms. In the first term the factors $f(0)/f$ and $\cosh(\nu z_0/r)/\cosh[\nu z_0/r(0)]$

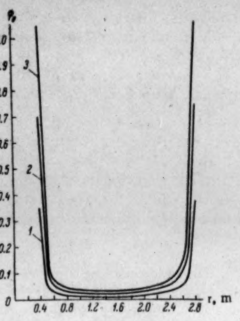

Fig. 1. Phase focusing of the particles. ψ, deg: 1) 20; 2) 40; 3) 60.

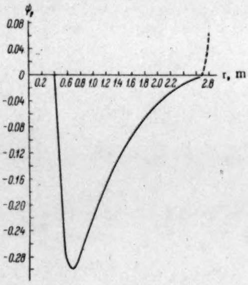

Fig. 2. Phase drift due to the quantity $\langle E_\varphi(\partial E_\varphi/\partial r)\rangle$.

are due to the H_z and E_r components of the rf field, which cause a rapid phase focusing of the particles[2] (Fig. 1); the result of this focusing (the small phase spread of the bunch of particles) is retained essentially to the final acceleration radius r_k. Outside the working region ($r > r_k$), the H_z component causes a phase defocusing. The maximum "phase-contraction" coefficient is

$$k_p = \left.\frac{\sin\psi}{\sin\psi_0}\right|_{\substack{f=1\\ \operatorname{ch}\frac{\nu z_0}{r}\cong 1}} = \frac{\operatorname{ch}\frac{\nu z_0}{r_0}}{f(0)} \cong 20. \tag{20}$$

The second term, governed by the component E_φ and its radial variation, $\langle E_\varphi(\partial E_\varphi/\partial r)\rangle$, is independent of ψ and leads to a phase drift of all the particles as a unit (Fig. 2). Hence this term can be balanced by an appropriate radial variation of the static magnetic field.

Since phase drift (17) is equivalent to a change in the revolution frequency, we can introduce an additional correction into the functional dependence of the magnetic field on the radius, $B_z/B_0 = \gamma(\omega/\omega_0)$; this correction, which is numerically equal to φ'_{dr}, taken with a negative sign, cancels out the undesirable change in the revolution frequency. If this phase-drift compensation is provided for a particle with $\psi = 0$, the corresponding change in the static magnetic field is

$$\frac{B_z}{B_0} = 1 + \frac{\omega_0^2 r^2}{2c^2} - \varphi'_{dr} = 1 + \frac{\omega_0^2 r^2}{2c^2} - \frac{3}{2}\frac{|n_{el}|^2}{\nu^2}\left(\frac{rf'_r}{f} - 1 + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right). \tag{21}$$

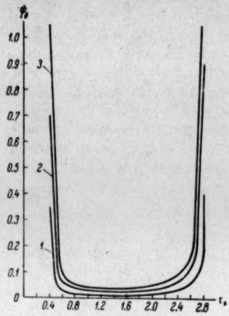

Fig. 3. Slow phase motion with balancing taken into account. ψ, deg: 1) 20; 2) 40; 3) 60.

The condition $\sin^2\psi_\theta \ll 3/2$ is satisfied automatically and is not used below. We also note that the change in the decay rate of the magnetic field caused by the term φ'_{dr} in Eq. (21) is negligible at all radii (it is on the order of 10^{-3}), so the corresponding change in the vertical motion can be neglected. Using (21), we transform Eq. (18) to the Bernoulli form:

$$\frac{dy}{dr} + \left(\frac{rf'_r}{f} + \frac{\nu z_0}{r^2}\operatorname{th}\frac{\nu z_0}{r}\right)y = \frac{|n_{el}|}{r}\left(\frac{rf'_r}{f} - 1 + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right)y^2,$$

for which the solution is

$$y = \frac{\operatorname{ch}\frac{\nu z_0}{r}}{f}\left[C - \int |n_{el}|\frac{d}{dr}\left(\ln\frac{f}{r\operatorname{ch}\frac{\nu z_0}{r}}\right)\frac{\operatorname{ch}\frac{\nu z_0}{r}}{f}\,dr\right]^{-1}.$$

Integrating by parts and using (10) we find, for the previous initial conditions,

$$\sin\psi_0 = \frac{\sin\psi\,\frac{f(0)}{f}\,\frac{\operatorname{ch}\frac{\nu z_0}{r}}{\operatorname{ch}\frac{\nu z_0}{r(0)}}}{1 - |n_{el}|\frac{r^2 f(0)\operatorname{ch}\frac{\nu z_0}{r}}{f\operatorname{ch}\frac{\nu z_0}{r(0)}}\sin\psi\int\limits_{r(0)}^{r}\left(\frac{rf'_r}{f} - 1 + \frac{\nu z_0}{r}\operatorname{th}\frac{\nu z_0}{r}\right)\frac{dr}{r^3}}. \tag{22}$$

Figure 3 shows the particle phase as a function of the radius with the compensation taken into account. We note that the phase drift due to the high acceleration rate is compensated completely only for $\psi = 0$, but even for $\psi \neq 0$ we see that the phase motion is still satisfactory. This circumstance justifies the use of approximate solution (19).

Accordingly, in magnetic field (21) the phase drift due to the acceleration rate is compensated, while the useful effect of the phase focusing is retained [the first term in (19)]. Furthermore, by varying the amount of compensation [e.g., through the coefficient $\alpha \sim 1$ of the term with φ'_{dr} in (21)], we can control the phases of all particles being accelerated as a unit and thus control the relation between the acceleration rate and the degree of focusing.

---

[1] It can be shown that in the general case of an azimuthally periodic field with a potential $U(r, \varphi, z, t)$ the electric-focusing index is

$$n_{el} = -\left\langle \frac{1}{2U_m} \frac{\partial^2 U}{\partial \varphi^2} \Big|_{z=0} \right\rangle,$$

where the averaging is carried out over the period of the structure.

[2] Here and below the numerical calculations are carried out for U^{20}_{238} ions with the following parameters (International Units): $\omega_0 = 16.08 \cdot 10^6$, $U_0 = 10^5$, $z_0 = 10^{-2}$, $d = 0.12$, $\nu = 23$. The radial profile of the rf field in a resonator having a central rod is $f = 0.77\, J_0(k_0 r) + 1.534\, N_0(k_0 r)$. The particles are accelerated from radius $r(0) = 0.403$ to $r_k = 2.1$.

Multiple-section linear electron accelerator with synchronized oscillators

V. F. Vikulov, V. A. Volodin, and O. S. Milovanov

(Submitted October 5, 1973)
Zh. Tekh. Fiz., 44, 1490-1493 (July 1974)

The control and frequency characteristics of multisection linear electron accelerators supplied with rf power from synchronized oscillators are found as functions of the parameters of the synchronous, regime for the particular case of a two-section 10-MeV accelerator driven by two synchronized magnetrons. The calculated and experimental characteristics are compared.

The operating characteristics of a linear electron accelerator in which the rf power is supplied from synchronized oscillators are different from the characteristics of a multiple-section linear electron accelerator with other rf-supply systems. Examples of other systems are the parallel and series supply with rf power from a single oscillator or parallel supply from oscillators synchronized by a master oscillator. These distinguishing features are due to changes in the synchronous frequency, power, and phase in a system with synchronized self-excited oscillators caused by changes in the coupling parameters or in the resonant frequency and power of one or more of the oscillators.

A change in the phase difference between oscillators leads to a change in the phase at which the particles enter the accelerating systems; this phase change leads, in turn, to changes in the energy and energy spectrum of the particles. The effects of a change in the synchronous frequency or power of the oscillators on the particle dynamics in the accelerator are obvious and do not require special analysis.

As an example we analyze the control and frequency characteristics of a two-section, 10-MeV linear electron accelerator in which the sections are supplied rf power separately by two synchronized magnetrons. By "control characteristics" here we mean the functional dependence of the electron energy on the phase with which the particles enter the second section.

Figure 1 shows a block diagram of the accelerator. The first section is a waveguide buncher with slowly varying dimensions. The second is an accelerating waveguide with uniform structure and phase velocity equal to the speed of light. Each section is 2 m long. The oscillator power is 1.3-1.5 MW. The coupler between the oscillators, Co (a narrow-wall directional coupler), and the phase shifters Φ_1 and Φ_2 are used to control the synchronization of magnetrons M_1 and M_2. Ferrite isolaters FR_1 and FR_2 serve as isolators between the oscillators and the accelerator sections. Phase shifter Φ_3 changes the phase with which the particles enter the second section and thus provides control of the particle energy. Two such (U-13) accelerators, constructed at the Moscow Engineering Physics Institute, were put into service in 1968 and 1969; the accelerator design and characteristics are described in detail elsewhere.[1-4] The operation of two synchronized self-excited oscillators (magnetrons) has been analyzed in the a weak-coupling approximation assuming identical magnetron characteristics, a wide-band coupler, and ideal matching of the rf system.[6-9]

Fig. 1. Block diagram of the accelerator. I_C, II_C) Accelerator sections; M_1, M_2) magnetrons; Φ_1, Φ_2, Φ_3) phase shifters; FR_1, FR_2) ferrite isolators Co) coupler.

The frequency f_C; the power levels P_1 and P_2; the phases of the reflection coefficients at the oscillator flanges, ψ_1 and ψ_2; the phase difference of the rf oscillations at the oscillator flanges, $\varphi_{22}-\varphi_{11}$; and that of the oscillations in the loads, $\varphi_{2C}-\varphi_{1C}$, in the stable-operation regime of the oscillators satisfy the following equations:

$$f_c=\frac{f_{01}+f_{02}}{2}-\frac{12}{5}F_0\Gamma_0\,\mathrm{tg}\,\theta\sqrt{\cos^2\theta-\left(\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0}\right)^2}, \tag{1}$$

$$P_1=P_0\left[1+2\Gamma_0\left(\sqrt{\cos^2\theta-\left(\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0}\right)^2}-\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0}\,\mathrm{tg}\,\theta\right)\right]^{-1}, \tag{2}$$

$$P_2=P_0\left[1+2\Gamma_0\left(\sqrt{\cos^2\theta-\left(\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0}\right)^2}+\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0}\,\mathrm{tg}\,\theta\right)\right]^{-1}, \tag{3}$$

$$\psi_1=\theta+\arcsin\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0\cos\theta}, \tag{4}$$

$$\psi_2=\theta-\arcsin\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0\cos\theta}, \tag{5}$$

$$\varphi_{22}-\varphi_{11}=\frac{1}{2}(\psi_1-\psi_2)=\arcsin\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0\cos\theta}, \tag{6}$$

$$\varphi_{2c}-\varphi_{1c}=\beta(l_2-l_1)+\Phi_3+\arcsin\frac{f_{01}-f_{02}}{\frac{24}{5}F_0\Gamma_0\cos\theta}, \tag{7}$$

where f_{01} and f_{02} are the resonant frequencies of the oscillators; $\theta=(2\pi/\Lambda)l_0$ is the electrical length of the transmission line between the oscillators; F_0 is the pulling factor for the magnetron; $\Gamma_0 \ll 1$ is the coupling between the oscillators, since $P_{01}=P_{02}$; $P_{01}=P_{02}=P_0$ is the power level of the oscillators for operation with a matched load; Λ is the wavelength in the waveguides of the rf transmission line; β is the phase constant; $\beta=(2\pi/\Lambda)$ is the geometric length of the rf transmission lines between the oscillators and the sections; and Φ_3 is the phase shift of the wave in phase shifter Φ_3.

The criterion for operating stability of the synchronized oscillators is

$$-\arccos \frac{|f_{01}-f_{02}|}{\frac{24}{5} F_0\Gamma_0} < \theta < \arccos \frac{|f_{01}-f_{02}|}{\frac{24}{5} F_0\Gamma_0}. \tag{8}$$

Experimental study of the this type of synchronized operation of self-excited oscillators has verified (1)-(8).

When the parameters of the synchronous operation are changed, and provided that the changes in the synchronous frequency and the relative particle velocity are small ($\Delta f_c/f_c \leq 10^{-3}$; $\Delta\beta_e/\beta_e \leq 10^{-3}$ at a particle energy of 5 MeV) and that the gap between the sections is no longer than 1 m, the increment in the phase with which the particles enter the second section can be written

$$\Delta\varphi_{in} = \arcsin\left(\frac{f_{01}-f_{02}}{\frac{24}{5} F_0\Gamma_0 \cos\theta}\right)_2 - \arcsin\left(\frac{f_{01}-f_{02}}{\frac{24}{5} F_0\Gamma_0 \cos\theta}\right)_1 + (\beta_2-\beta_1)(l_2-l_1). \tag{9}$$

We see from Eqs. (1)-(7) that the oscillators operate at the same synchronous frequency at different combinations of resonant frequencies and electrical lengths of the transmission line between the oscillators; on the other hand, various methods can be used to tune the synchronous frequency, i.e., the frequency of the rf power supply of the accelerator. For example, one or both of the resonant frequencies of the oscillators can be changed, or the electrical length of the transmission line between the oscillators can be changed. In the former case, however, the power, the phase difference between the oscillations of the oscillators, and the phases of the reflection coefficients are different; in the latter case these quantities are functions of the method used to adjust the synchronism frequency. According to (9), there is an analogous change in the phase with which the particles enter the second section. The net result is a change in the energy of the accelerated electrons.

The nature of the frequency characteristics is thus a function of the method used to adjust the synchronous frequency, while the nature of the control characteristics is a function of the parameters of the synchronous regime in which the characteristics are studied.

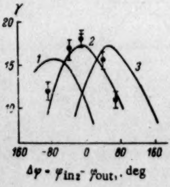

Fig. 2. Control characteristics. P = 11 MW, I = 50 nA/pulse. Solid curves) calculated. 1) f_{c0} + 1 MHz; 2) f_{c0}; 3) f_{c0} − 1 MHz. The experimental points correspond to $f_c = f_{c0}$.

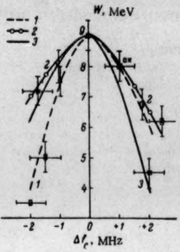

Fig. 3. Frequency characteristics of the accelerator. The solid and dashed curves are calculated. $\theta_{ini} = \Delta f_{0ini} = 0$, $\Gamma_0 = 0.1$, P = 1.2 MW, I = 50 mA/pulse. 1) f_{01} = var, f_{02} = const; 2) $f_{01} = f_{02}$ = var; 3) f_{02} = var; f_{01} = const.

In Figs. 2 and 3 the calculated and experimental characteristics of the U-13 accelerator are shown. The calculations carried out for the particle dynamics in the accelerator incorporate the effect of the coupler on the longitudinal motion of the electrons. The distribution of the phase velocity of the wave along the length of the accelerator has been found experimentally by a nonresonant-perturbation method.[5] The nominal operating parameters of the synchronized magnetrons are taken to be $f_{01} = f_{02} = f_c$, $\theta = 0$, $\Gamma_0 = 0.1$-0.2, and $P_{01} = P_{02}$. Theory and experiment show that these conditions optimize the stability of the frequency, the power, the phase difference between the oscillators, and the phase with which the particles enter the second section. From the data in Figs. 2 and 3 we see that the calculated results agree with experiment, implying that the assumptions used in the analysis are valid.

In conclusion the authors thank V. N. Gusarov for assistance in the calculations and L. I. Kudinov for assistance in the accelerator experiments.

Control of output energy in linear electron accelerators

V. N. Golovin and N. P. Sobenin

(Submitted September 27, 1972; resubmitted October 1, 1973)
Zh. Tekh. Fiz., 44, 1494-1498 (July 1974)

A method of control of beam output energy in a linear electron accelerator is described. The method lies in injecting bunches of small phase width (~ 60-90°) whose phase relative to the high-frequency wave is determined by a phase shifter; these are injected into a waveguide buncher with an equilibrium phase of $\pi/2$. With this method the beam output energy can be controlled up to energies approaching the rest energy. The mean beam output energy and the energy spread are determined. Possible implementation schemes are suggested.

The range of applications of linear electron accelerators can be greatly extended if the output energy of the beam can be made adjustable. Various methods for varying the output energy of the beam are employed, depending on the range of variation of electron energy that is required. Thus, methods of regulating the energy by varying the frequency of the supply source or its power have been developed.[1] Methods of regulating the energy in systems consisting of two or more sections are known.[2] In this case the energy can be varied over a wide range by varying the phase of the accelerating wave at the input to the second or following sections. However, these methods do not lend themselves to regulation of the energy up to levels approaching the electron rest energy. The method described below is free from this shortcoming, and can be used to vary the output energy over a wide range, almost to the rest energy.

The method uses a waveguide section with a constant equilibrium phase, equal to $\pi/2$, in which bunches of a small phase width are accelerated. This system has advantages over other methods of varying the output energy. Thus, for a given intensity parameter function and a given accelerator length, it is possible to obtain a mean beam output energy close to the maximum possible value. Moreover, output energies close to the rest energy can be obtained.

To bring out the physical principles involved, we consider the axial motion of particles in such a system. The following equations describe the axial dynamics of particles in a linear electron accelerator:

$$\left.\begin{aligned}\frac{d\gamma}{d\zeta} &= A(\zeta)\sin\varphi,\\ \frac{d\varphi}{d\zeta} &= 2\pi\left[\frac{1}{\beta_{ph}(\zeta)} - \frac{\gamma}{\sqrt{\gamma^2-1}}\right],\end{aligned}\right\}$$

where γ is the particle energy (in units of the rest energy); $A(\zeta)$ is the intensity parameter function (in dimensionless units); φ is the phase of the particles; $\beta_{ph}(\zeta)$ is the wave phase velocity function (in units of the velocity of light); and ζ is the accelerator length (in dimensionless units).

In an accelerator with a constant equilibrium phase equal to $\pi/2$ the wave phase velocity function is chosen from the requirement of synchronism with particles at a maximum of the accelerating field.

Assume that electron bunches of small phase width are injected into such a system, and that their position relative to the high-frequency field can be varied by a phase shifter. It follows from the equations above that no particle with an initial phase different from $\pi/2$ can acquire an energy greater than or equal to the energy of an equilibrium particle; accordingly, particles can "slip" relative to the high-frequency wave. The magnitude of the phase slip is determined by the distance from the maximum of the accelerating field: The further the particle is from the maximum, the greater its slip relative to the wave. Certain particles, injected in a decelerating field, lose a considerable fraction of their energy in the initial section of the accelerator, and drop out of the stable acceleration made for the fundamental wave. The subsequent phase motion of such particles reduces to a strong slip relative to the high-frequency waves. It is the presence of this physical mechanism in accelerators with $\varphi_{equ} = \pi/2$ that enables the output energy of the beam to be regulated over wide limits.

Let us consider an example of the use of an accelerator with $\varphi_{equ} = \pi/2$ to regulate the beam output energy. In the calculations the accelerator length ξ (in dimensionless units) is taken to be $\xi_k = 13.62$; the intensity parameter function has the following form:

$$A(\xi) = a_0 + a_1\xi + a_2\xi^2 + a_3\xi^3,$$

where $a_0 = 0.6$, $a_1 = 180$, $a_2 = 0.0556$, $a_3 = -0.00391$. The injection energy of the electrons is 120 keV ($\gamma_{in} = 1.236$).

The intensity parameter function and the wave phase-velocity function along the length of the accelerator are shown in Fig. 1. In the calculations the input phase width of the beam is given the values $\Delta_{in} = 60, 90, 120, 180°$. The mean beam energy is determined using the following equation:

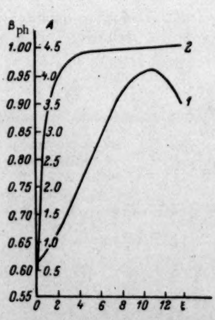

Fig. 1. Intensity parameter function $A(\xi)$ (1) and wave phase velocity function $\beta_{ph}(\xi)$ (2) along length of waveguide buncher with constant equilibrium phase $\varphi_{equ} = \pi/2$.

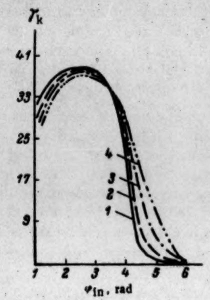

Fig. 2. Dependence of beam output energy on mean input phase of bunch for various values of the input phase width of bunch. Δ_{in_1} = 60°, Δ_{in_2} = 90 (2), Δ_{in_3} = 120 (3), Δ_{in_4} = 180° (4).

$$\gamma_{k_m} = \frac{\sum\limits_{i=1}^{N} \gamma_i}{N},$$

where N is the number of particles for a beam of given phase width. The number of particles is taken from 30 to 90.

Figure 2 shows the output energy vs the mean input phase of the bunch for various values of the phase width of the bunch at the input. For small phase widths (60–90°) and φ_{in} = 2–3 the beam has a maximum energy $\gamma_{k_{mn}}$ = 38.08. This is close to the maximum possible, which, for the intensity function in Fig. 1, is equal to

$$\gamma_{k_{max}} = \gamma_{in} + \xi_k\left(a_0 + \frac{1}{2}a_1\xi_k + \frac{1}{3}a_2\xi_k^2 + \frac{1}{4}a_3\xi_k^3\right) = 39.26.$$

When the mean phase of the beam is varied in the direction of a decelerating wave the mean energy decreases and, in the limit, tends to a value close to unity. Increasing the phase width of the beam to 120–180° is inexpedient, since the region in which low energies are achieved is reduced sharply. The input phase width is also determined by the requirements on the output energy spread. Figure 3a shows the output energy spread (over the basis) as a function of the phase position of the bunch at the input to the section for various values of Δ_{in}. It follows from this figure that minimum energy spreads are obtained for maximum and minimum beam energies, at intermediate values. The energy spread increases. However, if the energy is estimated over 70% of the trapped particles, a reduced energy spread is obtained (Fig. 3b). When the phase of the beam is varied the main portion of the electrons have the same energy on the average; only a few particles have very different energy. If stringent demands are imposed on the energy spectrum in the variation of the output energy, these particles determine the input phase width of the bunch.

In order to compare the different methods of energy control we introduce the output-energy regulation coefficient, defined as the ratio of the maximum bean output energy to the minimum: $r = \gamma_{k_{max}}/\gamma_{k_{min}}$. In any method of control the value of this coefficient cannot be greater than $r_{max} = \gamma_{k_{max\ poss}}$, where $\gamma_{k_{max\,poss}}$ is the maximum possible energy for a given intensity function $A(\xi)$.

The value of the control factor for the present method works out to be r = 38.08/1.2 = 32 in the given example for a bunch phase width of 60°. This is not far from the maximum possible value r_{max} = 39.26.

In a number of cases it is important to know the reduction of the absolute energy spread for low mean output energies of the beam. Let us estimate how the basic parameters of the accelerator affect the output energy spread at low energy levels. It turns out that in an accelerator with $\varphi_{equ} = \pi/2$ low energy levels are achieved with a strong phase slip of the bunch relative to the high-frequency field. With an accuracy sufficient for qualitative calculations the phase slip can be regarded as a linear function of the length of the section since β_{ph} is close to unity over a large part of the accelerator and the particle energy is close to unity. The energy spread in the case of strong phase slip relative to the high-frequency wave is given by the difference in the energies which the particle acquires when it is in an accelerating half-wave and which it loses when it is in a decelerating half-wave, i.e., the energy spread depends on the value of the intensity parameter.

In a structure with a constant gradient the maximum possible energy spread of low-energy particles can be estimated using the equation

$$\Delta\gamma_{k_{max\ poss}} = \frac{A_0}{\pi} = \frac{eE\lambda}{\pi m_0 c^2},$$

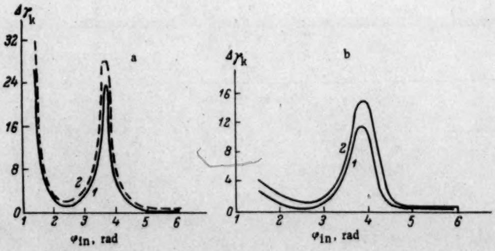

Fig. 3. Output energy spread over total number (a) and over 70% of trapped particles (b) vs phase position of bunch for different input phase widths. Δ_{in_1} = 60°, Δ_{in_2} = 90° (2).

Thus, the maximum energy spread at low output energies decreases linearly with decreasing intensity parameter A_0 (or E). Accordingly, in accelerators with $\varphi_{equ} = \pi/2$ designed for regulating the beam output energy over wide limits, the energy spread at low energy levels can be reduced by decreasing the value of the intensity parameter towards the end of the accelerator.

We note that the energy spread is also reduced by increasing the supply frequency.

Let us consider ways of putting the proposed method into effect. Two schemes are possible; these differ in the method of obtaining bunches of small phase width. The first scheme consists of a microwave generator, an injector, a chopping device, and a waveguide section with $\varphi_{equ} = \pi/2$. Bunches with phase width 60-90° are obtained with the aid of the chopper and the output energy is controlled by locating the bunches into different phases of the high-frequency wave. In the second scheme, consisting of a microwave generator, an injector, a bunching section, an attenuator, a phase shifter, and a waveguide section with $\varphi_{equ} = \pi/2$, bunches of phase width 60-90° are produced by the bunching section. The use of a bunching waveguide section means that this scheme has an increased trapping coefficient. The bunches are injected into the section with $\varphi_{equ} = \pi/2$ where, in order to reduce the energy spread, the high-frequency field is made to fall off at the end or over a large part of the section.

The example of output energy regulation considered above is very specific. It is distinguished by an intense accelerating field ($A_{max} \simeq 4$), and, accordingly, by a sharp rise in the phase velocity function. Smaller values of the intensity parameter result in a reduction of the maximum beam output energy and thus also of the regulation coefficient. However, it is easier to realize the phase velocity function of the wave when the intensity parameter is small.

Thus, by using accelerators with a constant equilibrium phase of $\pi/2$, it is possible to effect strong control of the beam output energy with high control factors.

(Submitted July 26, 1973)
Zh. Tekh. Fiz., 44, 1499-1506 (July 1974)

X-ray structural studies have been carried out on epitaxial films of $Al_xGa_{1-x}As$ solid solutions and two-sided heterostructures prepared from them and used in injection lasers. The lattice constant of the $Al_xGa_{1-x}As$ solid solutions is measured as a function of the concentration and found to deviate significantly from the Vegard law. The AlAs lattice constant is found to be 5.6675 ± 0.0005 Å. Rocking curves recorded for multilayer structures reveal a degradation of the crystal structure near heteroepitaxial boundaries. X-ray topography reveals defects in these regions, which are apparently due to a discontinuity in the lattice constant at the heteroepitaxial boundary. A study is made of the effect of the dislocation density in the GaAs substrate and in the structure itself on the characteristics of injection lasers prepared from two-sided heterostructures. Dislocations significantly degrade the laser characteristics (the threshold and efficiency) only at densities $N_d \gtrsim 10^5$ cm^{-2}. A study is made of the effects of structural defects, the thickness of the active layer, and the doping level on the rate of the progressive degradation of injection lasers using two-sided heterostructures. The rate of increase in the threshold current due to the degradation increases in diodes with a thin active layer (thinner than 1 μ). Doping has essentially no effect on the degradation rate.

INTRODUCTION

Two-sided heterostructures of the $Al_xGa_{1-x}As-GaAs-Al_xGa_{1-x}As$ type are widely used in injection lasers because they permit significant improvements in the characteristics of lasers that operate at room temperature.[1-5] Important current problems are an increase in the reproducibility of the characteristics and an increase in the reliability of injection lasers. It has been shown that heterojunctions in the AlAs−GaAs system are of high quality in terms of both their optical and recombination properties.[6] It must be noted that in ordinary heterojunctions, in which the variations of x is 0.2-0.3, there is a jump in the lattice constant, Δa, many times the characteristic value for homojunctions in GaAs, where this jump is due to a gradient in the impurity concentrations. It is known that the defects associated with impurity-concentration gradients in GaAs can influence the characteristics of lasers.[7-9] We have therefore felt it useful to study the extent to which heterojunctions affect the defect properties of crystals and the basic properties of lasers. We report here on a study of the crystal defects of two-sided heterostructures in several series of samples, among which the lowest-threshold lasers operate continuously at 300°K (ref. 4); characteristic values for the better diodes are a threshold near 1 kA/cm^2 (the lowest value is 940 A/cm^2 with a resonator 500μ long) and a differential efficiency of about 40% (up to 80% at 77°K).

METHODOLOGICAL QUESTIONS

The two-sided heterostructures are grown by liquid epitaxy from molten gallium−aluminum−arsenic solutions on n-type GaAs substrates in the (100) orientation. The active region is doped with impurities such as Ge, Si, Zn, and Te (to a concentration of about 10^{17} cm^{-3}); the n-type and p-type layers of the $Al_xGa_{1-x}As$ are doped with tin and germanium, respectively (the concentrations are $\sim 1 \cdot 10^{18}$ and $5 \cdot 10^{18}$ cm^{-3}). The substrates are doped with Te or Sn [concentration of $(1\text{-}3) \cdot 10^{18}$ cm^{-3}]. The dislocation density in the substrate is varied from $N_d \leq 10^2$ cm^{-2} to 10^5 cm^{-2}. Furthermore, dislocations at a density of $N_d \sim 10^7$ cm^{-2} are introduced into the substrate and into other parts of the heterostructure by deformation in a three-point bending setup at 450°C.

To measure the lattice constants of the solid solutions we prepare undoped-crystal films (having an electron density of $\sim 2 \cdot 10^{16}$ cm^{-3}) 5-15 μ thick. A JXA-3A x-ray microanalyzer is used to monitor the compositional homogeneity along the thickness of the samples. The x-ray structural analysis includes (1) determination of the lattice constant a as a function of the composition of the solid solution, (2) measurement of the width of the rocking lines ($B_{H/2}$), recorded by means of a two-crystal spectrometer at various parts of the heterostructure, and (3) x-ray topography of the heterostructures by the Berg−Barrett method.

The x-ray structural analysis of the two-sided heterostructures is carried out with oblique sections, and the rocking curves are measured at characteristic structural points (Fig. 3a). The sample surfaces are chemically polished in a $H_2SO_4 : H_2O_2$ (3 : 1) mixture. The Cu $K_{\alpha 1}$ line is monochromatized by a dislocation-free germanium crystal.

Luminescent diodes and injection lasers are synthesized in the standard manner by splitting along cleavage planes. The resonator length is in the range 400-600 μ. The laser characteristics are measured at 300°K in pulses 0.1-0.2 μsec long at a repetition frequency of 1-2 kHz.

LATTICE CONSTANT OF THE SOLID SOLUTION

The x-ray structure studies of typical heterojunctions with x ∼ 0.2 reveal a lattice-constant discontinuity Δa of about $3.5 \cdot 10^{-3}$ Å, i.e., at least twice that expected on the basis of a linear interpolation of the lattice constants of AlAs and GaAs according to refs. 10 and 14. In this connection we have performed more detailed measurement of the lattice constant of solid solutions of the $Al_xGa_{1-x}As$ system over a broad range of compositions; the results are shown in Fig. 1. The sample with the most AlAs has

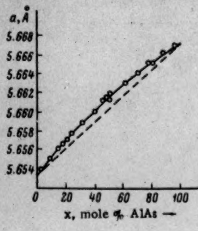

Fig. 1. Lattice constant in the GaAs–AlAs system as a function of the concentration.

TABLE 1

Lattice	a, Å	Reference	Thermal expansion coefficient, $\alpha \cdot 10^6$ deg^{-1}	Reference
GaAs	5.6534 (273° K)	[10]	5.8	[11]
AlAs	5.6622 (300° K)	[13]	6.63	[12]
	5.6605 (273° K)	[14]	5.2	[14]
	5.6675*(300° K)			

*Found through extrapolation of the present data.

a composition of $Al_{0.96}Ga_{0.04}As$ and is grown by liquid epitaxy from a molten aluminum–arsenic alloy on a GaAs substrate. Extrapolation of the functional dependence of the lattice constant on the concentration to x = 1 yields $a(AlAs) = 5.6675 \pm 0.0005$ Å, significantly different from the values given in the literature (Table 1).

A possible explanation for this discrepancy is that the previous measurements of a(AlAs) were carried out with AlAs powders containing certain impurities. Furthermore, AlAs is susceptible to corrosion, and this susceptibility can be even more important when a powdered material is used.

The functional dependence of the lattice constant on the $Al_xGa_{1-x}As$ composition (Fig. 1) displays a positive deviation from the Vegard law, i.e., from a linear $a(x)$ functional dependence. This deviation reaches a broad maximum in the center of the composition range. This deviation in the GaAs–AlAs system apparently cannot be described by geometric models of elastic spheres. The relative excess displacement volume ($\Delta V_{di}/\Delta V$) for this system can be described by the empirical equation

$$\frac{\Delta V_{\text{di}}}{\Delta V} \cong 0.308x(1-x). \tag{1}$$

The positive value of ΔV_{di} means that the activity coefficients of GaAs and AlAs in the $Al_xGa_{1-x}As$ solid solution are larger than unity, i.e., the components of the real solution have higher activities than in the ideal solution of the same composition. This circumstance in turn affects the mutual repulsion of the components in the solid solution and indicates a short-range order of the stratification type.

CRYSTAL DEFECTS OF THE HETEROSTRUCTURES

Figure 2 shows the measured values of $B_{H/2}(x)$ for films of the solid solution $Al_xGa_{1-x}As$ and the adjacent regions of the GaAs substrates. As mentioned previously, the epitaxial films are 5-15 μ thick. The film apparently affects the substrate because of the appearance of stress in the heterojunction. Because of the different thermal expansion coefficients of GaAs and AlAs (Table 1) the value of Δa at the heterojunction boundary is lower at the crystallization temperature of the epitaxial film than at room temperature. Accordingly, after cooling to room temperature the heterojunction is in a stressed state. Figure 3b shows the profile of $B_{H/2}$ along the thickness of one of the heterostructures; these measurements are carried out at characteristic points on oblique sections (Fig. 3a). We see that the heterojunction causes an appreciable broadening of the rocking curves; in addition to the broadening caused by the structural defects there is some additional broadening of the rocking curves from the epitaxial films of the solid solution due to fluctuations in the solution composition. We note that since the cor-

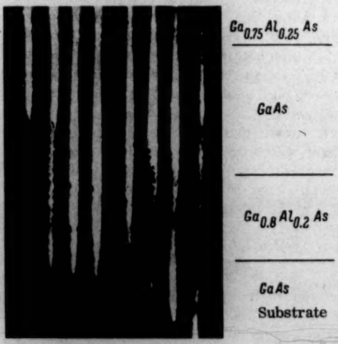

Fig. 4. X-ray topograms of an oblique section of a two-sided heterostructure (the GaAs active layer is about 7 μ thick). The seven successive topograms are recorded for various positions of the monochromator crystal in order to emphasize the reflections from all the layers forming the heterostructure. Reflection inhomogeneities are evident in the transition regions near the heterojunctions.

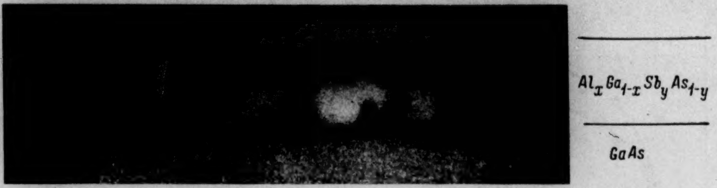

Fig. 5. Photomicrograph of a GaAs$-Al_xGa_{1-x}Sb_yAs_{1-y}$($x = 0.2, y = 0.1$) heterojunction in transmitted IR light.

responding reflection is superimposed on a reflection from the substrate we can only argue that the defectiveness of the active layer (GaAs) of the heterostructure is no worse than that of the boundary layer of the substrate.

X-ray topograms are recorded from samples (Fig. 3a) for which rocking curves were recorded in a scan over an oblique section. To obtain spatial resolution of the active region (GaAs) on the topograms we choose different compositions for the solid solutions at the heterojunctions with the active region (the usual difference was $\Delta x \sim 0.05$). In inspecting the region of homogeneous contrast at the reflection corresponding to the $Al_xGa_{1-x}As$ solid solution or GaAs on the resulting topograms (Fig. 4) we always observe regions 0.5-1 μ in size having a contrast different from that of the crystal matrix, extending in both directions from the heterojunction. The average size of these spots increases with increasing discontinuity in the lattice constant at the heterojunction.

Apparently, the most logical way to explain the regions observed on the topograms displaying a contrast different from that of the crystal matrix is to identify these regions as structural defects at the heterojunctions of the epitaxial films due to the difference in lattice constants. Similar defects have been observed at homojunctions in GaAs with a large jump in the impurity concentration ("planar" defects),[15] but the precise nature of these defects is not known. In two-sided heterostructures with a thin active layer such defects occupy a large part of the active volume and can cross the entire thickness of this volume if this thickness is less than 1 μ.

OPTICAL AND LASER CHARACTERISTICS OF THE HETEROSTRUCTURES

Observations of the heterostructures in transmitted light with an MIK-4 IR microscope reveal that in the overwhelming majority of cases the heterostructures contain no defects visible in IR light. At the same time, an increase in the discontinuity Δa beyond the values characteristic of this type of heterojunction rapidly leads to the appearance of large defects and then to the formation of a dark defect layer. Figure 5 shows an IR photomicrograph of a heterostructure with a GaAs$-Al_xGa_{1-x}Sb_yAs_{1-y}$ junction in which a lattice-constant discontinuity of $\Delta a \cdot a^{-1} > 1\%$ is achieved through the introduction of Sb. Dark regions are visible, extending 10-15 μ into the epitaxial film.

It is sometimes possible to use an IR polariscope to visualize the stress in heterostructures based on GaAs and $Al_xGa_{1-x}As$; estimates of the elastic-stress level near a heterojunction on the basis of calculations using the photoelastic constants[16] yield values below 200 kgf/cm^2. However, such stresses are capable of affecting the local value and ratio of the thresholds for TE and TM waves in lasers using two-sided heterostructures.

Observation of the near-zone pattern of the laser reveals that the inhomogeneities in the emission are frequently correlated with the stress distribution, although in most cases we are not able to identify the reason for the inhomogeneities. We have detected a certain correlation, however, with the defectiveness of the substrate, inferred from the dislocation density. The near-zone homogeneity and efficiency of the lasers are degraded significantly when the dislocation density in the substrate exceeds 10^5 cm^{-2} (Fig. 6), while the difference is negligible at lower densities. We can get some idea of the effect of the dislocation density in the substrate on the threshold characteristics of injection lasers from Fig. 7, which shows the integral distribution of samples with respect to the threshold current density, corrected to an active layer thickness of 1μ (over the thickness range studied, $0.8 < d < 2\,\mu$, the threshold current density in a two-sided heterostructure increases in proportion to the thickness).

Our study of the effect of the structural defectiveness on the degradation characteristics has included measure-

Fig. 6. Near field of laser diodes operating at 1 kHz and 0.2 μsec; the threshold is exceeded by a factor of $p_0 = 3$. a) $N_d = 10^4$ cm^{-2}; b) on a structure deformed by bending.

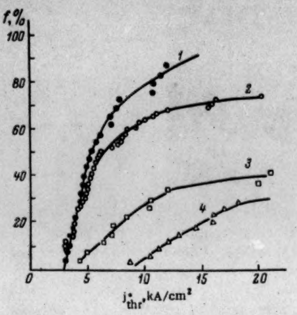

Fig. 7. Distribution of samples in series differing in the dislocation density in the GaAs substrate with respect to the reduced threshold current density j_{thr}/d at 300°K. 1) 10^2 cm^{-2}; 2) 10^4 cm^{-2}; 3) quenched substrate; 4) bending of structure.

ments of the initial rate of increase in the threshold current density under working conditions (pulse length of 0.2 μsec repetition frequency of 2 kHz, and temperature of 300°K) at a level above the threshold by a factor of 1.4-1.5. The threshold current is determined by extrapolating the linear region of the output characteristic P(I) to the abscissa. In operating over 3-6 h we determine the change in the threshold current due to the gradual degradation (aging) of the diodes. The better samples display a relative rate of increase in the threshold lower than the experimental error, corresponding to 10^{-3} sec^{-1}. We find that the thickness of the active layer of the two-sided heterostructure and the dislocation density in the substrate (provided that it is above 10^5 cm^{-2}) are among the factors affecting the degradation rate. Figure 8 shows the effect of d on dj_{n}/dt for various types of doping of the active layer; we see that at d ≈ 0.5 μ the degradation rate increases rapidly, while the effect of doping is slight.

The most rapid degradation is observed in diodes in which inhomogeneities are observed in the distribution of elastic stress near the heterojunction and near large defects.

Observation of the evolution of the laser near zone during accelerated degradation shows that this degradation is usually of an inhomogeneous nature. Figure 9 shows scan curves of the near zone recorded before and after tests as well as at intermediate times. The changes in the near zone resulting from degradation in this case cannot be offset by an increase in the pumping current, since certain parts of the near zone, which become degraded several times more rapidly than other spots of the near zone, suffer irreversible failure. This is particularly true of a region about 30 μ long to the right of the center of the end. Since this region does not display an unusual brightness at the beginning of the tests, and since self-destruction defects are not found at the ends of the diode after the tests, we can assume that the local degradation is due to internal defects in the crystal, which sharply reduce the efficiency of radiative recombination in a limited part of the active region. It is natural to assume that this process is initiated by the defects described above.

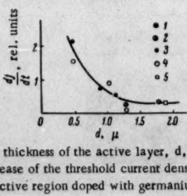

Fig. 8. Effect of the thickness of the active layer, d, on the degradation rate (the rate of increase of the threshold current density) dj_{thr}/dt for various situations: 1) Active region doped with germanium; 2) with tellurium; 3) with silicon; 4) undoped; 5) one-sided heterostructure.

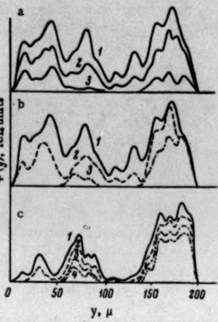

Fig. 9. Distribution of the radiation intensity in the near zone of the sample along the p–n junction. The initial parameters are a threshold current of 4.5 A and a differential efficiency of 16%. The sample gradually undergoes degradation over 20 h during operation at 1 kHz, 0.2 μsec, and a current of 20 A. a: Initial distribution during the aging period. 1) Initial distribution at 10 A; 2) after 2 h; 3) 6h. c: Final distribution. 1) 14; 2) 13; 3) 12; 4) 11 A.

The degrading of the reliability due to the defectiveness of the heteroepitaxial junctions poses a serious problem for the development of lasers using heterojunctions with a large relative jump in the lattice constant.

CONCLUSION AND RESULTS

The quality of a heterojunction and the characteristics of a laser in which it is used depend on the jump in the lattice constant at the chemical boundary. In this regard the GaAs–$Al_xGa_{1-x}As$ heterojunctions have a clear advantage over other heterojunctions because of the smallness of the value of Δa, although we have shown that the value of Δa in this case is roughly twice that assumed previously. The advantages of this system have been demonstrated by its practical use in heterojunction lasers. Nevertheless, x-ray structural studies of two-sided heterostructures and study of the laser degradation show that the heterojunctions cause a certain increase in the crystal defectiveness, which in turn affects the reliability of diodes having a thin active layer. In the latter diodes the heterojunction defects apparently span the entire layer.

The thickness of the defective region extending from the heterojunction increases rapidly with increasing Δa, reaching ~10-15 μ at $\Delta a/a$ ~1% (Fig. 5).

In GaAs–$Al_xGa_{1-x}As$ heterostructures with small jumps in the lattice constant at the junction ($\Delta a \leq 4 \cdot 10^{-3}$ Å with $\Delta x \leq 0.25$), impurities from groups III and V or other impurities can be used to compensate for this jump.

By reducing Δa in this manner it would be possible to improve the characteristics of lasers with a thin active region.

We can summarize our results as follows:

1. We have plotted the lattice constant of the $Al_x \cdot Ga_{1-x}As$ solid solutions as a function of the concentration. We find the lattice constant of AlAs to be 5.6675 ± 0.0005 Å.

2. We have used x-ray structural analysis to study the defectiveness of the heterostructures; we found that the $GaAs-Al_xGa_{1-x}As$ heterojunctions, by virtue of the jump in the lattice constant at the junction, are the source of the defects detected by the x-ray methods.

3. We have studied the correlation of the structural defectiveness of the two-sided heterostructures with the laser characteristics. We find that the characteristics of injection lasers are essentially independent of the nature of the dopant in the active region of the diodes. We find a rapid increase in the degradation rate in two-sided heterostructures having a thin active layer.

Determination of ionization potentials and electron affinities of certain elements by extrapolation

A. G. Kamenev, É. Ya. Zandberg, and V. I. Paleev
A. F. Ioffe Physicotechnical Institute,

Changes in the ionization potentials of elements in subgroups of the periodic table are proportional to changes in the next ionization potentials of adjacent elements of different subgroups because of the identical structure of the outer electronic shells. The proportionality factors differ, depending on the subgroups involved. This regularity is observed for elements beginning in the third row of the periodic table, provided that the outer electronic shell is filled in a regular manner in the transition of an atom of one subgroup to a neighboring atom of a different subgroup. Extrapolation on the basis of these regularities yields the following values (in volts): the first ionization potential V_1 for Fr (3.95); the second ionization potentials V_2 for Po (13.2), At (17.0) and Rn (18); and the electron affinities S of Rb (0.49), Cs (0.48), Fr (0.48), P (0.3), As (0.6), Te (1.96), Po (1.90), and At (2.90). The values of S(P) and S(As) are subsequently refined on the basis of the more accurate experimental determination of the values of S for reference elements in this subgroup.

The ionization potentials V (the first, second, and higher ionization potentials) and the electron affinities S are the most important properties of atoms, molecules, and radicals; however, experimental difficulties have prevented measurements of V_2 for certain elements and S for most elements. Calculations of S for many-electron atoms are carried-out by various approximate methods and lead to different results for certain elements. Various extrapolation approaches, e.g., those of refs. 1-3, are therefore used to evaluate S, and there has been much interest in establishing regularities in the behavior of S and V from element to element within the rows or subgroups of the periodic table. When such regularities are found it may become possible to predict the values of S and V for those atoms for which measurements of these properties have not yet been carried out.

To evaluate S and V here we use the extrapolation approach proposed in ref. 3, based on a comparison of the changes in the electron affinity in the alkali-metal subgroup with the changes in the ionization potentials in the subgroup of the adjacent alkaline earths. The comparison is based on the identical structure of the outer electronic shells of negative alkali ions and the atoms of the alkaline earths. It is assumed that the extent to which the electron affinity changes from element to element within the alkali-metal subgroup is the same as that for the change in the ionization potentials of the adjacent alkaline earth atoms. Hydrogen has been adopted as a reference element for which the value of S is known. The available experimental results on the electron affinities permit more general comparisons for elements of several subgroups.

Let us consider the sequences of values of V_1 and V_2 and those of the values of S and V_1 for those atoms in the subgroups which form isoelectronic series within rows with the correct filling of the outer electronic shell. In the determinations of S the first term of an isoelectronic series is the negative ion of the element whose affinity is to be determined. The value of S for this element is treated as the ionization potential of the negative ion.

Figure 1 shows the ionization potentials V of sequential numbers of isoelectronic series beginning with the negative halogen ions; the elements are ordered according to their atomic number N, and the dashed lines connect identically charged atoms forming the subgroups of elements in the periodic table.

From Fig. 1, we see that except for the first elements in the subgroups (F^-, Ne, Na^+, and Mg^{++}) the ionization potentials of the atoms within subgroups vary linearly, in a first approximation, from element to element. The deviation from this linearity for elements of the first and second rows can be attributed to the reduced shielding of the nuclear charge of these elements by electrons of the outer shells. It can be shown that the sequences of elements constituting the other subgroups in the periodic table display the same regularities.

On the basis of this essentially linear variation of the values of V within the subgroups for elements in the third and higher rows, we can assume the following proportionality:

$$\frac{V_q(N)}{V_{q+1}(N+1)}=\frac{V_q(N+Z)}{V_{q+1}(N+1+Z)}=K(q). \tag{1}$$

Here, Z is the change in the atomic number of the element in a subgroup corresponding to a change in the number of the row, q is the final charge state of the ionized particle (q = 0 for negative ions), and K(q) is a constant for the subgroups being compared.

Now let us compare the first ionization potentials $V_1(N)$ with the second ionization potentials $V_2(N+1)$ of neighboring atoms. The values of V_1 and V_2 are known accurately[4] for many atoms. The linear relationship between $V_1(N)$ and $V_2(N+1)$ which follows from Eq. (1) is illustrated well in Fig. 2 for several subgroups. In this figure the position of each given element of a subgroup

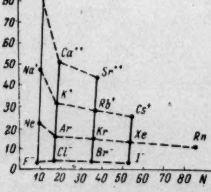

Fig. 1. Ionization potentials V_q of sequential members of isoelectric series beginning from the negative halogen ions. Here N is the atomic number of the element.

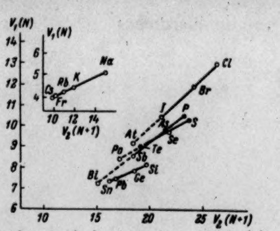

Fig. 2. Relation between the first ionization potentials of the elements and the second ionization potentials of the neighboring elements in different subgroups.

is governed by its first ionization potential $V_1(N)$ and by the second ionization potential of the neighboring element, $V_2(N + 1)$. The solid lines connect points within these subgroups corresponding to known values of $V_1(N)$ and $V_2(N + 1)$, taken from refs. 4 and 5. We see that the coefficient K(q) is in fact constant for the elements within a subgroup, and that it varies from one subgroup to another.

On the basis of these linear functional dependences $V_1(N) = f[V_2(N + 1)]$ we can use a linear extrapolation (dashed lines in Fig. 2) to evaluate the unknown values of V_1 or V_2 within the various subgroups, provided that one of these values is known (we emphasize that this procedure is possible only if the outer electronic shells in the isoelectronic sequence of neighboring elements are filled regularly, and we are not considering the elements in the first two rows of the periodic table). Through extrapolation we find the ionization potentials of the following elements: $V_1(\mathrm{Fr}) = 3.95$ V, $V_2(\mathrm{Po}) = 13.2$ V, $V_2(\mathrm{At}) = 17.0$ V, and $V_2(\mathrm{Rn}) = 18 \pm 1$ V. The error specified with the value of $V_2(\mathrm{Rn})$ is governed by the error assigned the value of $V_1(\mathrm{At})$ in ref. 5.

Similarly, we can trace the regularities in the values of S for atoms in several subgroups. For this purpose we use the values of S determined by surface ionization (SI), photodetachment of electrons from negative ions (PD) and spectroscopy (S).

Figure 3 shows the functional dependence between S(N) and $V_1(N + 1)$ for elements of several subgroups. Here the position of each element of a subgroups is governed by its electron affinity and by the first ionization potential of the neighboring element. The values of S(N) used and the method used to determine them experimentally are given in Table 1.

Figure 3 shows that in the functional dependence $S(N) = f[V(N + 1)]$ for elements of subgroups IVA and VIIA there is the regular behavior predicted by Eq. (1). In the other subgroups shown, the values of S are known for only two elements, but this information is a sufficient basis for determining the values of K(q) and, by extrapolation, the values of S for the other elements in the subgroups. The results are (in volts): S(Rb) = 0.49, S(Cs) = 0.48, S(Fr) = 0.48, S(P) = 0.3, S(As) = 0.6, S(Te) = 1.96, S(Po) = 1.90, and S(At) = 2.90. It should be noted that there can be errors in the values found for S(P) and S(As) because of the relatively poor accuracy with which S(Bi) and S(Sb) were determined.

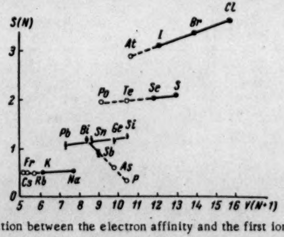

Fig. 3. Relation between the electron affinity and the first ionization potential of the neighboring element in various subgroups.

TABLE 1

Element	S(V)	Method	Reference
Na	0.542 ± 0.010	PD	[6]
K	0.501 ± 0.010	PD	
Si	1.24 ± 0.02	SI	[7, 13]
Ge	1.14 ± 0.03	SI	
Sn	1.16 ± 0.06	SI	[8, 13]
Pb	1.05 ± 0.08	SI	
Sb	0.90 ± 0.07	SI	[9, 13]
Bi	1.16 ± 0.06	SI	
S	2.0772 ± 0.0005	PD	[10]
Se	2.0201 ± 0.0003	PD	[11]
Cl	3.613 ± 0.003	S	[12]
Br	3.363 ± 0.003	S	
I	3.063 ± 0.003	S	

The values of S for the alkali metal atoms are evaluated in ref. 3 through the use of elements of the first row as reference elements. Furthermore, it is assumed there that the values of S in the alkali metal subgroup change from element to element to the same extent as the values of V_1 for the neighboring alkaline earths [equivalently, K(q) = 1]. This procedure leads to the low values of S for the alkali metal atoms.

We note in conclusion that this extrapolation method can be used to determine higher-order ionization potentials of certain elements. We have not studied the question of the values of K(q) or of the changes in these values from subgroup to subgroup; this question is of independent interest.

Evaluation of charge distribution in a crossed-field device from ion bombardment of the cathode

V. I. Malyugin and G. G. Sominskii
M. I. Kalinin Leningrad Polytechnic Institute

(Submitted July 5, 1973)
Zh. Tekh. Fiz., 44, 1511-1516 (July 1974)

A method is described for measuring the charge distribution in high-power crossed-field devices. The energy distribution of ions bombarding the cathode in a pulsed Amplitron with a cold secondary-emission cathode is investigated. The space-charge distribution in the Amplitron is determined from the ion bombardment data.

Although space charge plays an important role in the operation of crossed-field devices, there is little information available on the distribution of the electron cloud in actual amplifiers or magnetrons. This lack is explained primarily by the absence of simple and reliable methods for studying space-charge characteristics in crossed fields. Methods developed for studying space-charge characteristics in magnetron diodes[1–6] have certain shortcomings. A method suitable for analyzing the space-charge characteristics in M-type amplifiers and oscillators is proposed in ref. 7. An analysis of the end current (electron flow along the magnetic field) yields data on the radial space-charge distribution in a magnetron oscillator. However, because of difficulties associated with fringing fields, the most accurate data are obtained only for the electron-cloud regions near the cathode.

As follows from ref. 8, useful information on the space-charge distribution in crossed fields can be obtained from an analysis of the bombardment of the cathode by ions generated in ionization of residual gas by the electrons.

In this note we consider the relation between ion bombardment and the space-charge distribution.

ION CURRENT AND THE SPACE-CHARGE DISTRIBUTION

The ions that are formed in the interaction space of an M-type device under the action of an electric field move toward the cathode along trajectories that are essentially straight lines. Since the action of the microwave field on the ion motion is insignificant, the energy of the ions at the cathode is equal to the potential difference between their point of formation and the cathode surface eU. The current density of the ions striking the cathode with energies from eU to eU_a is

$$j_+ = -\int_U^{U_a} n\rho\sigma_{\text{eff}} \frac{r}{r_c}\frac{dr}{dU}\,dU. \qquad (1)$$

Here, ρ is the electron-charge density at a distance r from the axis of the system, U_a is the anode potential, r_c is the cathode radius, n is the residual-gas density, and σ_{eff} is the effective electron-impact ionization cross section of the gas. The value of n can be found from the pressure p in the device, $n = p/kT$ (k is the Boltzmann constant and T is the temperature). The effective cross section is generally determined as follows:

$$\sigma_{\text{eff}} = \int_{v_i}^{\infty} v^3 S(v)\,dv \int_0^{\pi} \sin\theta\,d\theta \int_0^{2\pi} f(v,\ \theta,\ \varphi)\,d\varphi. \qquad (2)$$

The integration is carried out from velocity v_i corresponding to ionization potential U_i, $v_i = \sqrt{2eU_i/m}$, e and m are the electron charge and mass, S(v) is the dependence of the ionization cross section on the total electron velocity v and $f(v,\ \theta,\ \varphi)$ is the electron velocity distribution function. Introduction of the electron velocity distribution function into the expression for σ_{eff} indicates that the electron motion can be randomized in the interaction space.[7,9–13] The electron velocity spread is given by an electron temperature T_e. Investigations[7,13] in high-power crossed-field devices show that T_e does not exceed $\sim 10^6$°K. In magnetron systems operating at anode voltages $U_a \sim 10^4$ V, the electron energy W is much greater then kT_e in a large part of the interaction space. Therefore, the randomization of the space charge is important in the effective ionization cross section σ_{eff} only near the cathode, where $W \leqslant kT_e$. The dimension of this region can be estimated on the basis of the results of ref. 13, where the electron velocity and temperature T_e are calculated. Figure 1 shows the ratio of kT_e to the electron energy $mv^2/2$ (curve 1) as a function of the radial coordinate r, as obtained from the data of ref. 13 for the magnetron amplifier described in refs. 8 and 14. Evidently $2kT_e/mv^2$ can approach unity only for $r - r_c \leqslant 0.2$ mm. This example indicates that in high-power magnetron devices operated at high anode voltages the effective ionization cross section σ_{eff} in Eq. (1) can be calculated in a large part of the interaction space without taking account of the electron velocity spread.

Differentiating both sides of Eq. (1) with respect to U, we obtain

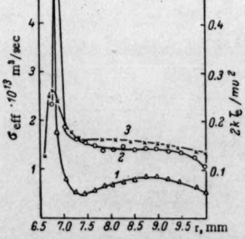

Fig. 1. 1) Dependence of $2kT_e/mv^2$ on the radial coordinate r; 2) characteristics $\sigma_{1\text{eff}} = \sigma_{1\text{eff}}(r)$, calculated on the basis of data of ref. 13; 3) characteristics $\sigma_{2\text{eff}} = \sigma_{2\text{eff}}(r)$, obtained for B = 0.215 T.

$$\frac{dj_+}{dU} = n\rho\sigma_{\text{eff}} \frac{r}{r_c} \frac{dr}{dU}. \tag{3}$$

Solving Eq. (3) together with the Poisson equation

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{dU}{dr}\right) = -\frac{\rho}{\varepsilon_0}, \tag{4}$$

we can obtain the density distribution of the space charge ρ over the radius for a known form of the dependence of dj_+/dU on U. The form of this dependence is determined experimentally in the present article on the basis of an analysis of the energy distribution of the ions bombarding the cathode.

METHOD OF MEASUREMENT AND APPARATUS

The measurements are carried out with the Amplitron described in refs. 8 and 14, which has cold, secondary-emission platinum cathodes. The Amplitron is started by a magnetron oscillator. The pulse length τ of the anode current I_a and the repetition frequency can be varied over wide limits. The device is pumped continuously. The pressure of the residual gas is below $5 \cdot 10^{-6}$ torr. Ion bombardment is investigated by admission of argon; the pressure is controlled by a needle valve.

To determine the form of the function $dj_+/dU = f(U)$ we use the system in Fig. 2. A metal cylinder 3 with a longitudinal 1-mm-wide slit 4 is placed inside a hollow cathode 1 with a diameter[1)] of 13 mm with a transverse slit 2 1.5 mm wide. The ions from the working space enter the system at the point of intersection of the longitudinal and transverse slits. By rotating cylinder 3 we can isolate ion beams from various sections of the interaction space with respect to the azimuth. Only the region that is covered by a diaphragm on the 4-mm-wide cathode 5 remains inaccessible. The ions passing inside the analyzing system must pass through the grids 6 and 7 before they reach the collector 8.

In studying the ion bombardment of the cathode it is important to keep the electrons that bombard the cathode from striking the collector. The electrons passing into the analyzing system are shielded out in the drift space (~4 mm side) between the inner surface of the cylinder 3 and the grid 6. The ion energy distribution is analyzed by the retarding-field method in the space between the grids 6 and 7 by applying a pulsed voltage U. The pulses U are synchronized with the pulses U_a, and the pulse length is selected so that they completely overlap the pulse of the anode-current I_a. The drift space between grid 7 and collector 8(~2 mm) is a barrier for the electrons that result from ionization in the region between grids 6 and 7. Drift of secondary electrons from the collector along the magnetic field is eliminated by choosing a collector in the shape of a small box with folded edges. The analyzing system is rigidly fixed in cylinder 3, which is rotated in vacuum by a special magnet device.

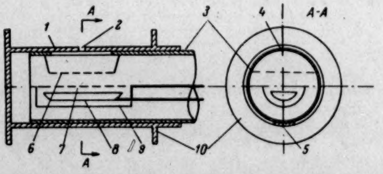

Fig. 2. Schematic representation of cathode with analyzing system, used for studying ion bombardment. 1) Cathode with transverse slit 2; 3) cylinder with longitudinal slit 4; 5) iris on cathode; 6, 7) grids; 8) ion collector; 9) guard electrode; 10) end shield.

The lower limit of the ion energy to be analyzed is determined by the distance between the collector 8 and the cathode surface, which is ~8 mm. In the investigated range of magnetic fields (B ≤ 0.235T) the minimum energy needed by an argon ion to reach the collector is less than 1 eV. Thus, for U = 0 essentially the total ion current incident on the cathode reaches the collector. When U > 0, only those ions formed in the working space of the Amplitron at distances at which the potential exceeds the value U reach the collector.

ENERGY DISTRIBUTION OF IONS BOMBARDING THE CATHODE

The analyzing system allows us to investigate the azimuthal distribution of ions over the cathode surface and the energy distribution of ions bombarding the cathode at different azimuthal angles. The dependence of the ion current I_+ on the azimuthal coordinate φ is measured for different values of retarding ion voltage. It turns out that there is a marked azimuthal variation of the ion current[2)] which does not change with increasing U. The fact that the variation is observed for retarding voltages up to U = 13 kV indicates that the azimuthal inhomogeneities of the space charge are preserved at large distances from the cathode and that they extend over large radial distances. The $I_+ = I_+(\varphi)$ characteristics are qualitatively similar over the entire investigated range of variation of magnetic field (0.15 ≤ B ≤ 0.235 T) and anode voltage (up to 25 kV).

A more complete representation of the energy spectrum of the ions bombarding the cathode is obtained by analysis of the retardation curves $I_+ = I_+(U)$, which are plotted for different values of the coordinate φ. Figure 3 shows typical $I_+/I_{+m} = f(U)$ characteristics, obtained for

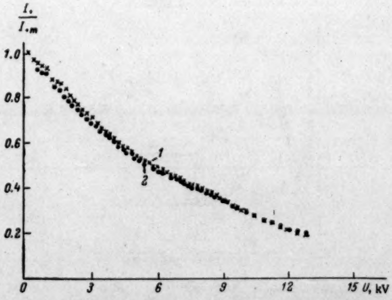

Fig. 3. The ratio I_+/I_{+m} as a function of the retarding voltage U (I_{+m} is the ion current for U = 0), measured at the maximum (curve 1) and the minimum (curve 2) azimuthal distributions of ion current; B = 0.215 Te, U_a = 19.4 kV.

magnetic field B = 0.215 T and anode voltage U_a = 19.4 kV for the maximum (curve 1) and the minimum (curve 2) azimuthal distributions of ion current. The quantity I_{+m} is the maximum value of the ion current for U = 0. As follows from the figure the form of the ion-current distribution varies insignificantly over azimuth.

CALCULATION OF RADIAL SPACE-CHARGE DENSITY DISTRIBUTION IN AN AMPLITRON

The value of dj_+/du necessary for calculating the density of the space charge ρ is obtained by differentiating the experimentally measured retardation curves. The $j_+ = j_+(U)$ characteristics are processed by regression analysis using a computer.

The value of the effective ionization cross section is determined neglecting the randomization of the space charge. The dependence of σ_{eff} on r is calculated for two types of electron velocity distributions in the interaction space, known from literature. Curve 2 of Fig. 1 represents the function $\sigma_{eff} = \sigma_{eff}$ (r), obtained on the basis of the data of ref. 13. Curve 3 $[\sigma_{eff} = \sigma_{eff}(r)]$ is obtained under the assumption that there is a Brillouin velocity distribution $v = (eB/2m)r \times (1 - r_c^2/r^2)$ up to the synchronization radius r_{syn}; for $r > r_{syn}$ it is assumed that the electrons are synchronized with the high-frequency wave. With different electron velocity distributions we obtain similar values of σ_{eff}, which indicates that the values of σ_{eff} do not depend critically on the particular electron velocity distribution.

In solving the system of equations (3) and (4) we use the data on the value of the ionization cross section S(v) of argon from ref. 15. In calculating the gas density ion we take the gas temperature T equal to the cathode temperature. The argon pressure in the working space of the Amplitron is determined directly from the ion current[14] assuming that I_+ depends linearly on p. The radial space-charge density distribution is calculated by numerical methods using a computer. Figure 4 shows the family of characteristics $\rho = \rho(r)$, obtained for B = 0.215 T, anode voltage U_a = 19.4 kV, and various values of φ. The functions 1 and 2 characterize the space-charge density distribution at the maxima of the azimuthal ion-current distribution at the cathode. Curves 3 and 4 are obtained at the minima of the $I_+ = I_+(\varphi)$ function. The characteristics $\rho = \rho(r)$, obtained when the effective ionization cross section is set equal to σ_{2eff} (solid lines) and calculated for the case $\sigma_{eff} = \sigma_{1eff}$ (dashed curves), differ insignificantly over a large part of the interaction space, except for the cathode region. According to these data, the form of the radial space-charge density distribution does not vary qualitatively with the azimuthal coordinate: There are two space-charge density peaks, one of which is near the cathode surface; the position of the second varies with φ. Near the maxima of the azimuthal ion-current distribution, located opposite the slit of the retarding system,[14] the extremal values of the space-charge density are attained at greater distances from the cathode than under the vanes [at the minima of the $I_+ = I_+(\varphi)$ curve]. After the second maximum of the $\rho = \rho$ (r) curve the change in space-charge density is insignificant.

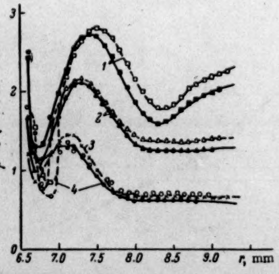

Fig. 4. Dependence of space-charge density ρ on radial coordinate r obtained with the effective ionization cross section set equal to σ_{2eff} (solid lines) and calculated for the case $\sigma_{eff} = \sigma_{1eff}$ (dashed curves). 1, 2) Characteristics $\rho = \rho(r)$ at the maximum (respectively, φ = 70° and φ = 340°) of the azimuthal ion-current distribution; 3, 4) the function $\rho = \rho(r)$ at the minima of the $I_+ = I_+(\varphi)$ (for φ = 240° and φ = 90°).

The form of the characteristics $\rho = \rho$ (r) does not vary qualitatively with changes in the mode of operation of the device. Data on the space-charge distribution near the cathode agree with data obtained earlier, in a study of the end current, on the form of the characteristics $\rho = \rho$ (r) in a magnetron oscillator.[7]

Summing up our study we note the following:

1. The method developed here enables us to measure the radial space-charge distribution in crossed-field devices. The proposed method is relatively simple, it does not disturb the electron cloud, and can be recommended for analyzing the high-density space charge in high-power M-type devices.

2. The energy distribution of ions bombarding the cathode in a pulsed Amplitron with a cold secondary-emission cathode has been investigated.

3. On the basis of the data on the ion bombardment of the cathode we have calculated the $\rho = \rho(r)$ curves for various sections of the interaction space of an experimental Amplitron the $\rho = \rho$ (r) characteristics have two maxima. We observe a radial displacement in the space-charge-density peak that is not at the cathode with a variation in the coordinate φ.

The authors are grateful to E. A. Nefed'evoi, who participated in the measurement, to V. P. Balabin for help with the numerical calculations, and to S. A. Frdirikhov for his interest.

---

1) Anode diameter D_a = 20 mm.

2) These data agree with the results published earlier in a study of the azimuthal distribution of ion current.[8]

Thermal conditions for a sandwich cold cathode

F. M. Benson, P. E. Troyan, and Yu. B. Yankelevich
Tomsk Institute of Automatic Control Systems and Radio Electronics
(Submitted February 18, 1973; resubmitted July 31, 1973)
Zh. Tekh. Fiz., 44, 1517-1520 (July 1974)

The thermal operating conditions of a metal–dielectric–metal system used as a cold electron source are analyzed. In the steady state the system reaches + 100°C. The temperature distribution in the sandwich is governed by the substrate properties. A thermal analysis is made of the operation of a thin-film cathode under pulsed conditions.

Thin-film metal–dielectric–metal systems have found extensive application in modern microelectronics as capacitors, diodes, switches, etc.

One recent application of the system is as a nonincandescent or cold electron source (a sandwich cold cathode)[1] (Fig. 1).

Extremely strong electric fields arise in a thin-film metal–dielectric–metal system, even at low voltages, causing intense field emission from the lower electrode into the dielectric. Some of the electrons accelerated in the dielectric film pass through the upper metal film and, after overcoming the potential barrier at the metal–vacuum interface, leave the system. The transfer coefficient of such a system (the ratio of the electron current into vacuum to the total current through the metal–dielectric–metal system) is usually in the range 10^{-7}-10^{-2}, since most of the electrons are absorbed in the upper metal electrode. The energy of the electrons accelerated in the field is dissipated nearly completely in the upper metal film, causing heating of the latter. The electron acceleration itself is accompanied by the scattering of electrons in the dielectric, which also tends to heat the system.

This heating can cause important changes in the structural properties of the upper metal electrode and can even melt it; the system can crack as a result of the thermoelastic stress arising because of the different expansion coefficients of the components of the system, the conductivities of the metal electrodes can change, etc.

In the systems which we have studied, based on the $Al-Si_3N_4-Al$ structure, the through current reaches a density of 5-10 A/cm^2 at a voltage drop of 10-15 V across the dielectric film. Sandwich cathodes made from this system, on glass substrates, usually fail rapidly (parts of the cathode burn, and the glass substrate cracks). Accordingly, it is very important to analyze the thermal conditions of a thin-film metal–dielectric–metal system in order to determine the optimum operating conditions and the optimum choice of structural components.

We turn now to an analysis of the temperature fields in a metal–dielectric–metal system in vacuum operating under steady-state or pulsed conditions. The structure is shown schematically in Fig. 1, where d_1, d_2, and d_3 are the thicknesses of the sandwich components, and D is the substrate thickness.

1. THE HEAT-SOURCE APPROXIMATION

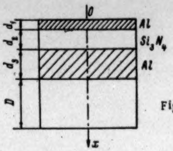

Fig. 1. Construction of a "sandwich" cathode.

Heat is evolved in the dielectric and the upper metal electrode in accordance with the distribution of absorbed energy resulting from the scattering and absorption of hot electrons. In view of the complexity of the analytic distribution function for the energy absorbed in the dielectric film, we assume that all the heat is evolved in the upper metal electrode; we do not introduce any simplifications regarding the conditions for heat transfer from the sandwich. Scattering of hot electrons in the upper metal electrode of a sandwich has been studied experimentally in detail.[2,3]

The number of electrons leaving the upper electrode is given by $n_0 S \exp(-d_1/l)$, where n_0 is the number of electrons incident per unit time on a unit area of the upper electrode; S is the area of this upper electrode; l is the "attenuation length" for the hot electrons, a function of their energies, which are in turn governed by the acceleration and scattering in the dielectric and by the properties of the upper-electrode material;[4] and d_1 is the thickness of the upper electrode. The number of electrons absorbed in the upper electrode is then equal to $n_0 S[1-\exp(-d_1/l)]$. Writing the through current of the system as $i_S = q/t = n_0 S_0 l$, and denoting the voltage applied to the electrodes by U_0, we find that the heat evolved in a unit volume of the upper electrode is

$$Q=\frac{i_S U_0}{S d_1}\left[1-\exp\left(-\frac{d_1}{l}\right)\right]. \qquad (1)$$

In sandwich cathodes the condition $d_1 \approx 2l$ is usually arranged in order to provide the necessary conductivity of the upper electrode and the necessary conditions for the scattering of hot electrons in it. Then we can approximate the heat source by

$$Q(x)=\frac{i_S U_0}{S d_1}, \qquad (1a)$$

which is constant for given values of i_S and U_0.

2. STEADY-STATE TEMPERATURE FIELD IN THE METAL–DIELECTRIC–METAL SYSTEM

We assume that heat is removed from the upper electrode by thermal conductivity. The heat loss due to IR radiation of the free surface of the upper electrode is very small (2%) because of the small area of this electrode and its mirror finish. Convective heat transfer from the surface of the upper electrode, due to collisions with residual gas molecules, is also negligible (on the order of a fraction of 1%). In sandwich cathodes the linear dimensions of the emitting surface are much larger than the thickness of the thin-film metal electrodes, so that it is difficult to remove heat from the lateral surfaces through conducting contacts unless special measures are taken. We can therefore take the one-dimensional approach to determine the steady-state temperature field T(x) in the system (Fig. 2); this field is found from the solutions of the following four heat-conduction equations:

$$\frac{d^2T_1(x)}{dx^2} = -\frac{1}{\lambda_1}Q;\quad \frac{d^2T_i(x)}{dx^2} = 0\ (i = 2, 3, 4)\,, \tag{2}$$

with the adiabatic boundary condition at the free surface of the upper electrode and the isothermal boundary condition at the lower free surface of the substrate. Since the values of d_i (i = 1, 2, 3) are negligibly small, and since $d_i \ll D$, we can omit all terms in the solutions of system (2) containing d_i^2 or $d_i d_j$ $(i \neq j)$. We then find that the temperatures in all the thin-film components of the sandwich are equal:

$$T_1(x) = T_2(x) = T_3(x) = T_S(x), \tag{3}$$

and equal to the temperature at the substrate surface, T_S, with $x = d_1 + d_2 + d_3$. It follows that the thermal situation in a thin-film sandwich (Fig. 2) is governed completely by the comparatively thick substrate, which is described by

$$T_S = \frac{U_0 i_S}{S\lambda}\left[1 - \exp\left(-\frac{d_1}{l}\right)\right]D, \tag{4}$$

where λ is the thermal conductivity of the substrate.

It follows from (4) that the sandwich can be cooled most efficiently if the substrate is a good heat conductor.

Study of the operation of sandwich cathodes over a broad temperature range has shown that the emission current is stable up to 100°C. When the heat evolution corresponds to ~ 150 W/cm², Eq. (4) predicts a temperature reaching 600°C for a sandwich on a glass substrate. Cathodes on a sapphire substrate [λ = 4.2 W/cm · deg)] operate reliably and stably ($T_S \simeq 100°C$).

3. PULSED OPERATION

Since the response time of cold cathodes is extremely short, they can be used to produce high current densities in pulsed operation.

Since the temperature distribution in a thin-film sandwich is governed by the temperature field of the massive substrate, in an analysis of the thermal regime under pulsed conditions we can treat sandwich and substrate as a unit and describe them by means of simply the heat-conduction equation for the substrate:

$$\frac{\partial T}{\partial t} = \varkappa\frac{\partial^2 T}{\partial x^2} + \frac{Q}{cp}, \tag{5}$$

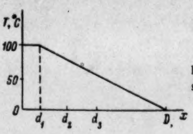

Fig. 2. Topological thermogram of a sandwich cathode in the steady-state.

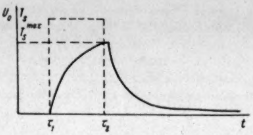

Fig. 3. Applied-voltage pulse (dashed lines) and chronological heating thermogram for a sandwich cathode (solid curve).

where ϰ = λ/cp, where λ is the thermal conductivity, c is the specific heat, and p is the density.

We restrict the analysis to finding the effect of a single rectangular heat pulse produced in the plane of the upper metal electrode with an abscissa equal to zero and which spans the entire thickness of the system, D. Between time τ_1 and τ_2 the rectangular heat pulse is described by an equation found from Eq. (5) (ref. 5):

$$T_S = \frac{i_S U_0}{S\lambda}\left[1 - \exp\left(-\frac{d_1}{l}\right)\right]D \times \sum_{m=0}^{\infty}\frac{8}{(2m+1)^2\pi^2}\left\{\exp\left[-\frac{(2m+1)^2}{4D^2}\pi^2\varkappa(t-\tau_2)\right] - \exp\left[-\frac{(2m+1)^2}{4D^2}\pi^2\varkappa(t-\tau_1)\right]\right\}, \tag{6}$$

which is a series which converges quite rapidly. Assuming m = 0, we find a simplified equation, from which we can easily find numerical values, describing the heating between $\tau_1 = 0$ and τ_2:

$$T_S = \frac{i_S U_0}{S\lambda}\left[1 - \exp\left(-\frac{d_1}{l}\right)\right]D \times \left\{\exp\left[-\frac{2.5}{D^2}\varkappa(t-\tau_2)\right] - \exp\left(-\frac{2.5}{D^2}\varkappa t\right)\right\}. \tag{7}$$

Figure 3 shows the applied-voltage pulse (the dashed lines) and a chronological heating thermogram for a sandwich cathode (solid curve). Evaluation of the pulsed operation on the basis of (7) shows that a sandwich cold cathode on a glass substrate having λ = 0.7 W/(m · deg) can operate reliably at 50 Hz at a length of up to $5 \cdot 10^{-4}$ sec of the voltage pulse; the heat evolution during the pulse is ~ 150 W/cm².

Nanosecond x-ray pulses

G. A. Mesyats
Atmospheric Optics Institute, Siberian Branch,
Academy of Sciences of the USSR, Tomsk
(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 1521-1527 (July 1974)

Nanosecond x-ray pulse generators are used both in the study of rapid processes and for normal radiography. The generator tubes contain either field emission cathodes or cathodes that use explosive emission of electrons. Explosive emission occurs as a result of the interaction with the cathode of a dense plasma formed by the explosion of needles on the cathode. The heating and explosion processes of these needles are considered. The voltage—current characteristics of nanosecond x-ray tubes with this type of emission are subject under certain conditions, to the "three-halves" law. A calculation of these characteristics must take account of the configuration of the cathode plasma. A calculation is made of the parameters of nanosecond x-ray pulses in generators operating by the discharge of a storage capacitor and of a line through the tube which has a large or small number of emission centers. Satisfactory agreement is obtained with the available experimental results.

1. INTRODUCTION

Nanosecond x-ray pulse generators are used in the study of rapid processes and also in normal radiography.[1] The electrons in the generator tubes are obtained either by field emission or by means of an electric discharge in a high vacuum.[2] While the operating mechanism of field-emission x-ray tubes is well understood, the operations of discharge tubes is not clear.

A very fertile concept in the explanation of the operation of these tubes is that the electrons are emitted during the explosive destruction of cathode microneedles as a result of the field emission current.[3] This phenomenon has been called explosive electron emission.[4] The presence of microscopic projections on the cathode surface means that the electric field at these projections is several times greater than the average electric field in the vacuum gap. This produces a greater field emission current from the projections so that they heat up and explode. The same effect of course occurs if metal needles are used for the cathode. The metal vapor from the cathode diffuses into the vacuum and is ionized by the electrons from the cathode; the resulting plasma is known as the cathode flare. The formation of a dense plasma at the cathode surface produces an amplification of the electron current from the cathode. These electrons will be extracted by means of the electric field at the cathode which is formed, apparently, by charge separation in the plasma.[5] The electron current flow in the vacuum gap depends on the rate of expansion and the number of cathode flares, the length of the gap, the applied potential, and the electrodes configuration. The aim of this paper is to calculate the principal parameters of nanosecond x-ray pulses from discharge tubes from the relations governing the explosive electron emission.

2. HEATING AND EXPLOSION OF MICRONEEDLES ON THE CATHODE OF AN X-RAY TUBE

We consider the simplified problem of a cylindrically shaped microscopic emitter under the action of a current of density j (Fig. 1a). If the height of the emitter $h \gg r$ and $h \gg \sqrt{at}$, where t is time and a is the thermal conductivity, we can neglect heat losses due to conductivity and get

$$\rho c \frac{\partial T}{\partial t} \simeq j^2 \varkappa_0 T, \qquad (1)$$

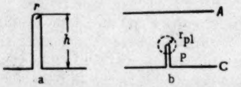

Fig. 1. a) Heating of a microprojection; b) Voltage —current characteristics of a diode with a projection (P) on the cathode (C); A is the anode and r_{pl} = vt is the radius of the cathode flame plasma.

where ρ, c and $\varkappa = \varkappa_0 T$ are the density, specific heat and resistivity of the cathode material, and T is the absolute temperature. It follows from (1) that

$$\int_0^{t_d} j^2 dt = \frac{\rho}{\varkappa_0} \int_{T_0}^{T_k} \frac{c}{T} dT. \qquad (2)$$

If we take $j(t) \simeq \text{const}$ and $c(T) = \text{const}$, we can use (2) to calculate the time t_d required to reach some critical temperature T_{cr}, at which the explosion occurs:

$$j^2 t_d \approx \frac{\rho c}{\varkappa_0} \ln \frac{T_{cr}}{T_0}. \qquad (3)$$

A more rigorous analysis of the emitter heating requires allowance for the fact that the average energy with which the conduction electrons move from inside the metal to the emission boundary is different from the average energy after emission. This leads to heating of the cathode at low temperatures and cooling at high temperatures (the Nottingham effect). In addition, the density of the electron current emitted by the cathode depends on temperature (thermofield emission). When these effects are taken into account, the nature of the relationship between t_d and j remains the same as in (3) but the coefficient of $\rho c/\varkappa_0$ changes. For tungsten, in particular, this coefficient is equal[6] to ~ 55. The $j^2 t_3$ = const relationship is in good agreement with experimental results on the delay time for explosion of tungsten microneedles.[7]

The metal vapor formed after the explosion of needles is ionized by the electrons from the cathode which flow through it. The movement of the plasma (cathode flare) can be represented as the dispersion of a gaseous sphere in space.[8,9] The relevant equations to describe this contain the inertial characteristics of the ions and the total kinetic parameters (pressure, for example) of the electrons and ions. In the self-similar limit, in particular, when the size of the cathode flare becomes much greater than its initial value (transit time t ≫ 10^{-9} sec), we can write the expansion velocity as

$$v \approx \sqrt{\frac{4\gamma}{\gamma-1}(\varepsilon_{i0}+z\varepsilon_{e0})}, \tag{4}$$

where γ is the effective adiabatic coefficient for the plasma, z is the average charge number of the ions and ε_{i0} and ε_{e0} are certain initial specific energies for the electron and ion components.

If we take[8,9] $\gamma = 5/3$ and z = 3, with ε_{i0} as the specific sublimation energy and ε_{e0} corresponding to the Fermi energy in the cathode metal, we get the expansion velocity as v = (2-3) · 10^6 cm/sec (Al, Mo, Cu) and v = 10^6 cm/sec (Pb). These figures are in good agreement with the experimental data,[10] and the model we have used explains the fact that v is a constant (i.e., it does not depend on the interelectrode gap or the applied potential difference).

3. VOLTAGE–CURRENT CHARACTERISTICS FOR NANOSECOND X-RAY TUBES

Flynn's idea that the current is limited by the space charge in the plasma front–anode electrode system[11] has been used to calculate the voltage–current characteristics of a tube with explosive electron emission. However, the plasma electrons in explosive emission are not formed by auxilliary sources (as in ref. 11), but from the explosion of the needles. We first consider the characteristics of a diode in which one needle explodes. Suppose that the emitted plasma sphere has a radius vt (Fig. 1b). We assume that the conductivity of the cathode flare plasma is much greater than that of the diode. An exact solution of the system of partial differential equations which describe the movement of the electrons under space-charge-limited conditions is difficult for the case of an arbitrary electrode geometry. We therefore make use of the approximate methods suggested in the review by Ivy[12] who gives preference to the Matrikon and Truve method as being the most universal. In this method the electrostatic capacity of an arbitrary system of electrodes is equated to the capacity of a plane cylindrical or spherical condenser for which the usual "three-halves" power law is known to hold. The dimensions of the equivalent system are found by simple geometric considerations. These dimensions are then used to calculate the current. A large number of examples of the use of this method is given in refs. 12 and 13.

We first assume that the shape of the cathode flare is not spherical, but cylindrical. For a plane infinite anode the electron current

$$i = 2.33 \cdot 10^{-6} U^{3/2} \frac{2\pi r_a l}{(r_a - r_c)^2} \beta\left(\frac{r_a}{r_c}\right), \tag{5}$$

where $\beta(r_a/r_c) = (1 - r_a/r_c)^2 \theta^2 (r_a/r_c)$ and the function $\theta(r_a/r_c)$ is defined and tabulated in ref. 13. Assuming that the length of the cylinder $l = \pi vt$, the radius of the cathode $r_c = vt$, and the radius of the equivalent anode

$$r_a = r_c \left\{\frac{d}{r_c} + \left[\left(\frac{d}{r_c}\right)^2 - 1\right]^{1/2}\right\}$$

with vt ≪ d, we get

$$i = A_1 U^{3/2} \frac{vt}{d - vt}, \tag{6}$$

where d is the interelectrode distance and $A_1 = 2.2 \cdot 10^{-5}$ A · $V^{-3/2}$. A calculation of $i = f(U, t)$ by the method in which the specific capacities of the real and fictitious condensers are equated leads to a coefficient $A_1 = 3.7 \cdot 10^{-5}$ A · $V^{-3/2}$. An experimental study of the relationship[4] has shown that in fact $i/U^{3/2} \sim vt/(d - vt)$ and the coefficient of proportionality $A_1 = 3 \cdot 10^{-5}$ A · $V^{-3/2}$.

Equation (6) is valid for vt ≪ d. When vt ≥ d/2 the diameter of the sphere begins to exceed the interelectrode distance and a more correct equation is

$$i = 2.33 \cdot 10^{-6} U^{3/2} \frac{\pi (vt)^2}{(d - vt)^2}, \tag{7}$$

which expresses the three-halves power law for a plane diode. In order to calculate the parameters of x-ray pulses with $t_{\text{pul}} \geq d/2v$ it is best to use (7). This is the equation used by Flynn[11] for the calculation of microsecond x-ray pulses. If the cathode has more than one emission center and the distance between the centers is comparable to the interelectrode distance d, the current in the diode is given by

$$i = A_1 n U^{3/2} \frac{vt}{d - vt}, \tag{8}$$

where n is the number of centers. If the distance between the centers a ≪d, the current is found from experimental studies[14] to be

$$i = A_2 U^{3/2} \frac{s}{(d - vt)^2}, \tag{9}$$

where s is the area of the cathode and $A_2 = 2.33 \cdot 10^{-6}$ A · $V^{3/2}$.

In order to calculate the voltage–current relationships in systems with more complicated geometries we have to make direct use of the Matrikon–Truve method mentioned above. The capacity of the entire system can be determined by the usual conformal mapping technique. It is assumed that the characteristics of the real diode are similar to those of the fictitious diode. We may recall that the main assumption in this method is that the shape of the equipotential surfaces is the same with and without the space charge and they differ only in their potential values.

We have assumed above, in agreement with the experimental results of refs. 4 and 14, that a plasma cathode of arbitrary shape can, under certain conditions, be considered as an ordinary metal cathode. In this case we can use the methods developed for normal indirectly heated diodes to determine the voltage–current characteristics of diodes with explosive emission. However, this approach is only valid within certain definite limits. First, the current in the diode in a low vacuum might be greater than that given by the three-halves law because of neutralization by the electron space-charge current. Second, the current can be increased by the formation of a plasma at the cathode before the arrival of the main voltage pulse because of the explosion of needles from prepulses. The current can be amplified by factors of 10 or so in this way.[4] Third, deviations from (6) are observed when a single needle is used with a high average field in the diode because the explosion occurs at the side surfaces not only at the end of the emitter. The three-halves power law is then violated because a higher applied voltage means that a larger surface area emits electrons. Fourth, the power law is also violated at very high currents when the emission power of the plasma itself reaches saturation. This occurs when

$$n_e\sqrt{T_e}<A_1\sqrt{\frac{2\pi m}{ke^2}}\,U^{3/2}\frac{vt}{d}, \tag{10}$$

where n_e and T_e are the density and temperature of the plasma electrons, m and e are the mass and charge of the electron and k is the Boltzmann constant.

4. X-RAY PULSE PARAMETERS

The most widespread method of obtaining nanosecond x-ray pulses is to use the discharge of a condenser across the x-ray tube through a switching spark gap (S) in a compressed gas (Fig. 2). The switch is necessary[15] in order to connect the condenser to the tube in a time less than 10^{-9} sec. If the cathode has one or more independent emission centers and the anode is plane we get the following equation for the current and voltage if we neglect the inductance of the circuit and the resistance of the spark gap:

$$i+C\frac{dU}{dt}=0 \tag{11}$$

together with Eq. (8) and the initial conditions t = 0, $U = U_0$ and i = 0.

We can combine (8) and (11) into a single equation

$$\frac{dy}{dt}+By^{3/2}\frac{\tau}{1-\tau}=0, \tag{12}$$

where

$$x=\frac{id}{CU_0v},\quad y=\frac{U}{U_0},\quad \tau=\frac{vt}{d},\quad B=\frac{A_1ndU_0^{1/2}}{Cv}.$$

The length of the nanosecond x-ray pulses is usually such that $t_{\text{xpul}} \ll d/v$ and $\tau \ll 1$. The tube current and voltage are then

$$x=\frac{64B\tau}{(4+B\tau^2)^3},\quad y=\frac{16}{(4+B\tau^2)^2}. \tag{13}$$

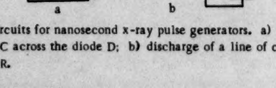

Fig. 2. Circuits for nanosecond x-ray pulse generators. a) Discharge of condenser C across the diode D; b) discharge of a line of characteristic resistance R.

The time to acheive maximum current and the value of this current are defined by the equations

$$t_{im}=\frac{2\sqrt{dC}}{\sqrt{5A_1nvU_0^{1/2}}}, \tag{14}$$

$$i_m=0.52\frac{U_0^{5/4}(CA_1nv)^{1/2}}{d^{1/2}}. \tag{15}$$

The intensity of the x radiation

$$P\sim iU^2. \tag{15'}$$

The time to the maximum intensity and the value of this intensity are defined by

$$t_m=\frac{2\sqrt{dC}}{\sqrt{13A_1nvU_0^{1/2}}}, \tag{16}$$

$$P_m\sim U_0^{13/4}\sqrt{\frac{A_1nvC}{d}}. \tag{16'}$$

The length of the x-ray pulse at the half-power points is

$$t_{\text{x pul}}=\frac{0.88\sqrt{Cd}}{\sqrt{A_1U^{1/2}nv}}. \tag{17}$$

If the condition $t_{\text{xpul}} \ll d/v$ is written in the form $t_{\text{xpul}} \le 0.3\ d/v$, then the above relationships are valid for $B \ge 12$.

For a cathode with a large number of emission centers the average distance between which $a \ll d$ and the emission area of which $s > d^2$, the current and voltage are calculated by solving (9) and (11). If the length of the pulse $t_{\text{xpul}} \ll d/v$, we get

$$U=\frac{U_0}{(1+\tau)^2},\quad i=\frac{2.33\cdot10^{-6}\,sU_0^{3/2}}{d^2(1+\tau)^3},\quad P\sim\frac{U_0^{7/2}s}{d^2(1+\tau)^7}, \tag{18}$$

where

$$\tau=\frac{t}{\theta},\quad \theta=\frac{8.7\cdot10^5\,Cd^2}{s\sqrt{U_0}}.$$

The length of the pulse at the half-power points is

$$t_{\text{x pul}}=5.6\cdot10^4\frac{Cd^2}{sU_0^{1/2}}. \tag{19}$$

Some nanosecond x-ray pulse generators use lines rather than condensers as storage devices. If the line is discharged across a tube with one or more emission centers, the current and voltage are described by a system of equations consisting of (8) together with

$$iR+U=U_0, \tag{20}$$

where R is the characteristic resistance of the line and U_0 is the charged potential of the line.

The time variation of the current and radiation intensity are given by

$$\frac{vt}{d-vt}=\frac{i}{A_1 n\,(U_0-iR)^{3/2}},\qquad (21)$$

$$P \sim i\,(U_0-iR)^2.\qquad (22)$$

The maximum radiation intensity

$$P_м \sim \frac{U_0^3}{R}\qquad (22')$$

is reached for a current $i_{xM} = U_0/3R$.

The time for maximum intensity

$$t_{xM}=\frac{d}{v}\,\frac{1}{1+\sqrt{\frac{8}{3}B_1}},\qquad (23)$$

where $B_1 = A_1 nRU_0^{1/2}$.

We define the length of the x-ray pulse as the time $t_{xpul} = 2t_{xm}$. To the accuracy of a constant coefficient, the total radiation dose can be determined from the equation $D \approx P_m t_{pul}$, and so

$$D \sim \frac{U_0^3}{Rv}\,\frac{1}{1+\sqrt{\frac{8}{3}A_1 nRU_0^{1/2}}}.\qquad (24)$$

It follows from (22)-(24) that the maximum intensity does not depend on the length of the gap, that the dose $D \sim d$, and that the pulse length $t_{xpul} \sim d$.

5. COMPARISON WITH EXPERIMENTAL RESULTS

The length of the x-ray pulse produced by the discharge of a long line across a vacuum gap was measured in ref. 16. The pulse has a square shape of length 300 nsec and an amplitude up to 200 keV; the characteristic impedance of the line is 66 Ω. The x-rays are recorded by a scintillation counter with an FÉU-36 photomultiplier and an n-terphenyl scintillator. The signal from the photomultiplier is recorded by means of a I2-7 oscilloscope and a UZ-5A amplifier with a bandwidth of 150 MHz. The cathode is a plane copper electrode on which several cathode flares were produced.

Figure 3 shows how the length of the x-ray pulse (at 0.1 of the amplitude) depends on the gap length d. Also shown is the relationship between the integrated radiation dose in the pulse and the value of d. These results confirm the principal theoretical conclusions that for a line discharge $D \sim d$ and $t_{xpul} \sim d$.

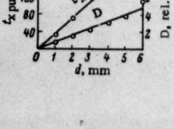

Fig. 3. Relationship[16] of the length of the x-ray pulse and the relative radiation dose D on the gap length d.

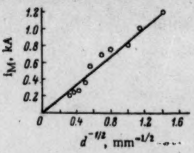

Fig. 4. Relationship between the amplitude of the electron current pulse i_M and the quantity $d^{-1/2}$ for an x-ray tube with a needle cathode and a plane anode for discharge through this tube of a condenser through a spark gap in compressed nitrogen (P = 10 atm).

The $t_{xpul} \sim d$ prediction is also in agreement with results which can be obtained by analyzing the oscillograms of Freytag,[17] who studied the x-ray radiation produced by the discharge of a line across a tube with a needle cathode.

We can use the experimental results of Vavilov[18] to verify Eq. (15). Figure 4 shows the relationship between the amplitude of the electron current pulse in the tube and the inverse square root of the gap length, i.e., $d^{-1/2}$; this relationship from (15) is a linear one (C = 30 pF and U_0 = 180 kV). The dipole of the x-ray tube used in ref. 18 contained a needle cathode and a plane anode. The value of t_{xpul}, calculated from (19) can be compared with the experimental value[19] for U_0 = 100 kV and C = 30 pF. If the ratio d^2/s = 1-2, the calculated value is 5-10 nsec and the experimental value ~ 10 nsec.

Thus the available experimental data on the x-ray pulse parameters do not contradict the above calculations.

Superconducting magnetic shields

S. I. Bondarenko and V. I. Sheremet

Physicotechnical Institute of Low Temperatures,
Academy of Sciences of the USSR, Khar'kov

(Submitted December 18, 1972; resubmitted August 28, 1973)
Zh. Tekh. Fiz., 44, 1528-1533 (July 1974)

An experimental study has been made of superconducting magnetic shields of various shapes and sizes in external fields from $1 \cdot 10^{-3}$ to 350 Oe. The possibility of creating a magnetic "vacuum" by means of superconducting shields is considered. A vacuum of less than $3 \cdot 10^{-6}$ Oe has been obtained in a volume of 0.6 liters in an external field of $5 \cdot 10^{-2}$ Oe. The stability of the vacuum, measured with a superconducting quantum magnetometer, is better than $1 \cdot 10^{-8}$ Oe.

INTRODUCTION

Work has been carried out during the last few years on the properties of superconducting magnetic shields and the creation by means of such shields of a magnetic "vacuum" (magnetic field smaller than that of the earth).[1-5]

The interest in these problems is due to a series of new physical ideas on ways of testing the validity of the general theory of relativity, on field theory, and in biophysics.[1,6] The use of superconductors for shielding is also of importance in the development of some fundamentally new instruments, in particular, high-sensitivity superconducting quantum magnetometers.

We report here on an experimental study of the shielding possibilities of stationary superconducting shields in the form of thin-walled cylindrical shells with a) open ends and b) a hemispherical bottom. We impose an external magnetic field H_e of known magnitude and measure the increase of the field H_i inside the shield.

The same shields are used to obtain a magnetic vacuum. A method has been devised to bring a superconducting shield in a magnetic field H_{e0} into the superconducting state so that the field, or part of it, is expelled from the shield cavity. A magnetic vacuum H_{i0} is thus created. It is of interest, in studying these properties of superconducting shields, to consider the effect of the magnitude of the external field, the shape and size of the shield, the material and its state of purity, and the method of bringing the shield into the superconducting state.

EXPERIMENTAL APPARATUS

The apparatus for studying the shielding properties of superconducting shields and for obtaining a magnetic vacuum (Fig. 1) consists of a metal helium cryostat 1 with the superconducting shield 2, a system for introducing liquid-helium 3, and an auxiliary isolating helium cryostat 4 placed in the superconducting shield inside of which the temperature can be set to any value from liquid-helium temperature to room temperatures. The apparatus also contains a system 5 for cancelling the earth's magnetic field, a solenoid 6 for producing an external field up to 300 Oe and a magnetometer unit 7. The Kh18H10T stainless steel helium cryostat has the same diameter as the neck of the helium bath – 150 mm – and a height of 1000 mm. The preliminary cooling of the cryostat and fittings is achieved by means of liquid-nitrogen.

Two types of isolating cryostat are used: a glass, double-walled nitrogen Dewar with an internal insulated volume diameter of 78 mm and a length of 900 mm and a

metal triple-walled unit using nitrogen shielding with an inside diameter (for the insulated volume) of 65 mm and a length of 900 mm. After the introduction of helium into the cryostat the temperature is $-30°C$ in the first unit and $+13$ to $+15°C$ in the second.

The support for the superconducting shields, which are in the form of thin-walled shells (usually of lead), is fixed to the flange of the isolating cryostat. The flange also carriers the lines for supplying the helium and a hermetic feed-through with the electric wires to the thermometers (germanium and Allen-Bradley types), the level indicator, heater, and a superconducting quantum magnetometer which has been developed by the Physicotechnical Institute of Low Temperatures of the Academy of Sciences of the USSR.[7,8] The solenoid is 1000 mm long and has an inside diameter of 260 mm and a solenoid constant of 64 Oe/A. Two different compensation systems can be used: 1) circular Helmholtz coils 1000 mm in diameter along three orthogonal axes; 2) squared Fanzelau rings 2000 mm on a side. The first system can create a homogeneous field (gradient $5 \cdot 10^{-5}$ Oe/cm) in a sphere 150 mm in diameter and the second in a sphere 400 mm in diameter. The same ring systems are used to create an increment ΔH_e in the external field.

The preliminary attenuation of the magnetic field, and specially of its time variations, is achieved by means of a triple-layer ferromagnetic cylindrical shield with a plane bottom made of 79 nm Permalloy 1.5 mm thick, 450 mm in diameter and 1200 mm high. This shield attenuates the external field of the earth by a factor of 440 in the longitudinal direction and a factor of 600 in the transverse direction; the attenuation of variations is 30 and 50 times respectively. The normal level of variations in our laboratory varies up to 200 $\gamma (\gamma = 10^{-5}$ Oe).

The magnetometer unit contains a superconducting quantum magnetometer 8 and a ferroprobe system with a block of small ($l = 10$ mm) ferroprobes 9 which allow the longitudinal and transverse components of the magnetic field in the superconducting shield to be measured simultaneously. The smallest field which can be detected by the ferroprobe unit is $3 \cdot 10^{-6}$ Oe. The zero drift of the magnetometer is less than $1 \cdot 10^{-5}$ Oe in 8 h. The ferroprobe block is placed on a movable calibrated rod by means of which the probes can be either rotated about the longitudinal axis of the superconducting shield or moved in the vertical direction along the axis of the shield.

A superconducting quantum magnetometer is used to measure the stability of the magnetic vacuum obtained in the superconducting shield. The sensitivity of the magnetometer is $1 \cdot 10^{-8}$ Oe. The ring of the magnetometer head is 100 mm in diameter and is made from 0.05 mm diameter niobium wire with Clark contacts; it is placed 80 mm from the bottom of the shield.

The shields are made from: 1) 99.99% pure lead by cold pressure and galvanic deposition on to a copper base followed by etching; 2) from 99.9% pure niobium by electric deposition from a melt of the salts on to a copper base, again followed by etching.

Characteristic sizes of the shields are: internal diameter from 65 to 140 mm, length from 200 to 550 mm, and wall thickness from 0.5 to 2.5 mm.

In the shielding experiments the magnetic field which penetrates through the hole in the superconducting shield into the inside cavity is measured in two directions: parallel and perpendicular to the axis. The ratio of the components of the applied external field to the components in the cavity of the superconducting shield gives the shielding coefficient.

There is no penetration of the field through the walls of the shield until the critical values are reached (hundreds of Oe).

An analysis of the possible methods of creating a magnetic vacuum by means of superconductors and of the methods which have already been suggested shows that the simplest technique, and one which is quite effective, is the use of the Meissner effect, which occurs when the superconductor goes over into the superconducting state. This process takes place in a definite sequence, starting at the lowest point of the shield in the cryostat. In the shield with a hemispherical bottom the dynamics of the magnetic field expulsion process as the shield goes over into the superconducting state can be illustrated as in Fig. 2.

As soon as the lowest part of the hemisphere becomes superconducting the magnetic field lines pass around this section as a result of the Meissner effect. As the boundary between the normal and superconducting phases moves upwards, a greater part of the material and, as can be seen from Fig. 2, of the cavity inside (because of the particular shape chosen) becomes free of any magnetic field or at least carriers a weaker field.

A higher vacuum can, of course, be obtained by the successive transition of a number of coaxial shields into the superconducting state. Each shield gives a certain attenuation K and for a total of n shields we may expect an overall attenuation equal to the product of the individual K_n ($n = 1, 2, 3, \ldots$).

We have studied both one- and two-step field attenuation by this method. In the latter case the two shields are thermally isolated by means of plastic foam shells with wall thicknesses of 10 mm.

DISCUSSION OF EXPERIMENTAL RESULTS

The shielding is tested by applying fields from $H_e = 10^{-3}$ to $H_e = 350$ Oe. For a hollow lead cylindrical shield with open ends, made by extrusion or electrodeposition, the degree of shielding S (attenuation of the external field in the shield along its axis at a distance equal to the inside diameter) is $S_{long} = 900$ for the longitudinal component and $S_{tran} = 30$ for the transverse component. The values remain the same to within ± 15% for all the sizes tried (length l, diameter ϕ, and wall thickness t) for shields prepared by this method.

The method of fabricating the lead shield is found to affect the degree of shielding of the transverse and particularly of the longitudinal component. Thus for shields prepared by turning a lead sheet and welding along the generator of the cylinder, we find $S_{long} = 160$ and $S_{tran} = 25$ (for the same dimensions). It can be seen that the lon-

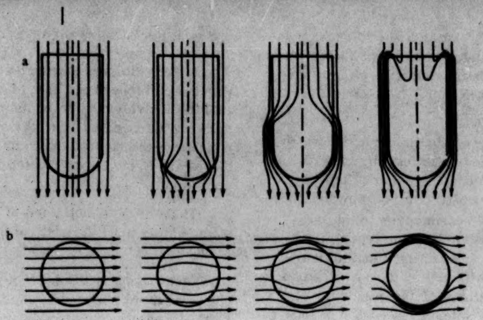

Fig. 2. Ejection of the magnetic field as the shield goes over the superconducting state. a) Longitudinal component of the magnetic field; b) transverse component.

gitudinal component is attenuated only 160 times in comparison with 900 in the previous case.

Shields in the form of a lead shell with a hemispherical bottom, made by extrusion or electrodeposition, have $S_{long} = 1500$ and $S_{tran} = 40$ with a maximum scatter of ± 15% between one shield and another.

A shield of the same shape made from niobium ($\varnothing$ 70 mm, $l = 230$ mm, $t = 1.5$ mm) has $S_{long} = 1200$ and $S_{tran} = 40$. In all cases the measurements are made at a temperature $T = 4.2°K$.

Measurements of the maximum shielded field are made on an extruded lead shield with a hemispherical bottom ($\varnothing$ 85 mm, $l = 440$ mm, $t = 1.5$ mm). A ferroprobe is placed at the lowest point of the isolating cryostat at a distance of 25 mm from the bottom of the shield. The longitudinal field at which the material begins to go over to the intermediate state and the field to penetrate the shield is found to be 252 Oe. The penetrating field H_l increases smoothly but if H_e goes even slightly above 252 Oe H_l begins to rise more rapidly and the shield ceases to screen at all at $H_e = 270$ Oe.

We are now preparing to carry out measurements on the maximum transverse component of a magnetic field which can be shielded. The degree of shielding remains independent of the frozen-in field in the shield right up to the point at which the superconductivity begins to be destroyed.

The frozen-in field has a high stability. In order to verify this, it is first necessary to choose the shield dimensions so that the variations in the external field are attenuated by a sufficiently high factor at the point where the recording head is placed. The value is usually chosen so that for known S_{long} and S_{tran} the expected variations in H_l for given variations in H_e are much smaller than the sensitivity of the recording head. Measurements of the stability of a 0.4 Oe frozen-in field by a ferroprobe showed that any variations were smaller than the sensitivity of the magnetometer.

We have now begun measurements of the stability of the frozen-in fields in superconducting shields with open ends by means of a high-sensitivity superconducting quantum magnetometer. The results will be published elsewhere.

We now turn to the results on the creation of a magnetic vacuum by means of superconducting shields with a hemispherical bottom. Because of the Meissner effect, these shields produce an attenuation of the frozen-in field in the shell cavity.

It is found that in order to achieve the maximum magnetic vacuum it is necessary that two important conditions be satisfied: a) There should be a sufficiently high temperature gradient along the shield during the transition to the superconducting state; b) the cooling should be sufficiently slow.

A high temperature gradient along the shield is necessary in order that the initial annular superconducting zone which forms at the apex of the hemisphere should be of minimal size. The magnetic flux trapped by this annulus in fact determines the maximum possible level of the magnetic vacuum in the superconducting shield. Moreover, with a high temperature gradient it is much easier to ensure a slow propagation of the superconducting phase.

A slow supply of helium into the cryostat and thermal isolation of the shields from the cold helium vapor by means of plastic foam sleeves enables us to get a gradient of $dT/dl \simeq -0.5$ deg/cm during the transition into the superconducting state and a boundary propagation rate of $dl/dt \simeq 0.5$ cm/sec.

It can be seen from this that the prediction by this method of the transition process into the superconducting state is a rather complicated thermomagnetic problem which still awaits analysis and theoretical solution. The total Meissner effect probably depends on the mechanical stressing of the material, its chemical purity and the type of inclusions, the surface state and the kind of superconductor.

Our extruded lead shields are tested after preparation in both annealed and nonannealed states. The annealing is carried out for 6–10 h in a vacuum of 10^{-3} torr at $t = 200°C$. The experiments show that this treatment and the use of lead with an initial industrial purity and a final purity of 99.99% do not essentially alter the maximum attainable magnetic vacuum (for a given method of bringing

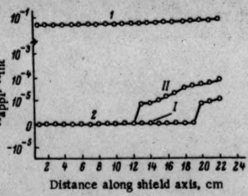

Fig. 3. Distribution of the external magnetic field along a two-layer shield before the transition to the superconducting state (1) and of the frozen-in magnetic field after the transition of both shields (2). I, II) Distributions of the longitudinal and transverse components of the frozen-in field respectively.

the shield into the superconducting state and for a particular surface quality).

For one lead shield with $\varnothing = 140$ mm, $l = 550$ mm, $t = 2$ mm in an external field $H_{e0\,long} = H_{e0\,tran} = 1 \cdot 10^{-3}$ Oe, a magnetic vacuum lower than the limit of sensitivity of the ferroprobe ($3 \cdot 10^{-6}$ Oe) is obtained throughout the entire volume of the shield at 14-15 cm from the bottom. In an external field $H_{e0} = 5 \cdot 10^{-2}$ Oe a field of $H_{i0\,long} = 2 \cdot 10^{-4}$ Oe and $H_{i0\,tran} = 4 \cdot 10^{-5}$ Oe is recorded at a height of 14 cm from the bottom, i.e., the attenuation in this volume for an external field of $1 \cdot 10^{-3}$-$5 \cdot 10^{-2}$ Oe is not less than $K_{long} = 250$ for the longitudinal component and not less than $K_{tran} = 1250$ for the transverse component.

In the case of two shields, brought successively into the superconducting state with a time interval of about 200 sec, a magnetic field of less than $3 \cdot 10^{-6}$ Oe is obtained in the lower part of the inner shield at a length of 11 cm from the bottom for an external field of $5 \cdot 10^{-2}$ Oe; the dimensions are $\varnothing_1 = 140$ mm, $l_1 = 550$ mm, $t_1 = 2$ mm, $\varnothing_2 = 110$ mm, $l_2 = 500$ mm, $t_2 = 2$ mm.

Figure 3 shows the external field distribution along the axis of the shield (1), and the distribution of the frozen-in field after the two shields have gone over into the superconducting state (2). The curves with the Roman numerals I and II indicate the distributions of the longitudinal and transverse components respectively.

The stability of the magnetic vacuum is measured at a height of 8 cm from the bottom of the shield by means of a quantum magnetometer with a sensitivity to change in magnetic flux of $3.9 \cdot 10^{-6}$ mks which, for a uniform field across the head, corresponds to a change in the magnetic field of $1 \cdot 10^{-8}$ Oe. The time constants of the instrument is ~ 5 sec. It turns out that the stability of the vacuum is never worse than $1 \cdot 10^{-8}$ Oe. A further increase in the sensitivity of the magnetometer will enable the stability of the field in the shield to be measured more accurately.

The results of the experiments carried out on the apparatus we have developed for cryogenic magnetic measurements are therefore as follows: 1) The degree of shielding of superconducting lead and niobium shields of various shapes and sizes, prepared by cold pressure working and electrodeposition has been determined at a temperature of 4.2 K; 2) a method has been investigated for obtaining a magnetic vacuum by using the Meissner effect in lead cold-drawn shields with a hemispherical bottom, and the attenuation coefficients for the longitudinal and transverse magnetic fields have been obtained; the great possibilities for this type of superconducting shield and this method of obtaining a stable magnetic vacuum have been shown; 3) the stability of the frozen-in field has been measured in cylindrical superconducting shields with open ends and the stability of the magnetic vacuum in a shield with a hemispherical bottom has been determined.

The authors are grateful to I. M. Dmitrenko for useful discussions.

Effect of the adsorption rate on the diffusion of deuterium through nickel

Yu. I. Belyakov, Yu. I. Zvezdin, A. A.Kurdyumov, and G. G. Nevdakha

A. A. Zhdanov Leningrad State University

(Submitted July 17, 1973)
Zh. Tekh. Fiz., 44, 1534-1538 (July 1974)

A procedure described previously is used to study the penetrability of nickel membranes with respect to deuterium from the molecular phase (P_m), from a gas discharge (P_c), and atomized on incandescent tungsten (P_{at}). The functional dependences of P_m and P_{at} on temperature display slope changes; these are attributed to an effect of the rate at which deuterium is adsorbed from the molecular phase onto the nickel surface.

There is currently much interest in the effect of the rates of interfacial processes on the penetration of hydrogen isotopes through metals.[1-3]

Kunin et al.[1] have solved the diffusion problem, assuming the interfacial reactions to occur much more slowly than diffusive mass transport in the bulk metal. These authors give the following equation for the gas flow through a membrane on one of whose sides a relatively slow interfacial reaction is occurring with a rate constant K and on whose other side all reactions occur rapidly:

$$P=\frac{\Gamma p}{\frac{1}{K}+\frac{d}{D}}, \tag{1}$$

where Γ is the Henry constant, p is the gas pressure, d is the membrane thickness, and D is the diffusion coefficient of the gas in the metal.

Generally speaking, Eq. (1) is derived for the case in which a monatomic gas penetrates a membrane; nevertheless, it is valid for the penetration of a diatomic gas dissociating at the metal surface if the gas pressure is held constant.

The penetrability of nickel membranes of various thicknesses with respect to hydrogen has been studied experimentally[3] over the temperature range 250-800°C. It follows from these results that the classical functional dependence $P_m \sim 1/d$ yields to a situation in which the penetrability is independent of the membrane thickness as the thickness is reduced. On the basis of these experiments and Eq. (1) Kunin et al. derived the following equation for the functional dependence of K on the temperature:

$$K=4.1\cdot 10^{-2}\exp\left[-\frac{2700}{RT}\right], \tag{2}$$

where R is the universal gas constant (in calories per mole per degree), and T is the Kelvin temperature.

However, it is unclear whether Eq. (2) describes some single process or the resultant effect of several interfacial reactions characterized by approximately equal activation energies. It is this question which we are concerned with here.

To distinguish between reactions occurring on the entrance and exit sides of the membrane, we use the method described in ref. 4 for studying penetrability in cathode absorption of deuterium from a glow discharge.

We have also carried out experiments on the penetration of deuterium atomized on an incandescent tungsten filament located near the entrance surface of the sample.

Studying the penetrability P_m of nickel membranes of various thicknesses as a function of the temperature for the direct interaction with molecular deuterium (p = 3 torr), we find slope changes at d < 0.3 mm (Fig. 1). The slope of the linear parts of the curves in the low-temperature region corresponds to an activation energy of 14.6 kcal/g-at. i.e., a value which agrees with the known activation energies for the penetrability of nickel with respect to deuterium.[5] Over this temperature range the proportionality $P_m \sim 1/d$ is satisfied (Fig. 2), implying that the rates of all the interfacial reactions are large in comparison with that of diffusive transport in the interior of the membrane.

As the temperature is raised the activation energy for the penetrability of sufficiently thin samples (d < 0.3 mm) (Fig. 1) decreases and the proportionality $P_m \sim 1/d$ is disrupted (Fig. 2). These results constitute evidence that the penetration is limited by the rate of interfacial reactions under these conditions. From Eq. (1) we calculate

$$K=7\cdot 10^{-3}\exp\left[-\frac{2500}{RT}\right], \tag{3}$$

in good agreement with the functional dependence found in ref. 3 [see (2)].

To determine the diffusion coefficient for deuterium in nickel, D, which is required for the calculation of K, we use the buildup method to measure the steady-state gas flow through a sample 0.6 mm thick. Curve 5 in Fig. 1 shows the functional dependence log D = $f(10^3/T)$. The discontinuities in the functional dependences of P_m and D on the temperature are due to the change in the diffusion coefficient and the solubility of deuterium in nickel at the Curie point (≈ 360°C) (ref. 5). These discontinuities are not observed in very thin samples, apparently because the interfacial reactions are less sensitive than diffusion or dissolution to structural changes.

Under the conditions prevailing in a gas discharge

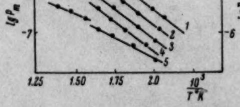

Fig. 1. Penetrability P_m of nickel membranes of various thicknesses as a function of the temperature. d, mm: 1) 0.05; 2) 0.12; 3) 0.3; 4) 0.6; 5) diffusion coefficient of deuterium in nickel as a function of the temperature.

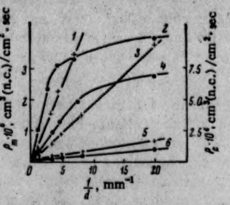

Fig. 2. The functional dependences $P_m(d)$ (curves 2, 4, 6) and $P_c(d)$ (1, 3, 5) for various temperatures. T, °K: 1, 2) 645; 3, 4) 600; 5, 6) 500.

the deuterium concentration in the surface layers of the nickel is governed by penetration and cathode sputtering,[4] rather than by activated interfacial reactions. Accordingly, the concentration is not a function of the temperature or the membrane thickness, i.e., of the rate of diffusive removal. We can therefore distinguish between slow interfacial reactions at the entrance and exit surfaces of the membrane: If the penetration rate is limited by a reaction at the exit surface, the $P_c \sim 1/d$ functional dependence is not satisfied, even under gas-discharge conditions;[6] if, on the other hand, some reaction at the entrance side is the slowest step, the functional dependence $P_c \sim 1/d$ is retained at small d during cathode absorption of deuterium from the glow discharge, in contrast with the case of penetration from the molecular phase; this behavior is in fact observed in our experiments (Fig. 2).

At the entrance side of the membrane two processes occur, whose activation energies can turn out to be approximately equal to the value of 2.5 kcal/g-at, which appears in (3): activated chemisorption and migration of atoms over the surface. A third interfacial reaction on the entrance side – dissolution (i.e., the conversion of atoms from an adsorbed to an absorbed state) – has a much higher activation energy (~25 kcal/g-at) (ref. 2, 5, 7).

Migration can play a role if we assume that the number of possible dissolution paths is limited and that the chemisorbed deuterium atoms must spend a certain time in motion over the surface in order to reach an absorbed state. However, it is difficult to believe that this process could be manifest in some manner at coverages Θ near a monolayer. It is apparently just such coverages with which we are dealing, since the deuterium pressure is ≥ 3 torr. Furthermore, this process is not due to recombination or dissociation, so its rate must be proportional to the surface concentration of deuterium atoms, C_{ads}, and must be a weak function of the pressure at $\Theta \approx 1$ ($C_{ads} \sim p^n$, where $n < 0.5$) (ref. 7).

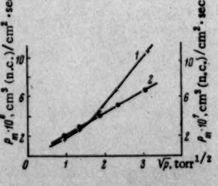

Fig. 3. The penetrability P_m as a function of the deuterium pressure p. T, °K: 1) 645; 2) 500.

Analysis of our isotherms for the penetrability of nickel membranes (d = 0.05 mm thick) with respect to molecular deuterium shows that at $T < T_0$, at which the proportionality $P_m \sim 1/d$ holds, the proportionality $P_m \sim p^{1/2}$ also holds (Fig. 3). In this case the proportionality holds because all the surface processes occurring on the entrance side of the sample occur so rapidly that a deuterium concentration equal to the solubility under the given conditions is established in a surface layer of the metal, and the solubility of deuterium in a metal is known[8] to be proportional to $p^{1/2}$.

At $T > T_0$, with an appreciably stronger influence of surface reactions, we find $P \sim p^n$, where n is approximately equal to unity (Fig. 3). According to current ideas,[7,9] such a functional dependence on the pressure holds when the step limiting the penetration is chemisorption at the entrance side of the membrane.

We have carried out experiments on the penetration of deuterium atomized on incandescent tungsten; the results of these experiments are shown in Fig. 4. Curves 1 and 2 in this figure show the functional dependence on the temperature of the penetrability P_{at} of nickel membranes 0.05 mm thick with respect to deuterium partially atomized on a tungsten filament heated to 2300°K. The filament temperature is measured by means of a pyrometer. Curves 4 and 3 in this figure show the same functional dependences with the atomizer turned off.

Curves 1 and 2 display two linear regions (I and II), whose slopes are markedly different. In temperature range II the deuterium flux through the membrane is a weak function of the temperature. At a certain temperature T_0, which varies with the deuterium pressure, there is a slope change coinciding with the slope change on the curve showing the penetration of deuterium from the molecular phase as a function of the temperature. At $T > T_0$ there is an appreciable increase in the flux with increasing temperature; the slope of region I is approximately equal to that of the functional dependence on the temperature of the penetrability from the molecular phase, in which case this penetrability is governed by the adsorption rate.

It should also be pointed out that P_m always increases with increasing pressure. The functional dependence of the flux on the pressure of molecular deuterium displays a different behavior when the atomizer is turned off: As the pressure of molecular deuterium is raised, the flux decreases rather than increases.

We believe that these results can be explained in the following manner.

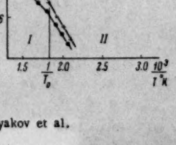

Fig. 4. P_m and P_{at} as functions of the temperature. p, torr: 1, 4) 3; 2, 3) 10.

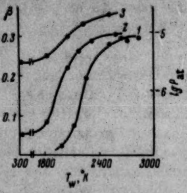

Fig. 5. Atomization coefficient β (1) and penetrability P_{at}. T, °K: 2) 500; 3) 645.

The increase in the deuterium flux through the membrane with the atomizer turned off over the entire temperature range studied undoubtedly results from the atomic deuterium. Evidence in favor of this conclusion is the strong similarity of the functional dependences of the penetrability and the atomization coefficient[10] on the temperature of the tungsten filament (Fig. 5). There is some difference between these curves, probably due to errors in the pyrometric measurement of the filament temperature and the distortion of the penetrability curves at low atomization coefficients because of the penetration of the deuterium from the molecular phase.

In our case the partial pressure of molecular deuterium is much higher than that of atomic deuterium, so that the metal surface is largely covered by chemisorbed deuterium atoms, formed in the dissociation of deuterium molecules on the nickel surface. The penetration of these atoms into the metal is hindered somewhat, since the energy evolved in the chemisorption is less than the activation energy for dissolution. As a result, some of the chemisorbed atoms are at thermal equilibrium with the metal surface, so that the probability for their dissolution is reduced even further.

The energy levels of the deuterium atoms and molecules in the gas phase differ by the dissociation energy (~ 50 kcal/g-at), so that sorption of atomic deuterium on the nickel is not an activated process, and the probability for the dissolution of atomic deuterium is much higher than that for atoms produced in the dissociation of deuterium molecules on the nickel surface and which have arrived at a thermal equilibrium with the surface. However, the chemisorption of the atomized deuterium can occur only on that part of the surface $(1-\Theta)$ not covered by atoms chemisorbed from the molecular phase.

We note that the small surface area capable of chemisorbing atomic deuterium from the gas phase and the rapid diffusive removal lead to a situation in which the deuterium concentration in the metal C is much lower than the equilibrium solubility S which can be achieved through the interaction of atomic deuterium with nickel under the given conditions. For this reason the reactions at the interface between the metal volume and surface are displaced toward absorption for the case of previously atomized deuterium, and the absorption rate is known[9] to be proportional to $1-C/S$.

Assuming that the accommodation coefficient for atomic deuterium and the rate at which atomic deuterium is chemisorbed by the metal surface are quite large, we can assume that the flux measured in our experiments with an atomizer is approximately equal to the rate at which atomic deuterium is absorbed from the gas phase, W:

$$P_{at} \approx W = N(p)\,\alpha(p)\left(1-\frac{C}{S}\right)(1-\Theta), \tag{4}$$

where N(p) is the efficiency of the atomizer, governed by the number of deuterium atoms produced per unit time, and $\alpha(p)$ is a coefficient taking into account the recombination of deuterium atoms in the interior and at the walls of the diffusion cell.

Accordingly, at sufficiently low temperatures, for which Θ is approximately equal to unity and is relatively independent of the temperature (II in Fig. 4), the deuterium flux at constant pressure is also a weak function of the membrane temperature.

At $T > T_0$ (I, Fig. 4), the penetration is limited by the adsorption rate, as was shown above. According to Barrer,[8] the result is a reduction of Θ and thus an increase of P_{at} [see (4)].

An increase in the pressure of the molecular deuterium at a fixed temperature causes an increase in the atomizer efficiency N(p); on the other hand it causes an increase in Θ and in the scattering of deuterium atoms by molecules. This scattering results in additional recombination of particles. These latter two factors very probably play an important role in these pressure and temperature ranges, so that P_{at} decreases as P increases.

(Submitted February 5, 1974)
Zh. Tekh. Fiz., 44, 1539-1541 (July 1974)

The stability of an ion-acoustic wave propagating in a collision-dominated, fully ionized hot-electron plasma is considered; the electron thermal energy considerably exceeds the electron rest energy. The growth rate is compared with the corresponding expression in nonrelativistic theory. It is shown that the growth rate is much smaller in a plasma with ultrarelativistic electrons.

When a fixed electric field $\mathbf{E}_0$ acts in a collision-dominated plasma to produce motion of the electrons relative to the ions the ion-acoustic wave becomes unstable if the steady velocity of the electrons V_{0e} is several times greater than the thermal speed of the ions.[1,2] These results, however, are valid only for a nonrelativistic plasma: $T_a \ll m_a c^2$, where T_a and m_a are the temperature (in energy units) and the rest mass of the electrons or ions.

Recently, a closed system of hydrodynamic equations has been obtained[3] for a fully ionized, collision-dominated plasma in which the ions remain nonrelativistic ($T_i \ll m_i c^2$) but the electrons are at a very high temperature ($T_e \gg m_e c^2$); it is assumed that the average speeds of motion of the plasma components are small ($V_a^2/c^2 \ll 1$). It has been shown that under these conditions the transport coefficients of the plasma are modified drastically and that in fact the actual system of hydrodynamic equations is quite different from the nonrelativistic transport equations obtained by Braginskii.[4]

It might be expected that the growth rates of the various collisional instabilities might be quite different for such a hot plasma and it is of particular interest to consider the case of ion-acoustic oscillations.

Assume that the external electric field and the wave vector **k** are directed along the z axis and that $V_{i0} = 0$. The system of transport equations for the one-dimensional case then has the form[3]

$$\left.\begin{aligned}
&\frac{\partial n_e}{\partial t}+\frac{\partial}{\partial z}(n_e V_e)=0,\\
&\frac{4n_e}{c^2}\left(\frac{\partial}{\partial t}+V_e\frac{\partial}{\partial z}\right)(T_e V_e)=-\frac{\partial}{\partial z}(n_e T_e)+\frac{4}{3}\frac{\partial}{\partial z}\left(\eta_e\frac{\partial V_e}{\partial z}\right)-n_e eE+R_e\\
&\quad+\frac{V_e}{c^2}Q_e+\frac{4}{3}\frac{1}{c^2}\frac{\partial}{\partial t}\left(V_e\eta_e\frac{\partial V_e}{\partial z}\right)-\frac{1}{c^2}\frac{\partial q_e}{\partial t}-\frac{2}{c^2}\frac{\partial}{\partial z}(q_e V_e),\\
&3n_e\left(\frac{\partial}{\partial t}+V_e\frac{\partial}{\partial z}\right)T_e+T_e n_e\frac{\partial V_e}{\partial z}=-\frac{\partial q_e}{\partial z}+\frac{4}{3}\eta_e\left(\frac{\partial V_e}{\partial z}\right)^2+Q_e\\
&\quad+\frac{4}{3}\frac{1}{c^2}V_e\eta_e\frac{\partial V_e}{\partial t}\frac{\partial V_e}{\partial z}-\frac{1}{c^2}V_e\frac{\partial q_e}{\partial t}-\frac{2}{c^2}q_e\frac{\partial V_e}{\partial t}-\frac{2}{c^2}V_e q_e\frac{\partial V_e}{\partial z},\\
&\frac{\partial n_i}{\partial t}+\frac{\partial}{\partial z}(n_i V_i)=0,\\
&m_i n_i\left(\frac{\partial}{\partial t}+V_i\frac{\partial}{\partial z}\right)V_i=-\frac{\partial}{\partial z}(n_i T_i)+\frac{4}{3}\frac{\partial}{\partial z}\left(\eta_i\frac{\partial V_i}{\partial z}\right)+n_i eE+R_i\\
&\frac{3}{2}n_i\left(\frac{\partial}{\partial t}+V_i\frac{\partial}{\partial z}\right)T_i+n_i T_i\frac{\partial V_i}{\partial z}=-\frac{\partial q_i}{\partial z}+\frac{4}{3}\eta_i\left(\frac{\partial V_i}{\partial z}\right)^2+Q_i.
\end{aligned}\right\}\quad(1)$$

Here, we have introduced the quantities

$$\left.\begin{aligned}
&R_e=-0.87\frac{m_e^* n_e}{\tau_e^*}(V_e-V_i)-0.17n_e\frac{\partial T_e}{\partial z}\\
&\quad+\frac{1}{3}0.17T_e\frac{\partial n_e}{\partial_z}+\frac{1}{3}0.17en_eE,\\
&q_e=0.46n_eT_e(V_e-V_i)-\varkappa_e\frac{\partial T_e}{\partial z}+\frac{1}{3}\frac{T_e\varkappa_e}{n_e}\frac{\partial n_e}{\partial z}+\frac{1}{3}e\varkappa_eE,\\
&Q_e=-R_e(V_e-V_i)-Q_i,\\
&R_i=-R_e-\frac{V_e}{c^2}Q_e,\ q_i=-\varkappa_i\frac{\partial T_i}{\partial z},\ Q_i=\frac{3m_e^* n_e}{m_i\tau_e^*}(T_e-T_i).
\end{aligned}\right\}\quad(2)$$

The thermal conductivities and viscosities of the electrons and ions in (2) are

$$\left.\begin{aligned}
&\varkappa_e=0.72\frac{n_eT_e\tau_e^*}{m_e^*},\ \varkappa_i=3.9\frac{n_iT_i\tau_i}{m_i},\\
&\eta_e=0.21n_eT_e\tau_e^*,\ \eta_i=0.96n_iT_i\tau_i,
\end{aligned}\right\}\quad(3)$$

where n_e and n_i are the electron and ion densities respectively,[3] the electron "mass" $m_e^* = 4\,T_e/c^2$, and the scattering time τ_e^* for electrons at ions is different from the expression obtained in nonrelativistic theory, whereas the scattering time of ions by ions remains unchanged:

$$\tau_e^*=\frac{3T_e^2}{\pi e^4 L n_i c},\quad \tau_i=\frac{3m_i^{1/2}T_i^{3/2}}{4\pi^{1/2}Le^4n_i}\quad(4)$$

(L is the Coulomb logarithm).

Knowing the collisional transfer of momentum from ions to electrons R_e, we can easily find the velocity of the electrons relative to the ions:

$$\mathrm{V}_{e0}=-1.08\frac{e\tau_{e0}^*}{m_{0e}^*}\mathrm{E}_0.\quad(5)$$

If we consider long wavelengths, $kd \ll 1$ [$d=(T/4\pi e^2 n)^{1/2}$ is the Debye radius], we can neglect div E in Poisson's equation and we then assume plasma neutrality, $n_e = n_i \equiv n$. After linearization the continuity equations for electrons and ions give

$$n'=\frac{kV_i'}{\omega}n_0=\frac{V_i'-V_e'}{V_{0e}}n_0,\quad(6)$$

where n_0 is the equilibrium density of electrons and ions and ω is the frequency [we look for small perturbations in the hydrodynamic quantities n', V_e', V_i', and T_e'' and T_i' in the form $\exp(-i\omega t + ikz)$]. By means of (6) we can linearize the equations of motion and of thermal balance for electrons and ions but the resultant system is rather complicated even if we neglect the electron inertia, which is of order $(\omega/kc)^2$, as is usually done in considering low-frequency ion-acoustic oscillations. However, we can simplify the problem if we consider a plasma with a high electron thermal conductivity but a low ion conductivity so that $\tau_{e0}k^2c^2 \gg \omega \gg \tau_{i0}(k^2T_0/m_i)$ ($T_{0e} = T_{0i} \equiv T_0$ is the equilibrium value of the electron and ion temperature in the plasma). In this case the linearized hydrodynamic equations become

$$\left.\begin{aligned}
&\frac{T_e'}{T_0}=-i\frac{\omega-kV_{0e}}{0.25k^2c^2\tau_{e0}}\frac{n'}{n_0},\\
&\frac{T_i'}{T_0}=\frac{2}{3}\left(1-i2.6k^2\frac{T_0}{m_i}\frac{\tau_{0i}}{\omega}-i8\frac{T_0}{m_ic^2}\frac{1}{\tau_{e0}\omega}\right)\frac{n'}{n_0},\\
&\left(\omega^2-2k^2\frac{T_0}{m_i}+i1.28k^2\frac{T_0}{m_i}\tau_{i0}\omega\right)\frac{n'}{n_0}-k^2\frac{T_0}{m_i}\frac{T_e'}{T_0}-ik^2\frac{T_0}{m_i}\frac{T_i'}{T_0}=0.
\end{aligned}\right\}\quad(7)$$

Setting up the dispersion equation and introducing the real and imaginary parts of $\omega(\omega = \omega_0 + i\gamma)$, we have

$$\left.\begin{aligned}\omega_0 &= k\left(\frac{8}{3}\frac{T_0}{m_i}\right)^{1/2},\\ \gamma &= -\frac{T_0}{m_i c^2 \tau_{e0}}\left(1-\frac{2kV_{0e}}{\omega_0}\right) - 0.96k^2\frac{T_0}{m_i}\tau_{i0}.\end{aligned}\right\} \quad (8)$$

It is evident from (8) that the ion-acoustic mode becomes unstable when $V_{0e} > V_{cr}$, where

$$V_{cr} = \left(\frac{8}{3}\frac{T_0}{m_i}\right)^{1/2}(0.50 + 0.48k^2c^2\tau_{e0}\tau_{i0}). \quad (9)$$

In comparison with the nonrelativistic expressions,[2] V_{cr} is much higher and the growth rate γ is reduced by a factor $(T_1/m_ec^2)^{1/2}$ (T_1 is the equilibrium temperature of the electrons and ions in nonrelativistic theory).

In conclusion the author wishes to thank N. L. Tsintsadze for his interest.

Correction of third-order angular aberration in a system with two electrostatic mirrors

V. V. Zashkvara
Institute of Nuclear Physics,
Academy of Sciences of the Kazakh SSR, Alma-Ata

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 1541-1543 (July 1974)

The ion-optical configuration of a two-stage electrostatic energy analyzer is discussed. The analyzer consists of two electrostatic electron mirrors, one hyperbolic and one cylindrical, matched in such a way that the total spherical aberration of the system in the direction of the dispersion is proportional to the fourth power of the divergence half-angle in the plane of the axial trajectory.

The analyzer with a hyperbolic mirror proposed by Bredov[1] exhibits second-order angular focusing in the plane of symmetry of the field and first-order focusing in the transverse plane. In an analyzer with a cylindrical mirror[2] there is second-order focusing with respect to the angle of divergence of the beam in the axial plane and exact angular focusing with respect to the angle of divergence in the plane of the azimuthal cross section. The corresponding ion-optical diagrams are the same: In both cases point sources of charged particles and foci which are nearly points are located outside the analyzing fields on the axes of symmetry parallel to the generation of the deflecting electrodes. Spherical aberrations, which determine the longitudinal broadening of the images, are proportional to the cube of the half-angle of divergence of the beam $\Delta\alpha$ in the plane of the axial trajectory. The third-order aberrations are of opposite sign in hyperbolic and cylindrical electrostatic mirrors, making possible a system of two electron mirrors, in which the third-order angular aberration in the direction of the dispersion is corrected completely. The ion-optical diagram of such a two-stage analyzer consisting of matched hyperbolic 1 and cylindrical 2 electron mirrors is shown in Fig. 1. A point source of charged particles 0 is located on the z axis in the plane of symmetry of the deflecting electrodes of the hyperbolic mirror. Point 0 is a distance H from the surface of the inner hyperbolic electrode, the angle of entrance of the central ray $\alpha_h = 51°55'$, and the focal length $L_h = 7.092$ H (ref. 1). For second-order focusing in a cylindrical mirror[2] the entrance angle $\alpha_c = 42°18'$, and the focal length $L_c = 6.1298\ r_1$, where r_1 is the radius of the inner cylindrical electrode. At point f the Gaussian foci of the two mirrors are superposed, and the axis of the cylindrical mirror z' passes through point f and is inclined to the axis of the hyperbolic mirror at an angle $\alpha_h - \alpha_c = 9°37'$. The geometry of the beam being analyzed is shown in Fig. 2 for the vicinity of the intermediate focus f. The axial ray is labelled 00', and the peripheral rays 11' and 22' bounding the beam have an angular spread $\pm\Delta\alpha$. Rays 33' and 44' make small angles with the axial trajectory. The dashed line is the caustic curve, which is the envelope of the family of rays. The segments a_h and a_c characterize the third-order angular aberrational broadening of the images of the hyperbolic and cylindrical mirrors in the axial directions along the z and z' axes respectively.

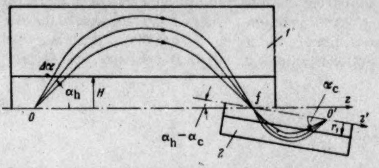

Fig. 1. Two-stage electrostatic energy analyzer. 1) Hyperbolic electron mirror; 2) cylindrical mirror.

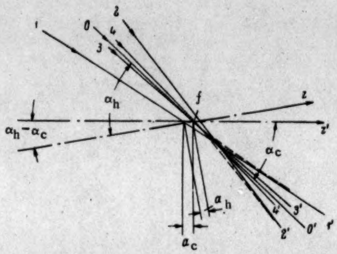

Fig. 2. Beam geometry in the vicinity of the intermediate focus.

To correct the angular aberration at the system exit, point 0' in Fig. 1, under the conditions considered, the characteristic dimensions H and r_1 must satisfy a relation obtained by requiring the equality of the third-order angular aberrations in the vicinity of the intermediate focus:

$$|a_c| \sin\alpha_c = |a_h| \sin\alpha_h, \tag{1}$$

where $|a_c|$ and $|a_h|$ are the absolute values of the third-order aberrations. The expression for a_c is[2]

$$a_c = -15.529 r_1 (\Delta\alpha)^3. \tag{2}$$

The third-order angular aberration of a hyperbolic mirror is not calculated in ref. 1. It must be determined from the expression[1] for L_h by finding $\partial^3 L_h/\partial\alpha^3$ when $\partial^2 L_h/\partial\alpha^2 = \partial L_h/\partial\alpha = 0$.

Thus,

$$a_h = \frac{1}{3!}\frac{\partial^3 L_h}{\partial\alpha^3}(\Delta\alpha)^3 = \frac{1}{3}\frac{H}{\varepsilon}\operatorname{ctg}^2\alpha_h\left[\frac{\beta^2(7+3\beta^2)}{(1-\beta^2)^2}\right.$$
$$\left. + 4\operatorname{ctg}^2\alpha_h\beta^2\frac{1-3\beta^2}{(1-\beta^2)^3} - 3\beta\,\operatorname{Arth}\beta\right](\Delta\alpha)^3. \tag{3}$$

It is established in ref. 1 that for double angular focusing of a beam in a hyperbolic mirror $\beta = -0.8438$ and $\varepsilon = -0.2957$. Substituting these values into Eq. (3) gives

$$a_{\mathrm{h}} = 5.4628H\,(\Delta\alpha)^3. \tag{4}$$

Now, substituting a_{c} and a_{h} into the condition for the compensation of the third-order aberration (1) we obtain the required relation between H and r_1:

$$r_1 = 0.4115H. \tag{5}$$

The ion-optical diagram in Fig. 1 is drawn by taking account of this relation. The fact that the axes of the electrostatic mirrors in the ion-optical diagram shown do not coincide leads only to an insignificant extra broadening of the intermediate image in the transverse plane by an amount $a_{\mathrm{h}}\gamma \sin(\alpha_{\mathrm{h}} - \alpha_{\mathrm{c}})$, where γ is the angular divergence of the beam of charged particles in the transverse plane, and there is first-order focusing with respect to the angle γ for the system as a whole, as for a hyperbolic mirror alone. On the basis of data in refs. 1 and 2 and Eq. (5) the energy dispersion of the mirror system is

$$\Delta L = 9.3118H\,\frac{\Delta u}{u} + 5.6038r_1\,\frac{\Delta u}{u} = 11.6178H\,\frac{\Delta u}{u}. \tag{6}$$

Linear transient response of a fully ionized plasma in a pulsed electric field

V. V. Istomin, S. P. Sher, and S. P. Dovgopol

S. M. Kirov Ural Polytechnical Institute,

(Submitted May 25, 1973; resubmitted December 4, 1973)
Zh. Tekh. Fiz., 44, 1543-1545 (July 1974)

A kinetic equation for the one-particle distribution function with a Landau collision integral is used to investigate the linear transient response of a fully ionized plasma in a pulsed electric field. General expressions are obtained for the electric current as a function of time and the energy absorbed by the plasma. Computer calculations are presented in the form of curves of the current and energy; these lead to the conclusion that the transition to the steady state is slower than in a weakly ionized plasma. For this reason, measurements of the electrical conductivity of a plasma can be lower than the Spitzer value if the measurements are not performed in the steady state.

An investigation of transient processes in a plasma in a pulsed electric field is of interest with regard to plasma heating. In ref. 1 this problem is considered for a weakly ionized plasma, where only electron–neutral collisions are considered; it is assumed that the electron velocity dependence of the collision frequency is proportional to v^s and s = 0,1 or 2. It is found that the parameters of the steady state are not appreciably affected by s.

In the present paper the transient process is considered in a fully ionized homogeneous plasma and it is shown that the velocity dependence of the collision frequency is very important.

We start with the kinetic equation for the single particle distribution function $f_e(\mathbf{v})$ with the Landau collision integral[2] linearized for an ideal Lorentzian gas:[3]

$$\left.\begin{aligned}\left(\frac{\partial}{\partial t}-\frac{e}{m}\mathbf{E}(t)\frac{\partial}{\partial \mathbf{v}}\right)f_e(\mathbf{v},t)=A\partial_r v^{-3}(v^2\delta_{rs}-v_r v_s)\partial_s f_e(\mathbf{v},t),\\ A=\frac{2\pi e^2 e_i^2 n_i L}{m^2},\end{aligned}\right\}\qquad(1)$$

where E(t) is a time-dependent electric field, $\partial_j = \partial/\partial v_j$, (j = x, y, z), n_i is the ion density, e and e_i are the electron and ion charge, respectively, and L is the Coulomb logarithm.[2] The contribution of electron–electron collisions is neglected in (1); this is justified by the small electron–ion mass ratio.[3] This procedure also allows us to use the Lorentzian model,[3] assuming the ion distribution function to be a delta function if the field frequencies are not too low.[1]

Assuming the field to be in the direction of the x axis, we use the linear approximation

$$f_e(\mathbf{v})=f^0(v)+\frac{v_x}{v}F(v,t),\quad f^0(v)=\left(\frac{m}{2\pi kT_e}\right)^{3/2}\exp\left(-\frac{mv^2}{2kT_e}\right).\qquad(2)$$

Solving Eq. (1) to the same approximation, we obtain

$$F(v,t)=\frac{e}{m}\frac{\partial f_0(v)}{\partial v}\Phi(v,t),\quad \Phi(v,t)=e^{-\frac{2At}{v^3}\int\limits_1^t dt' e^{\frac{2At'}{v^3}}E(t')}.\qquad(3)$$

The current $I(t) = -en_e\int d\mathbf{v}u_x f_e(\mathbf{v})$ (n_e is the electron density) is

$$I(t)=\frac{8n_e e^2}{3\sqrt{\pi}\,m}\int\limits_0^\infty dW W^4\Phi'(W,t)e^{-W^2},\qquad(4)$$

where Φ' is obtained from Φ by replacing $2A/v^3$ by ν(W),

$$\nu(W)=\frac{4\pi e^2 e_i^2 n_i L}{m^{1/2}(2kT_e)^{3/2}}W^{-3},\quad W\equiv\left(\frac{m}{2kT_e}\right)^{1/2}v.\qquad(5)$$

Further, we calculate the energy absorbed by the plasma in time τ:

$$\varepsilon(\tau)=\frac{1}{\tau}\int\limits_0^\tau dt I(t)E(t).\qquad(6)$$

We consider two cases separately: $E(t) = E_0$ = const and $E(t) = E_0 \cos \omega t$. In the first case

$$I_1(t)=I_0[3-\rho_1(at)],\quad a=\frac{4\pi e^2 e_i^2 n_i L}{m^{1/2}(2kT_e)^{3/2}},\qquad(7)$$

where I_0 is the steady-state current, $I_0 = I_1(\infty) = 8n_e e^2 E_0\cdot(3\sqrt{\pi m a})^{-1}$, and

$$\rho_{1'}(x)\equiv\int\limits_0^\infty dW W^7\exp(-W^2-xW^{-3}).\qquad(8)$$

Correspondingly,

$$\varepsilon_{1'}(\tau)=\varepsilon_0\left[3-\frac{945\sqrt{\pi}}{64a\tau}+\frac{\rho_1(a\tau)}{a\tau}\right],\qquad(9)$$

where $\varepsilon_0 = I_0E_0$. In the second case

$$I_2(t)=I_0\left[\cos\omega t\rho_2\left(\frac{\omega}{a}\right)+\frac{\omega}{a}\sin\omega t\rho_3\left(\frac{\omega}{a}-\lambda_1\left(\frac{\omega}{a},at\right)\right)\right],\qquad(10)$$

where

$$\begin{Bmatrix}\rho_2(\alpha)\\ \rho_3(\alpha)\end{Bmatrix}=\int\limits_0^\infty dW\begin{Bmatrix}W^7\\ W^{10}\end{Bmatrix}e^{-W^2}(1+\alpha^2W^6)^{-1},\qquad(11)$$

$$\lambda_1(\alpha,x)=\int\limits_0^\infty dW W^7(1+\alpha^2W^6)^{-1}\exp(-W^2-xW^{-3}).\qquad(12)$$

Further, in the second case we have for the energy

$$\begin{aligned}\varepsilon_{2'}(\tau)=\varepsilon_0\Big[&\frac{1}{2}\left(1+\frac{\sin 2\omega\tau}{2\omega\tau}\right)\rho_2\left(\frac{\omega}{a}\right)+\frac{\sin^2\omega\tau}{2a\tau}\rho_3\left(\frac{\omega}{a}\right)\\ &+\frac{\cos\omega\tau}{a\tau}\lambda_2\left(\frac{\omega}{a},a\tau\right)-\frac{\omega\sin\omega\tau}{a^2\tau}\lambda_3\left(\frac{\omega}{a},a\tau\right)-\frac{1}{a\tau}\rho_4\left(\frac{\omega}{a}\right)\Big],\end{aligned}\qquad(13)$$

where

$$\rho_4(\alpha)=\int\limits_0^\infty dW W^{10}(1+\alpha^2W^6)^{-2}e^{-W^2},\qquad(14)$$

$$\begin{Bmatrix}\lambda_2(\alpha,x)\\ \lambda_3(\alpha,x)\end{Bmatrix}=\int\limits_0^\infty dW\begin{Bmatrix}W^{10}\\ W^{13}\end{Bmatrix}(1+\alpha^2W^6)^{-2}\exp(-W^2-xW^{-3}).\qquad(15)$$

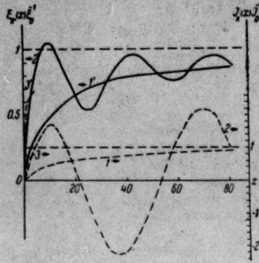

Fig. 1. Transient process for the current and the energy absorbed by the plasma during the pulse.

The integrals for ρ_i and λ_i are not expressed in elementary or special functions: They were calculated on a computer for $x \in [0.85]$ and $\alpha = 0.1$. The values obtained are $\rho_2(0.1) = 1.899$, $\rho_3(0.1) = 11.768$, and $\rho_4(0.1) = 6.990$. Curves of the functions $I_k(at)\ J_0^{-1}$ and $\varepsilon_k(a\tau)\ \varepsilon_0^{-1}$ have been plotted from the results of these calculations (see Fig. 1). Curves 1 and 1' correspond to k and k', curves 2 and 2' correspond to k and k'. For comparison, we give curves 3 and 3' from ref. 1 which describe the functions $I_1(at)\ I_0^{-1}$ and $\varepsilon_1(a\tau)\ \varepsilon_0^{-1}$ for a weakly ionized plasma with a constant (not dependent on velocity) collision frequency.

Comparison of curves 1 and 3 (1' and 3') clearly indicates that in a fully ionized plasma the transition to the steady state is much slower than in a weakly ionized plasma. This fact can be explained as due to the predominance, in a weakly ionized plasma, of short-range collisions with neutrals; in a fully ionized plasma there is a long-range Coulomb interaction between particles. In the case of an ac field, a slower transition to the steady-state occurs (curves 2 and 2') with the presence of characteristic oscillations.

In conclusion we note, first, that the slow transition to the steady state in a fully ionized plasma can evidently cause a discrepancy (toward smaller) between the electrical conductivity measured experimentally and that calculated according to the Spitzer equation[4] if the experiment is not carried out under rigorous steady-state conditions. This fact is mentioned in ref. 5.

Second, it is clear that although the conditions for absorption (and thus heating) are favorable in a weakly ionized plasma, periodic modulation of the pulse provides fairly intense absorption in a fully ionized plasma up to the transition to the steady state.

Capillary gravitational waves and the mechanogalvanic effect

E. D. Korlyakov
S. O. Makarov Leningrad College of Marine Studies
(Submitted September 25, 1973; resubmitted December 25, 1973)
Zh. Tekh. Fiz., 44, 1545-1546 (July 1974)

The movement of aqueous solutions of electrolytes relative to a continuous interface with a solid medium produces a potential gradient along the tangent to the interface. This phenomenon (the mechanogalvanic effect) is of an electrodynamic nature. A theoretical and experimental analysis for an interface between an electrolyte and a solid is given in the review of ref. 1. The quantitative explanation of the effect for this case is based on the Helmholtz–Smolukhov theory of the double electric layer and the theory of motion in a viscous liquid. The assumptions made below suggest that the mechanogalvanic effect should also be observed in relative motion between a liquid and a gas phase.

It was established as early as 1915 that the surface of a liquid at an interphase boundary with a gas is covered by a double electric layer, which is entirely inside the liquid and is not caused by the contact with the gas.[2] Frenkel[3] analyzed the orientation of molecules at a free liquid surface and showed that if the quadrupole moment of the molecules is taken into account, as in the case of water, the surface would be covered by a double electric layer; the presence of absorbed molecules with active dipole groups produces double layers with a considerably higher jump in potential than in pure liquids.

It has been shown experimentally[4] that if a stream of air whose density is ρ(kg/m^3) moves at a velocity v(m/sec), then a tangential frictional force of

$$F = 2 \cdot 10^{-4} \rho v^2 \text{ N},$$

acts on each square meter of water.

If we carry out calculations similar to those for the mechanogalvanic effect at an electrolyte/solid interface,[1] we find that for a boundary between an aqueous solution of electrolyte and air the potential gradient that is produced by relative motion is given by the expression

$$E = 2 \cdot 10^{-4} \frac{\delta}{\zeta \varepsilon_0 \varepsilon} \rho v^2,$$

where ρ is the density of air, v is its velocity relative to the solution, ζ is the zeta potential (electrokinetic potential), and δ is the effective thickness of the surface layer. This equation shows, for example, that at an air speed of about 2 m/sec a field strength of around 0.5 mV/m is to be expected. Since a stream of air generates surface waves at a liquid interface, the production of these waves and the appearance of the electric field are interrelated.

An experimental study of the mechanogalvanic effect at the interface between an aqueous solution and air has been performed with the method and apparatus described in the review of ref. 1. It might be noted that in the present case the investigation is made more difficult by the fact that the effect also occurs at the measuring electrodes when a wave motion is produced; the noise thus measured is known as wave noise.[5] In the laboratory, investigations are made below the point at which the wave noise becomes distinctly observable. For air speeds up to 3 m/sec, the experimental data agree, in order of magnitude, with the theoretical calculations. Thus, for example, an air speed of 2 m/sec over sea water (the most widely occurring natural electrolyte) produces an alternating field of from 0.5 to 1 mV/m. Thus an air stream produces both surface waves and an alternating current at the interface.

General electrodynamic principles suggest that the alternating currents must set up alternating magnetic fields. It is interesting to note in this connection that studies of sea waves under natural conditions by means of a cesium magnetometer have shown the presence of magnetic fields accompanying wave motion.[6] It also follows from geophysical data that there is a close connection between the characteristics of wave motion and the induced magnetic fields.[7]

We might note that an experimental study has established that surface waves are produced when an alternating current is passed through an electrolyte in an external magnetic field;[8] this is the inverse effect to the generation of surface waves and electromagnetic fields by the mechanogalvanic effect at an electrolyte–air interface. Further studies of this effect are needed and would be useful in understanding processes occurring in diffusion and mixed kinetics.

Elimination of spherical aberration in an axial plasma lens

S. V. Lebedev and A. I. Morozov

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 1547-1548 (July 1974)

The conditions under which spherical aberration can be eliminated from an axial plasma lens are analyzed. A necessary condition for this elimination is a parabolic potential profile along the magnetic lines of force.

The focusing properties of an axial plasma lens used to focus dense, neutral ion beams are analyzed in ref. 1. The lens under consideration here is a ring carrying a current R_0; a potential difference U_0 is applied betweeen the ring and the source.

In an experimental study of a lens of this type,[2] it has been shown that the focal length of the lens agrees with that calculated in the thin-lens approximation.[3] It has also been found that when a system of electrodes is used to vary the profile of the electric potential along the magnetic lines of force changes occur in the magnitude of the spherical aberration; this aberration is minimized in the case of a parabolic $\Phi(\Psi)$ profile,

$$\Phi = K_1\Psi + K_2\Psi^2, \tag{1}$$

where K_1 and K_2 are constants, Ψ is the magnetic flux function, and $\Phi(\Psi)$ is the scalar potential of the electric field.

We can show that functional dependence (1) is a necessary condition for the elimination of spherical aberration for the case of an arbitrary magnetic field configuration in the lens. We write the flux $\Psi(r, z)$ as a power series in r, retaining only the first two terms:

$$\Psi = \frac{r^2}{2} H - \frac{r^4}{4!} H'', \tag{2}$$

where H(z) is the magnetic field at the axis, and the primes denote differentiation with respect to the z coordinate. In the same approximation the generalized potential[4] $V = (e^2/Mc^2)(\Psi^2/2r^2) + e\Phi(\Psi)$, which governs the motion of a particle in a plane, can be written

$$V = \frac{r^2}{2}\left[\frac{e^2}{Mc^2}\frac{H^2}{4} + e\frac{d\Phi}{d\Psi}H\right] + \frac{r^4}{4}\left[-\frac{e^2}{Mc^2}\frac{1}{12}HH' - e\frac{d\Phi}{d\Psi}\frac{H''}{3!} + e\frac{d^2\Phi}{d\Psi^2}\frac{H^2}{2}\right]. \tag{3}$$

Substituting (3) into the equation of motion

$$\ddot{r} = -\frac{1}{M}\frac{\partial V}{\partial r}, \quad \ddot{z} = -\frac{1}{M}\frac{\partial V}{\partial z}, \tag{4}$$

and assuming the velocity $\dot{z}$ to be constant along the axis of the lens, we find the angle through which the ion trajectory is refracted in passage through the lens:

$$r' = -\frac{1}{M}\frac{1}{\dot{z}}\int_{-\infty}^{0}\frac{\partial V}{\partial r}\frac{1}{\dot{z}}\,dz = -\frac{1}{M}\frac{1}{\dot{z}_0}\int_{-\infty}^{z}\left\{r\left[\frac{e^2}{Mc^2}\frac{H^2}{4} + e\frac{d\Phi}{d\Psi}\right] + r^3\left[-\frac{e^2}{M^2c^2}\frac{1}{12}HH'' - e\frac{d\Phi}{d\Psi}\frac{H''}{3!} + \frac{e}{M}\frac{d^2\Phi}{d\Psi^2}\frac{H^2}{2}\right]\right\}dz. \tag{5}$$

From Eq. (5), using the thin-lens approximation, we find the focal length taking spherical aberration into account:

$$\frac{1}{F} = \frac{1}{v_0^2}\int_{-\infty}^{+\infty}\left[\frac{e^2}{M^2c^2}\frac{H^2}{4} + \frac{e}{M}\frac{d\Phi}{d\Psi}H\right]dz - \frac{r_0^2}{v^2}\int_{-\infty}^{+\infty}\left[\frac{e^2}{Mc^2}\frac{1}{12}HH'' - \frac{e}{M}\frac{d\Phi}{d\Psi}\frac{H}{3!} + \frac{e''}{M}\frac{d^2\Phi}{d\Psi^2}\frac{H^2}{2}\right]dz. \tag{6}$$

The second term in (6) gives the spherical aberration, v_0 is the total ion velocity, and r_0 is the beam width. Clearly, if the spherical aberration is to be eliminated, the second term in (6) must vanish. Substituting (1) into (6), and taking account of the spatial confinement of the fields in the lens, we find that the spherical aberration is suppressed under the condition

$$\frac{1}{12}\frac{e^2}{M^2c^2}\int_{-\infty}^{+\infty}(H')\,dz + \frac{e}{M}k_2\int_{-\infty}^{+\infty}H^2dz = 0, \tag{7}$$

and from this condition we find

$$k_2 = -\frac{1}{12}\frac{e^2}{Mc^2}\frac{\int_{-\infty}^{+\infty}(H')^2\,dz}{\int_{-\infty}^{+\infty}H^2dz}. \tag{8}$$

For the magnetic field of the plasma lens analyzed in ref. 1,

$$H = \frac{2I_0R^2}{(z^2 + R^2)^{3/2}}, \tag{9}$$

where R is the ring radius, the value of k_2 is

$$k_2 = -3\cdot 10^{-2}\frac{1}{R^2}\frac{e}{Mc^2}. \tag{10}$$

We can conclude that in contrast with ordinary axial lenses used in ion optics, spherical aberration can be eliminated in a plasma lens if the electric field is specified in form (1). We note that the focal length is independent of k_2.

Achromatic plasma–lens system

A. I. Morozov and S. V. Lebedev

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 1548-1549 (July 1974)

Annular plasma lenses with axisymmetric focusing fields differ markedly from their vacuum analogs (which focus low-density electron and ion beams). In particular, plasma lenses can display a different velocity dispersion and can be either converging or diverging lenses. Because of these properties systems of plasma lenses without chromatic aberration can be designed, by analogy with ordinary (visible-light) optics.

Plasma lenses are designed for use in focusing neutral ion beams; their basic properties and methods for designing them are given in ref. 1. When the axisymmetric focusing electromagnetic fields are chosen appropriately, annular plasma lenses (i.e., lenses which focus tubular ion beams) can be constructed which have various velocity dispersions. Furthermore, such lenses can be either converging or diverging. These properties make it possible to stabilize the focal point (to eliminate longitudinal chromatic aberration) by analogy with ordinary (visible-light) optics. In light optics achromatic lenses are obtained by cementing together two lenses, one converging and the other diverging, with a relatively pronounced dispersion. Accordingly, by replacing these lenses by their plasma-optics analogs, we can reproduce an optical system.

Let us assume that the focal lengths of the two lenses are

$$F_1 = F_{10}\left(\frac{v}{v_0}\right)^{n_1}, \quad F_2 = F_{20}\left(\frac{v}{v_0}\right)^{n_2}. \tag{1}$$

Here v_0 is the characteristic ion velocity, n_1 and n_2 are positive definite numbers, and F_{10} and F_{20} are the focal lengths of the lenses at velocity v_0.

If the characteristic distance between the lenses is L, and if the source is a distance a_1 from the first lens (Fig. 1), the focal point is found from the familiar equations

$$\frac{1}{a_1} + \frac{1}{b_1} = \frac{1}{F_1}, \quad \frac{1}{a_2} + \frac{1}{b_2} = \frac{1}{F_2}, \quad a_2 = L - b_1. \tag{2}$$

Introducing the auxiliary variables

$$\alpha = \frac{1}{a_1}, \quad \beta = \frac{1}{b_2}, \quad \omega_1 = \frac{1}{F_1}, \quad \omega_2 = \frac{1}{F_2}, \tag{3}$$

we can rewrite (2), incorporating the stabilization condition

$$\frac{\partial b_2}{\partial v} = 0 \tag{4}$$

as

$$\frac{1}{\omega_1 - \alpha} + \frac{1}{\omega_2 - \beta} = L, \quad \left(\frac{\omega_1 - \alpha}{\omega_2 - \beta}\right)^2 = -\frac{n_1}{n_2}\frac{\omega_1}{\omega_2}. \tag{5}$$

It follows that with $n_1 > 0$ and $n_2 > 0$ stabilization of the focus requires that one lens be converging and the other diverging (e.g., $\omega_1 > 0$, $\omega_2 < 0$).

System (5) can be written in a more compact form if we introduce

$$\frac{1}{\omega_1 - \alpha} = \xi, \quad \frac{1}{\omega_2 - \beta} = \eta, \quad \frac{n_1}{n_2} = \theta$$

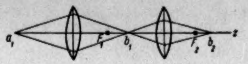

Fig. 1

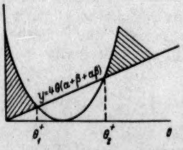

Fig. 2

and set L = 1.

Then we replace (5) by

$$\xi + \eta = 1, \quad \frac{\eta}{\xi} = -\theta\frac{1 + \xi\alpha}{1 + \eta\beta}. \tag{6}$$

Then

$$\eta = \frac{-1 + \theta(1 + 2\alpha) \pm \sqrt{(1-\theta)^2 - 4\theta(\alpha + \beta + \alpha\beta)}}{2(\beta + \alpha\theta)}. \tag{7}$$

From the condition for the positive definiteness of the discriminant

$$D = (1-\theta)^2 - 4\theta(\alpha + \beta + \alpha\beta) \geqslant 0, \tag{8}$$

we find the ratio $n_1/n_2 = \theta$ at which stabilization is possible.

Figure 2 shows regions with $D \geq 0$. The slope of the line $y = 4\theta(\alpha + \beta + \alpha\beta)$ is a function of the optic power of the lenses. We see that stabilization is possible under the conditions $\theta < \theta_1^*$ and $\theta_1^* > \theta_2$. We note that these regions correspond to the visible-light system. Under the condition $\theta < \theta_1^*$ the first lens must be converging ($\omega_1 > 0$) and the second must be diverging ($\omega_2 < 0$); if a real image is to be obtained we must arrange $\omega_1 > |\omega_2|$. In the region $\theta > \theta_2^*$ we must use lenses satisfying $\omega_1 < 0$, $\omega_2 > 0$, and $|\omega_1| < \omega_2$.

We can superpose the converging and diverging lenses, i.e., we can arrange L = 0. Now the stabilization condition is $\omega_1 = -\theta\omega_2$. A real image is obtained if $\theta < 0$. This result follows from the focal length of this "superposed" system:

$$\beta = \omega_2(1 - \theta), \quad \alpha = 0. \tag{9}$$

Multiple-aperture ion source for electromagnetic mass separator

S. V. Lebedev

(Submitted October 5, 1973)
Zh. Tekh. Fiz., 44, 1550 (July 1974)

From the ion-optics standpoint, multiple-aperture sources are "broad" sources; in their current form they are unsuitable for use in mass separators since the source width affects the resolution of the separator.

This shortcoming of multiple-aperture sources can be avoided by choosing appropriately the potential distribution on the extracting electrodes. As an example we consider the use of a multiple-aperture source for an electromagnetic separator with a fixed magnetic field (Fig. 1). We assume that two source slits are a distance δR apart and that the potentials on the extracting electrodes are different, equal to Φ_1 and Φ_2, respectively ($\Phi_2 > \Phi_1$). For ions of mass M_0 the velocities of the ions emerging from the first and second slits are

$$v_1 = \sqrt{-\frac{2e}{M_0}\Phi_1}, \quad v_2 = \sqrt{-\frac{2e}{M_0}\Phi_2}. \tag{1}$$

Since the magnetic field is fixed, the Larmor radii of the ions moving at the velocities v_1 and v_2 are constant and equal to

$$R_1 = \frac{v_1}{\omega_H}, \quad R_2 = \frac{v_2}{\omega_H}, \tag{2}$$

where $\omega_H = eH_0/(M_0c)$ and H_0 is the magnetic field of the separator. The beams emerging from these slits are focused (for masses M_0) at a distance

$$\delta l = 2(R_2 - R_1) - \delta R \tag{3}$$

apart.

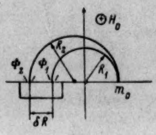

Fig. 1

We see that the focal points coincide if the potentials on the electrodes are chosen to satisfy

$$\delta R = 2(R_2 - R_1) = 2\frac{\Delta v}{v_1}R_1, \tag{4}$$

where $\Delta v = v_2 - v_1$.

Accordingly, the source "width" can be compensated through an appropriate choice of potentials. The mass dispersions for the beams emerging from the first and second slits are, respectively,

$$\delta_1 = 2\frac{\delta M}{M_0}\frac{v_1}{\omega_H}, \quad \delta_2 = 2\frac{\delta M}{M_0}\frac{v_1}{\omega_H} + 2\frac{\delta M}{M_0}\frac{\Delta v}{\omega_H}, \tag{5}$$

where δM is the mass spread.

It follows from (5) that if $\Delta v/\omega_H \ll R_1$ (e.g., with $\delta R/R \sim 0.08$ and $\Delta v/v_1 \sim 0.04$), the blurring of the focal point for mass $M_0 + \delta M$ is a quantity of second order for the case in which two slits are used.

Viscous momentum transport in a gaseous mixture

B. M. Markeev

Institute of Problems of Mechanics,
Academy of Sciences of the USSR, Moscow

(Submitted September 24, 1973; resubmitted January 7, 1974)
Zh. Tekh. Fiz., 44, 1550-1553 (July 1974)

The transport equations for a gaseous mixture are analyzed on the basis of the 13-moment approximation through an expansion of the distribution function about the Maxwellian values for the average partial velocity of the component. The transport equations contain an additional viscous force in the second approximation in the small Knudsen number. This latter circumstance leads to a finite mean mass velocity under the condition Δp = 0 in the motion of a binary mixture between plates in the field of partial pressure gradients tangential to the plates.

Transport-equation theory for a gaseous mixture is derived on the basis of the 13-moment approximation in refs. 1-3. The distribution function is expanded about the Maxwellian values in the mean mass velocity in order to obtain transport equations.

Below we analyze viscous momentum transport in a multicomponent gaseous mixture on the basis of an expansion of the distribution function about the Maxwellian values in the mean partial velocity of the component. We include the gradient of the heat flux together with the gradient in the partial velocity in solving the equation for the viscous-stress tensor in the first approximation in the small Knudsen number. We show that this approximation of the distribution function provides a more detailed description of the behavior of the mixture than the approximation in refs. 1-3; in particular, it leads to the appearance of additional viscous forces in the equations of motion for the components. We consider the problem of gas flow between parallel plates in the field of partial pressure gradients tangential to the plates.

We show that under the influence of these partial gradients the gas moves with a finite mean mass velocity even if the gradient in the total pressure vanishes.

1. The transport equation for the quantities ψ_α can be obtained by multiplying the left and right sides of the kinetic equation by the given quantity and then integrating over velocities. Successively setting $\psi_\alpha = 1$, $m_\alpha v_\alpha$, and $(m_\alpha/2)(v_\alpha - u_\alpha)$, and expanding the distribution function about the Maxwellian values for the mean partial velocity of the components, we find the continuity equation, the momentum-conservation equation, and the energy-conservation equation:

$$\frac{\partial n_\alpha}{\partial t} + \operatorname{div} n_\alpha u_\alpha = 0, \tag{1.1}$$

$$n_\alpha m_\alpha\left[\frac{\partial u_\alpha}{\partial t} + (\mathbf{u}_\alpha\nabla)\,\mathbf{u}_\alpha\right]_k + \nabla_k n_\alpha T_\alpha - \nabla_j\sigma_{\alpha kj} = R_{\alpha k}, \tag{1.2}$$

$$\frac{3}{2}n_\alpha\left[\frac{\partial}{\partial t} + (\mathbf{u}_\alpha\nabla)\right]T_\alpha + n_\alpha T_\alpha(\nabla u_\alpha) + (\nabla\mathbf{q}_\alpha) - \sigma_{\alpha ks}(\nabla_k u_{\alpha s}) = Q_\alpha, \tag{1.3}$$

where n_α, u_α, $\sigma_{\alpha ij}$, and q_α are the number density of the particles, the mean velocity, the viscous-stress tensor, and the heat-flux vector for particles of species α.

Multiplying the kinetic equation by $\psi_\alpha = m_\alpha(v_\alpha - u_\alpha)_k(v_\alpha - u_\alpha)_s$, $(m_\alpha/2)(v_\alpha - u_\alpha)^2(v_\alpha - u_\alpha)_k$, and integrating over velocities, we find the transport equations

$$\frac{\partial}{\partial t}\sigma_{\alpha kl} + \nabla_s(u_{\alpha s}\sigma_{\alpha kl}) + \sigma_{\alpha ks}(\nabla_s u_{\alpha l}) + \sigma_{\alpha sl}(\nabla_s u_{\alpha k})$$
$$-\frac{2}{3}\delta_{kl}\sigma_{\alpha sp}(\nabla_s u_{\alpha p}) - \frac{2}{5}(\nabla q_\alpha)_{kl} - n_\alpha T_\alpha(\nabla u_\alpha)_{kl} = -R_{\alpha kl}, \tag{1.4}$$

$$\frac{\partial}{\partial t}q_{\alpha k} + (\mathbf{u}_\alpha\nabla)q_{\alpha k} + \frac{7}{5}q_{\alpha k}(\nabla_s u_{\alpha s}) + \frac{2}{5}q_{\alpha s}(\nabla_k u_{\alpha s})$$
$$+\frac{5}{2}\left(\frac{n_\alpha T_\alpha}{m_\alpha}\right)\nabla_k T_\alpha - \left(\frac{T_\alpha}{m_\alpha}\right)\nabla_s\sigma_{\alpha ks} + \frac{7}{5}(q_{\alpha s}\nabla_s)u_{\alpha k}$$
$$-\frac{7}{2}\left(\frac{\sigma_{\alpha ks}}{m_\alpha}\right)\nabla_s T_\alpha + \left(\frac{\sigma_{\alpha ks}}{n_\alpha m_\alpha}\right)(\nabla_s n_\alpha T_\alpha - \nabla_l\sigma_{\alpha sl})$$
$$= R_{\alpha kss} - m_\alpha^{-1}\left[\frac{5}{2}T_\alpha\delta_{kl} - \left(\frac{\sigma_{\alpha kl}}{n_\alpha}\right)R_{\alpha l}\right], \tag{1.5}$$

where $(A, B)_{kj} = A_k B_j + A_j B_k - (2/3)\delta_{kj}(A_s B_s)$.

2. The right sides of the transport equations can be written as follows:

$$R_{\alpha i} = -\sum_\beta\left(\frac{n_\alpha n_\beta T}{n\,[D_{\alpha\beta}]_1}\right)u_{\alpha\beta} - \sum_\beta\zeta_{\alpha\beta}\left(\frac{q_{\alpha i}}{m_\alpha n_\alpha} - \frac{q_{\beta i}}{m_\beta n_\beta}\right), \tag{2.1}$$

$$R_{\alpha ik} = \frac{p^2\sum\limits_\beta a_{\alpha\beta}\sigma_{\beta ik}/p_\beta}{p_\beta}, \tag{2.2}$$

$$\left[R^{(3)}_{\alpha kss} - \frac{5}{2}\frac{T_\alpha}{m_\alpha}R_{\alpha k}\right] = \frac{5}{2}\frac{T_\alpha}{m_\alpha}\left[-\frac{p^2}{T_\alpha}\sum_\beta b_{\alpha\beta}\left(\frac{q_{\beta k}}{p_\beta}\right) - \sum_\beta\left(\frac{T_\alpha}{m_\alpha}\right)\zeta_{\alpha\beta}u_{\alpha\beta k}\right], \tag{2.3}$$

$$Q_\alpha = \left(\frac{m_{\alpha\beta}}{m_\alpha}\right)\left\{\sum_\beta\left(\frac{n_\alpha n_\beta T}{n\,[D_{\alpha\beta}]_1}\right)u^2_{\alpha\beta} + \sum_\beta\zeta_{\alpha\beta}u_{\alpha\beta i}\left(\frac{q_{\alpha i}}{m_\alpha n_\alpha} - \frac{q_{\beta i}}{m_\beta n_\beta}\right)\right., \tag{2.4}$$

where $u_{\alpha\beta} = u_\alpha - u_\beta$; $y_\alpha = n_\alpha/n$; $n = \sum\limits_\alpha n_\alpha$, and equations for $[D_{\alpha\beta}]_1$, $\zeta_{\alpha\beta}$, $a_{\alpha\beta}$, and $b_{\alpha\beta}$ are given, e.g., in ref. 3.

3. The values of $\sigma_{\alpha kl}$ and q_α are determined from system (1.4), (1.5). In the first approximation in the small Knudsen number we find

$$q^{(1)}_{\alpha i} = -\eta_\alpha\nabla_i T - \left(\frac{T}{p}\right)\sum_{\delta,\nu}y_\alpha\left(\frac{T}{m_\delta}\right)\zeta_{\delta\nu}\left(\frac{|b|_{\delta\nu}}{|b|}\right)u_{\delta\nu i}, \tag{3.1}$$

$$\sigma^{(1)}_{\alpha kl} = \left(\frac{2}{5}\right)p^{-1}\sum_\delta\left(\frac{|a|_{\delta\alpha}}{|a|}\right)y_\alpha(\nabla q_\delta)_{kl} + \sum_\delta\left(\frac{|a|_{\delta\alpha}}{|a|}\right)y_\alpha y_\delta(\nabla u_\delta)_{kl}, \tag{3.2}$$

where $\eta_\alpha = \sum\limits_\delta y_\alpha y_\delta(|b|\delta_\alpha/|b|)$ is the partial thermal conductivity, $|a|$ and $|b|$ are the determinants of systems (1.4) and (1.5), and $|a|_{\alpha\beta}$ and $|b|_{\alpha\beta}$ are the corresponding signed minors of element $\alpha\beta$. The heat-flux gradient is incorporated in (3.2) (cf. ref. 2). This gradient becomes important when the mixture moves at small Reynolds numbers.

In the second approximation in the small Knudsen number, the quantities $\sigma_{\alpha kl}$ and q_α are found from

$$-\frac{2}{5}(\nabla q^{(1)}_\alpha)_{kl} = -p^2\sum_\beta a_{\alpha\beta}\left(\frac{\sigma^{(2)}_{\beta kl}}{p_\beta}\right), \tag{3.3}$$

$$-\left(\frac{T}{m_\alpha}\right)\nabla_s\sigma^{(1)}_{\alpha ks}-\left(\frac{7}{2}\right)\left(\frac{\sigma^{(1)}_{\alpha ks}}{m_\alpha}\right)\nabla_s T+\left(\frac{\sigma^{(1)}_{\alpha ks}}{m_\alpha n_\alpha}\right)\nabla_s p_\alpha=-\frac{5}{2}\frac{p^2}{m_\alpha}\sum_\beta b_{\alpha\beta}\left(\frac{q^{(2)}_{\beta k}}{p_\beta}\right). \tag{3.4}$$

It follows from (3.3) and (3.4) that $\sigma^{(2)}_{\beta kl}$ and $q^{(2)}_\beta$ are of order Kn M (where $M = u/T^{1/2}m^{-1/2}$) if the second term in (3.2) is small in comparison with the first but larger than all others.

4. We consider the motion of a binary mixture between two planes in a field of partial pressure gradients. We locate the origin of the coordinate system halfway between the planes, which are separated by a distance 2L; the X axis is perpendicular to the planes, and the Z axis is parallel. System (1.1)-(1.5) with the sticking boundary conditions[1)] has the solution

$$\mathbf{u}_0=\left(\frac{\rho_1}{\rho}\right)\mathbf{u}_1+\left(\frac{\rho_2}{\rho}\right)\mathbf{u}_2=\left(\frac{p}{\mu}\right)(\nabla\ln p)\frac{1}{2}(x^2-L^2)-a(\mathbf{u}_1-\mathbf{u}_2), \tag{4.1}$$

$$\mathbf{u}_\alpha-\mathbf{u}_\beta=-\left(\frac{D_{\alpha\beta}}{y_\alpha y_\beta}\right)[\nabla y_\alpha+[a_p]_1\,y_\alpha y_\beta\nabla\ln p+[a_{T\alpha}]_1\,y_\alpha y_\beta\nabla\ln T]\left\{1-\frac{(\operatorname{ch}p^*x)}{\operatorname{ch}p^*L}\right\}. \tag{4.2}$$

Equations for $[a_p]_1$ and $[a_{T\alpha}]_1$ are given in refs. 3, 4; the constant a is given by

$$a=\left[\frac{n(m_\alpha+m_\beta)}{2\rho}\right]\left\{y_\alpha y_\beta[a_p]_1-\left[\left(\frac{\mu_\alpha}{\mu}\right)y_\beta+\left(\frac{\mu_\beta}{\mu}\right)y_\alpha\right]\frac{m_\beta-m_\alpha}{m_\alpha+m_\beta}\right\}+\frac{(\omega_\alpha-\omega_\beta)}{\mu},$$

where

$$p^{*-2}=\frac{(p^2_{11}+p^2_{22}+p^2_{12}+p^2_{21})}{(p^2_{11}p^2_{22}-p^2_{12}p^2_{21})},$$

$$\omega_\alpha=\left(\frac{2}{5}\right)\left(\frac{T}{p}\right)^2\sum_\beta\mu_{\alpha\beta}\left\{\left(\frac{\zeta_{\alpha\beta}}{m_\alpha}\right)\left(\frac{|b|_{\alpha\beta}}{|b|}\right)-\left(\frac{\zeta_{\beta\alpha}}{m_\beta}\right)\left(\frac{|b|_{\beta\beta}}{|b|}\right)\right\},$$

$$p^2_{\alpha\alpha}=(-\omega^*+\mu_{\alpha\alpha})\left(\frac{nD_{\alpha\beta}}{n_\alpha n_\beta T}\right),$$

$$p^2_\alpha=(\omega_\alpha+\mu_{\alpha\beta})\left(\frac{nD_{\alpha\beta}}{n_\alpha n_\beta T}\right),$$

and

$$\mu_{\alpha\beta}=\left(\frac{|a|_{\beta\alpha}}{|a|}\right)y_\alpha y_\beta.$$

In the first approximation of the Chapman–Enskog method[4] the mixture is described by a mean mass velocity, which is determined from the Navier–Stokes equation. The diffusion rates appear in the second approximation. Equation (4.1) for u_0 differs from the corresponding equation derived on the basis of the method of ref. 4 by the second term, which is the next term in the expansion in the parameter $Kn \ll 1$. In the case $\nabla p = 0$, the second term is of the first order of magnitude and governs the motion of a mixture with nonvanishing mean mass velocity.

In a binary gaseous mixture, by analogy with a single-component gas, steady-state flow is established because the "ideal" momentum flux due to the total pressure gradients is balanced by the total viscous momentum flux, which is directed from points characterized by a high velocity toward points characterized by a low velocity, and which is absorbed at the boundary. Since the distribution function is expanded about the Maxwellian values for the partial component velocity, the total viscous-stress tensor can be divided into two parts (for simplicity we neglect the Dufour effect):

$$\sigma_{kl}=\mu\,[(\nabla u_0)_{kl}+(\mu\rho)^{-1}(\mu_{\alpha\beta}-\mu_{\beta\alpha})(\nabla u_{\alpha\beta})_{kl}]. \tag{4.3}$$

These terms describe viscous momentum transport due to the mean mass and diffusion velocities. With $\nabla p = 0$ the condition $\sigma_{xy} = 0$ must be satisfied for steady-state flow. However, in contrast with a single-component gas, this latter condition is not satisfied with $u_0 = 0$, since, according to (4.3), there is an additional viscous momentum due to diffusion. Roughly speaking, we can say that this additional viscous momentum transport due to diffusion is also responsible for the finite mean mass velocity of the gaseous mixture in the case $\nabla p = 0$.

The author thanks A. A. Rukhadze for discussion.

[1)] Any creep velocity can be added to the right side of Eq. (4.1).

Atomic diffusion from a finite film over a solid surface

Yu. D. Kornyushkin

Leningrad Institute of Precision Mechanics and Optics

(Submitted June 29, 1973; resubmitted January 2, 1974)
Zh. Tekh. Fiz., 44 1553-1555 (July 1974)

An equation is derived describing the functional dependence on time of the concentration of atoms of a film on a solid surface taking account of surface diffusion. Equations are given for the concentration and the surface diffusion coefficient. An equation is derived for the total number of atoms in a finite region of the surface layer.

The physical properties of films are currently being exploited in various devices which find widespread use in microelectronics.[1] Diffusion processes,[2] including surface diffusion, should be taken into account in an explanation of the growth mechanism and properties of films. In particular, surface diffusion is responsible for the formation of islands in thin metal films.[3] For this reason, knowledge of the surface diffusion coefficient, or the law governing the distribution of the atomic concentration over the surface, is as important as knowledge of the corresponding coefficients for bulk diffusion.

The literature reveals several papers on the dynamics of surface diffusion, e.g., Drechsler[4] measured the surface diffusion coefficient of barium on the surface of a tungsten single-crystal and discussed this phenomenon. However, these experiments do not correspond to the basic theoretical conditions. Abramenkov et al.[5] examined surface diffusion, but the functional dependence which they derive is valid only for short periods of time and is thus of a highly specialized nature.

In this note we analyze the surface diffusion of atoms of a finite film, develop a method for calculating the surface diffusion coefficient from experimental data in the most general case, and find the functional dependence on the time of the atomic concentration at any point in the one-dimensional space.

We assume that there is initially a film of infinite length, of width $2x_0$ along the OX axis, and of thickness h on a solid surface. Bulk diffusion into the interior of the solid is very weak, so that the film atoms essentially diffuse only over the surface. The surface area of the solid is infinite. This formulation of the problem is essentially the same as that for the diffusion of atoms from a film of finite thickness into an infinite medium,[6] so that we can use the earlier results.

If we assume that some method is available for measuring the concentration of atoms which have diffused over the surface at various times and at a distance x from the center of the film, we can determine the law governing the concentration for any spatial point from

$$n_1=\frac{n_0}{2}\left[\Phi\left(\frac{x_0+x}{\sqrt{2Dt}}\right)+\Phi\left(\frac{x_0-x}{\sqrt{2Dt}}\right)\right](0\leqslant x\leqslant x_0), \qquad (1)$$

$$n_2=\frac{n_0}{2}\left[\Phi\left(\frac{x+x_0}{\sqrt{2Dt}}\right)-\Phi\left(\frac{x-x_0}{\sqrt{2Dt}}\right)\ (x_0\leqslant x\leqslant\infty)\right], \qquad (2)$$

where

$$\Phi(y)=\frac{2}{\sqrt{2\pi}}\int\limits_0^y e^{-u^2/2}\,du,$$

n_0 is the initial number of atoms per unit length in the film region, n_1 is the number of atoms per unit length within the original geometric boundary of the film at time t, n_2 is the number of atoms per unit length outside this original boundary at time t, x_0 is the distance from the center of the film to the observation point x_0 is the distance from the center of the film to its original geometric boundary, and D is the surface diffusion coefficient of the film atoms.

It follows from the form of Eqs. (1) and (2) that the function $n_1 = n_1(t)$ has no singularities, decreasing monotonically as time elapses; with regard to the function $n_2 = n_2(t)$, we note that at $t = t_m$ it reaches its maximum $n_{2\max} = n_2(t_m)$. From the condition for the extremum we find

$$t_m=\frac{xx_0}{D\ln\dfrac{x+x_0}{x-x_0}}. \qquad (3)$$

If we use the quantity t_m given by (3) as the unit of time in Eq. (2), we find

$$n_2=\frac{n_0}{2}\left[\Phi\left(\frac{z+1}{\sqrt{\dfrac{2z}{\ln\dfrac{z+1}{z-1}}\dfrac{t}{t_m}}}\right)-\Phi\left(\frac{z-1}{\sqrt{\dfrac{2z}{\ln\dfrac{z+1}{z-1}}\dfrac{t}{t_m}}}\right)\right], \qquad (4)$$

where $z = x/x_0 > 1$.

Figure 1 shows $n_2 = n_2(t/t_m)$ curves for z = 1.1, 1.4, and 2.0. It follows from this family of curves that the function $n_2(t/t_m)$ initially increases rapidly, with this increase being larger the smaller the value of z. In the region $t/t_m \approx 1.0$ the function varies weakly; at $t/t_m \geq 1.5$ the concentration $n_2(t/t_m)$ falls off linearly at an essentially constant rate.

Equations (1), (2), and (4) are valid if the concentration is measured over a surface region whose dimension along the OX axis is infinitesimally small. However, they are also valid for a finite part of the substrate surface, from $x - a$ to $x + a (x > x_0)$, to which the film atoms diffuse as a result of surface diffusion, provided that the

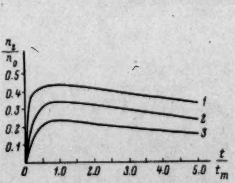

Fig. 1. Concentration at various times. z: 1) 1.1; 2) 1.4; 3) 2.

inequality

$$a \ll x - x_0. \tag{5}$$

is satisfied.

We now compare Eq. (2) with the experimental results, e.g., those of ref. 5. It follows from the data of refs. 5 and 7 that under these experimental conditions $x_0 = 2.5$ mm, $x = 3.5$ mm, $z = 1.4$, and $a \ll x - x_0$. With $D = 2.2 \cdot 10^{-6}$ cm/sec the experimental and theoretical functions $n_2(t)$ agree and the surface diffusion coefficient which we find by superimposing the experimental and theoretical curves corresponds to the surface diffusion coefficient given in ref. 5. Figure 2 shows the results calculated from Eq. (2) with the value found for D; also shown, with the same scale, are the experimental points from ref. 5. Comparison of these data reveals that the theoretical and experimental points agree within 15% over the entire range of t.

If, on the other hand, the substrate region within which the concentration $n_2(t)$ is determined has a finite width $2a$, so that inequality (5) does not hold, we must calculate the surface diffusion coefficient from

$$N_2 = \frac{n_0}{2}\left\{\int_{x-a}^{x+a}\left[\Phi\left(\frac{\xi + x_0}{\sqrt{2Dt}}\right) - \Phi\left(\frac{\xi - x_0}{\sqrt{2Dt}}\right)\right]d\xi\right\}, \tag{6}$$

where N_2 is the total number of film atoms which have diffused to the surface region between $x-a$ and $x+a$ by time t, and t, $\Phi(x)$ is the probability integral.

Evaluation of integral (6) through the use of

$$\Phi(z\sqrt{2}) = 1 - \operatorname{erf} cz, \quad \int_z^\infty \operatorname{erf} cy\,dy = \frac{1}{\sqrt{\pi}}e^{-z^2} - z \operatorname{erf} cz,$$

where

$$\operatorname{erf} cz = \frac{2}{\sqrt{\pi}}\int_z^\infty e^{-x^2}dx,$$

leads to

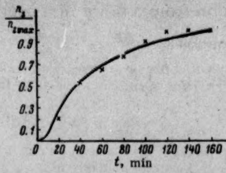

Fig. 2. Comparison of experimental and theoretical data. Solid curve) theoretical, according to Eq. (2) of the present work; points) experimental data of ref. 4.

$$\begin{aligned}\frac{N_2}{n_0} = \sqrt{\frac{Dt}{\pi}}\Bigg(&e^{-\frac{(x+a+x_0)^2}{4Dt}} - e^{-\frac{(x-a-x_0)^2}{4Dt}} + e^{-\frac{(x+a-x_0)^2}{4Dt}} - e^{-\frac{(x+a-x_0)^2}{4Dt}}\Bigg)\\ &+ \frac{1}{2}\Bigg[(x+a+x_0)\,\Phi\left(\frac{x+a+x_0}{\sqrt{2Dt}}\right)\\ &- (x-a+x_0)\,\Phi\left(\frac{x-a+x_0}{\sqrt{2Dt}}\right) + (x-a-x_0)\,\Phi\left(\frac{x-a-x_0}{\sqrt{2Dt}}\right)\\ &- (x+a-x_0)\,\Phi\left(\frac{x+a-x_0}{\sqrt{2Dt}}\right)\Bigg]\cdots\end{aligned} \tag{7}$$

Calculations show that when the values from ref. 5 ($x = 3.5$ mm, $x_0 = 2.5$ mm, $a = 0.2$ mm, and $D = 2.2 \cdot 10^{-6}$ cm^2/sec) are substituted into Eq. (7), the results agree with the results calculated from Eq. (2) within 1.0%.

We have thus shown that Eqs. (1) and (2) give an accurate description of the change in the concentration of film atoms due to surface diffusion. If the observation time is long the $n_2 = n_2(t)$ curve should display a maximum; in this case the surface diffusion coefficient can be determined from Eq. (3).

Ion focusing of an electron beam in deep melting of a metal

M. D. Gabovich, V. P. Kovalenko, O. A. Metallov,

O. K. Nazarenko, and S. K. Pats'ora

E. O. Paton Institute of Electric Welding,
Academy of Sciences of the Ukrainian SSR, Kiev

(Submitted December 24, 1973)
Zh. Tekh. Fiz., 44, 1556-1557 (July 1974)

Experiments with a model show that, the high-density electron beam in a welding channel cannot be attributed to ion focusing; this result is in disagreement with several explanations.

In several analyses[1-3] of the welding channel formed by an electron beam in a situation characterized by a dagger-shaped melting zone, it has been suggested that the electron beam experiences an additional compression due to ion focusing. In particular, it has been asserted[2] that the ion focusing reduces the beam diameter by an order of magnitude or more.

An attempt has been made to support this assumption by using the familiar theory of Davydov and Braginskii[4] and experimental data indicating the existence of a dense plasma in the welding channel.[3] However, this latter circumstance in fact renders the results of ref. 4 invalid for the case of electron-beam welding.

Estimates show that pronounced compression of an electron beam over some length L requires a field $E \approx 2dU_0/L^2$, where d is the initial beam diameter and U_0 is the accelerating voltage. With d = 0.1 cm, L = 1 cm, and $u_0 = 20$ keV, the field E should be $\approx 4 \cdot 10^3$ V/cm. Strong static fields of this magnitude would not be expected in the plasma formed by an electron welding beam. On the contrary, the experiments of ref. 3 indicate that these fields are weak.

Accordingly, the assumption that the beam compression in the welding channel results from ion focusing is open to question and would benefit from an experimental test.

We have therefore carried out an experimental study with a model in which the conditions correspond to those for an electron beam in a welding channel (Fig. 1). The electron beam 6 moving in a high vacuum is aligned along channel 7, drilled in a massive copper block 8. Channel 7 consists of two parts: a broad part (~ 1 mm in diameter, 2 cm long) and a narrow part (~ 0.3 mm in diameter and 1.2 cm long). Before the beam enters the channel its diameter is much larger than that of the narrow part of the channel; thus, in the absence of compression only a negligible part of the beam can reach collector 9. The air pressure in the channel can be adjusted over a broad range. The beam is deflected at a frequency of 50 Hz in order to prevent the channel walls from metlting in experiments in which the beam density is high. The beam passes through the channel in pulses much longer than the characteristic time for the plasma formation.

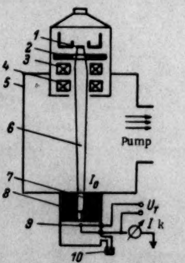

Fig. 1. The model apparatus. 1) Gun cathode; 2) anode; 3) focusing system; 4) deflecting system; 5) vacuum chamber; 6) electron welding beam; 7) channel; 8) water-cooled target; 9) collector-thermocouple; 10) gas heater.

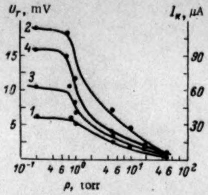

Fig. 2. Thermocouple emf and collector current as functions of the channel pressure. 1, 2) 20 keV, 70 mA; 3, 4) 10 keV, 3 mA. 1, 3) I_k; 2, 4) U_T.

Most of the measurements involved the determination of the electron-beam current to grounded collector 9 as a function of the channel pressure. If the beam were compressed at some pressure, there would be a corresponding increase in the collector current. To get more reliable measurement of the electron current reaching the collector we use a thermocouple to measure the relative power generated at the collector in addition to measuring the current in the collector circuit.

Figure 2 shows the results. If we assume that heat exchange between the collector and the chamber walls is not strongly influenced by the pressure under these experimental conditions (we check this point experimentally) we conclude that the current of the electron reaching the collector falls off monotonically with increasing pressure. No significant beam compression occurs. The current decrease can be explained on the basis of the scattering of the beam in the vapor–gas channel.

That this model is adequate for determining the role of ion focusing under the conditions actually prevailing in electron-beam melting is clear from the following considerations: The vapor pressure in the welding channel is known to reach 10^2-10^3 torr at a temperature of several thousand degrees.[1-5] The atomic density under these conditions should be roughly the same as in our experiments, in which the pressure and temperature are an order of magnitude lower. The lower gas temperature in the phototype apparatus and the relatively low beam velocity (in comparison with that under conditions of deeper melting) could only intensify the compression of the electron beam if ion focusing actually occurred under these conditions.

Accordingly, this direct experimental check with a model and the discussion show that ion focusing is not important for electron-beam welding.

N_2O-N_2 –He gasdynamic laser

Yu. I. Grin' and V. G. Testov
Institute of Radio Engineering and Electronics,
Academy of Sciences of the USSR, Moscow

(Submitted December 25, 1973)
Zh. Tekh. Fiz., 44, 1557-1558 (July 1974)

Lasing is observed in a shock-heated mixture of N_2O, N_2, and He issuing through a nozzle into vacuum. The optimum composition of the mixture is 10% N_2O, 20% N_2, and 70% He.

The onset of population inversion has been observed experimentally[1] in a ternary gas mixture of nitrous oxide, nitrogen, and helium preheated by a shock wave and subjected to adiabatic expansion through a wedge-shaped nozzle. Inversion takes place between the 00^01 and 10^00 levels of the N_2O molecule.

We have determined the optimum partial composition of the mixture for maximum amplification and observed lasing by placing mirrors that form an optical cavity at the nozzle exit.

The amplification of a weak signal is measured by means of the arrangement described in ref. 1. The results of the experiments show that the maximum inversion is realized in a mixture with the following composition: 10% N_2O, 20% N_2, and 70% He, at an incident-wave Mach number M = 2.8 (stagnation parameters: $T_0 \sim 1680°K$; $p_0 \sim 8$ atm). As Fig. 1 indicates, the gain for the given mixture is twice the value for a maixture[1] of 20% N_2O, 10% N_2, and 70% He. The position of the optical cavity is determined by measuring the gain along the flow; these measurements show that the gain decreases monotonically as the distance from the nozzle orifice is increased.

The cavity is placed at a distance of 15 mm from the nozzle orifice. The cavity consists of two mirrors with a diameter of 45 mm: one plane mirror 3 with an aperture diameter of 1 mm in the center (Fig. 2) and one concave mirror 2 with a radius of curvature of 990 mm. The reflecting surfaces of the mirrors are coated with an aluminum layer. The spacing of the mirrors is 27.1 cm. The cavity is located inside a supersonic chamber, from which the radiation is emitted through a KCl window 4.

Lasing is observed both independently of and simultaneously with the amplification measurement, making it possible to determine the temporal correlation between the amplification and lasing curves (Fig. 3). The arrangement for simultaneous measurement of amplification and lasing in a supersonic chamber equipped with four windows spaced at 90° angles is shown in Fig. 2.

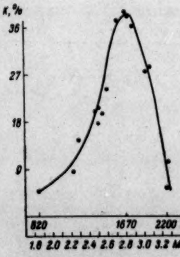

Fig. 1

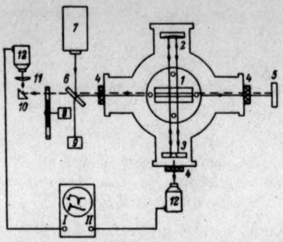

Fig. 2. Experimental arrangement. 1) Nozzle; 2) concave mirror; 3) plane mirror; 4) KCl mirror; 5) rotatable plane mirror; 6) opaque silicon mirror; 7) N_2O laser; 8) shutter; 9) thermocouple; 10) rotatable mirror; 11) lens; 12) detector (Ge–Au).

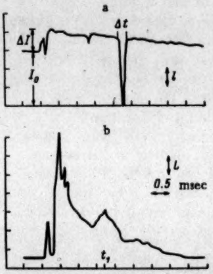

Fig. 3. Amplification (2) and lasing (b) oscillograms. I_0 and Δt are the amplitude and width of the calibration pulse.

Typical oscillograms of amplification and lasing signals are given in Fig. 3. The amplitude scale of the lasing and amplification signals is $L/l = 50$. It is seen that temporal correlation exists between the amplification and lasing signals. The lasing pulse is somewhat shorter than the amplification pulse. This is caused by the fact that the cavity losses at that time exceed the gain. the fact that the secondary maximum in the lasing pulse (time t_1) is possibly due to the dissociation process $N_2O \rightarrow N_2 + O$ and the resulting formation of vibrationally excited N_2 molecules, which transfer their energy to the N_2O molecules.[2,3]

Scattering of He^+ ions by the core of the He atom

Z. Z. Latypov and A. A. Shaporenko

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted January 8, 1974)
Zh. Tekh. Fiz., 44, 1559-1560 (July 1974)

The total cross sections for the following resonant processes involving electron capture and transfer of excitation energy are discussed as function of the collision energy: $He^+ + He \rightarrow He + He^+$, $He^*(2^1S) + He \rightarrow He + He^*(2^1S)$, and $He^*(2^3S) + He \rightarrow He + He^*(2^3S)$. The similar structures of these cross sections are explained on the basis of the scattering of the projectile particles by the core of the target atom.

We previously[1] detected a slight oscillation in the effective cross section for the resonant charge exchange

$$He^+ + He \rightarrow He + He^+ \tag{1}$$

over the collision-energy range 200-3200 eV. We attributed this structure to scattering of incident ions by the core of the target atom, predicted by theory.

According to the theory of ref. 2, the cross section for resonant electron transfer is

$$\sigma = 2\pi \int_0^\infty b \sin^2(\eta_g - \eta_u)\, db, \tag{2}$$

where b is the impact parameter and $\eta_g - \eta_u$ is the difference between the phase changes of the odd and even states. The functional dependence $\sigma(v)$ of cross section (2) on the collision velocity v is oscillatory if $\eta_g - \eta_u$ is independent of b. Two situations could be responsible for such a stationarity of the difference between the phase changes: a) the existence of an extremum in the difference $V_g - V_u$ between the levels of the even and odd states of the quasimolecule; b) scattering of the projectile by the core of the target ions. In this latter effect, the position of the classical turning point varies slowly as a function of the impact parameter when this parameter is small, giving rise to a weak functional dependence $\eta_g - \eta_u$ on b.

The He_2^+ quasimolecule has a series of pseudointersections between the ground-state $^2\Sigma g$ level, which dissociates into $He^+ + He(1s^2)$, and the excited-state $^2\Sigma g$ levels, which dissociate into $He^+ + He(1s, nl)$. Calculations[3] give R = 1.4 atomic units for the position of the lowest-lying pseudointersection, in agreement with the data from other sources. Accordingly, the difference $V_g - V_u$ for the He_2^+ ground states has an extremum if the even level of the ground state is adiabatic. Here the position of the extremum is given by R = 1.4 atomic units. However, it follows from ref. 3 that the parameters of the pseudointeractions of the $^2\Sigma_g$ levels are such that the He_2^+ system follows adiabatic levels at sufficiently high collision energies.

Using the method of ref. 4 to determine the difference $V_g - V_u$ from the experimental cross sections for resonant charge exchange, we analyzed the cross section for process (1). We assumed that the structure which we observed in this cross section is a regular oscillation. The results of this analysis show that the observed structure of cross section (1) could be due to a maximum in the difference $V_g - V_u$ at 1.5 eV with an internuclear distance of R = 5.8 atomic units. However, there is no such extremum in the difference between the levels of the He_2^+ ground states, so that this first possible explanation for the oscillation in the cross section must be discarded.

Hollstein et al.[5] have carried out an experimental study of the cross section for the resonant transfer of excitation energy in the collision of metastable He atoms with normal atoms,

$$He^*(2^1S) + He \rightarrow He + He^*(2^1S), \tag{3}$$
$$He^*(2^3S) + He \rightarrow He + He^*(2^3S) \tag{4}$$

over the energy range 150-2200 eV. They suggest that the structure which they have observed in the cross sections for processes (3) and (4) is probably due to an extremum in the difference $V_g - V_u$. Evans and Lane[6] have calculated the cross section for process (3) over the energy range $2 \cdot 10^{-2}$-10^3 eV in two manners: a) in the approximation of perturbed stationary states, making use of the most accurate adiabatic levels $^3\Sigma_u^+$ and $^3\Sigma_g^+$, which are given in the literature for He_2 for R > 1.3 atomic units; b) through the use of the adiabatic collisional $^3\Sigma_g^+$ level, constructed in the appropriate manner. The calculated cross sections are approximately equal to the experimental cross sections in magnitude, but the structures are markedly different. It follows that either the structures of experimental cross sections (3) are independent of the level difference $V_g - V_u$ at R > 1.3 atomic units, or the levels used in the calculations in ref. 6 are not sufficiently accurate.

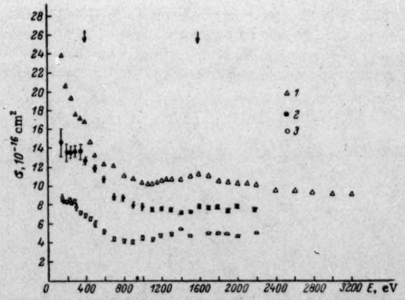

Fig. 1. Effective cross sections as functions of the collision energy. 1) Cross section for process (1) from ref. 1; 2) cross section for process (3) from ref. 5; 3) cross section for process (4) from ref. 5. The arrows show the maxima in the oscillatory components of the cross section for process (1).

Figure 1 shows the cross sections for process (1) according to ref. 1 and the cross sections for processes (3) and (4) according to ref. 5. The similarity observed among the cross-section structes for the three different processes implies a common origin of these structures. We believe that the structures observed in the cross sections for processes (1), (3), and (4) are due to scattering of the projectile particles by the cores of the target atoms, since it seems reasonable to assume a similarity between the scattering of He$^+$ ions and excited He* atoms by He atoms at small impact parameters. It follows from the amplitudes of the oscillation in the cross section for process (1) that, at the collision energies studied, the range in which the phase difference is stationary is governed by the values of the impact parameter: $0 < b \leqslant 1$ atomic unit. Accordingly, the levels of the He$^+$–He, He* (2^{1}S)–He, and He* (2^{3}S) systems must be similar for internuclear distances $R \leqslant 1$ atomic unit.

The authors thank V. V. Afrosimov and V. K. Nikulin for useful discussion.

Energy spectra of scattered particles in proton bombardment of a metal target

G. I. Zhabrev, V.A. Kurnaev, and V. G. Tel'kovskii

Moscow Engineering Physics Institute

(Submitted May 7, 1973; resubmitted January 2, 1974)
Zh. Tekh. Fiz., 44, 1560-1562 (July, 1974)

By measuring the fraction of neutrals in the scattered beam and the energy spectra of the ion components, the energy distributions of the total flux of reflected atomic particles can be obtained without dependence on charge. Spectra are found for bombardment of a Ni target at a glancing angle $\alpha = 15°$ by 20 keV protons. At a small scattering angle (20°) the spectral shape is in qualitative agreement with that calculated from multiple-scattering theory. At larger angles (55°) the spectral shape is characteristic of the single-scattering model.

In experiments on the reflection of medium energy light ions from a solid surface the charged components of the scattered beam have received the most attention. However, most of the particles leave the target surface as neutrals.[1] Various models of the scattering of light ions from a continuous medium[2,3] do not take account of electron exchange, which is responsible for the charge distribution of the reflected particles. Therefore, to make comparisons with experiment these theories require data on the total flux of the various charged components of the scattered beam.

For fixed angles of incidence and detection the energy distribution of the total flux of reflected particles $J^\Sigma(E)$ can be found from the spectrum of the i-th ion component $J^i(E)$ if $W^i(E)$ the probability of scattering of a particle of charge i from the target is known over the whole energy range of the spectrum for these angles. In this case

$$J^\Sigma(E) = \frac{J^i(E)}{W^i(E)}, \quad \sum_i W^i(E) = 1. \tag{1}$$

The fraction of neutrals in the scattered beam B_K can be determined by subtracting the charged components from the total flux. By using an integrating detector with counting efficiency K(E) independent of the charge of the particles the values obtained for various initial energies can be related to the probability $W^i(E)$ by the expression

$$B_K = 1 - \frac{\sum\limits_{i \neq 0} \int\limits_0^{E_K} J^i(E)\,K(E)\,dE}{\int\limits_0^{E_K} \frac{J^i(E)\,K(E)\,dE}{W^i(E)}}, \tag{2}$$

where E_K is the energy of the bombarding ions.

By measuring B_K and the energy spectra $J^i(E)$ for a sufficiently broad range of values of E_K and knowing K(E), $W^i(E)$ can be found by assuming that it is a smooth function. To do this we use successive approximations to find a $W^i(E)$ which satisfies Eq. (2) within the limits of accuracy of the experiment. Knowing $J^i(E)$ and $W^i(E)$ we use Eq. (1) to find the energy distribution of the total flux of reflected ions and atoms.

The method described has been used to study the small-angle scattering of hydrogen ions from a nickel target.[1] The energy spectra of the protons and negative hydrogen ions are determined by an electrostatic analyzer. A secondary emission detector with its entrance window covered with thin foil is used to determine the approximate fraction of neutrals in the scattered beam. The neutral and charged components of the beam are thus measured with the same efficiency. The instrument and the experimental procedure are described in detail in ref. 1, where data on the charge composition of the scattered beam are given.

Figure 1 shows the normalized proton energy spectra and the total flux of particles scattered at various angles φ relative to the initial direction of the beam. The spectra are obtained by bombarding a nickel target with 20 keV protons at a glancing angle $\alpha = 15°$. The figure also shows $W^{i=+1}$ found by the method described above for a scattering angle $\varphi = 20°$. The accuracy in finding $W^+(E)$ does not exceed 10% in the energy range from 5 to 30 keV. To this accuracy $W^+(E)$ for other values of φ does not differ from the curve given for $E/E_0 > 0.3$.

Figure 2 compares our spectra of $J^\Sigma(E)$ with those calculated by the single-scattering model, generalized to the case of oblique incidence of the particles on the target,[2] and by a theory[3] which treats the motion of particles in the medium by using the diffusion approximation in

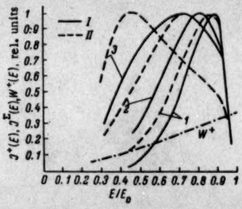

Fig. 1. Energy spectra of H^+ ions $J^+(E)$ and the total flux of particles $J^\Sigma(E)$ scattered at various angles in the proton bombardment of a nickel target at a glancing angle $\alpha = 15°$. W^+ is the probability of scattering particles in the form of protons. I) $J^+(E)$; II) $J^\Sigma(E)$; φ, deg: I) 20; II) 30; III) 55.

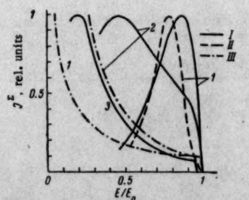

Fig. 2. Energy spectra of the total flux of scattered particles. I) experiment; II) multiple-scattering theory;[3] III) single-scattering theory;[2] α and φ in deg are respectively: 1) 15, 20; 2) 15, 55; 3) 45, 135 from data in ref. 5 for the bombardment of a nickel target by deuterons.

velocity space. In both cases a Coulomb interaction potential is assumed. Data on the slowing down power of Ni for protons obtained earlier in experiments with foils[4] are used in the calculations. For comparison the figure also shows a similar spectrum corresponding to the results of ref. 5 on the back scattering of deuterons.

While the single-scattering theory leads to an energy spectrum whose shape differs sharply from experiment at small angles, the spectrum corresponds more and more closely to this model at larger angles. For glancing angles, the shape of the distribution is adequately described by diffusion theory for the motion of the particles.[3] This confirms that multiple collisions have a definite effect in forming the beam scattered at small angles.

In conclusion the authors thank O. B. Firsov and V. M. Smirnov for helpful discussion.

Mode coupling in a double-anode discharge

Yu. G. Zakharenko and V. E. Privalov

D. I. Mendeleev All-Union Scientific-Research Institute of Metrology; Leningrad

(Submitted August 13, 1973; resubmitted October 25, 1973)
Zh. Tekh. Fiz., 44, 1562-1565 (July 1974)

Mode coupling is studied in a discharge with a common cathode and two anodes. The interaction of the fields generated by the striations in the two positive columns is investigated in detail. Within the locking range the system has features characteristic of any coupled oscillators. Field cancellation is observed. Striations appear in the cathode region as a result of interaction of the striations in the positive column.

Mode coupling in a glow discharge can lead to frequency pulling and locking and mode suppression.[1,2] It is of interest to investigate the interaction between modes in a coupled discharge establishing the possibility of controlling the mode parameters. We have investigated a discharge with a common cathode and two anodes. The discharge is produced in a T-shaped tube comprising a capillary (diameter 2.5 mm, length 200 mm) terminating at each end in a ring anode and a branch tube (diameter 6 mm, length 60 mm) perpendicular to the capillary, with an indirectly heated oxide cathode. To increase the reliability the measurements are performed on a series of such tubes with approximately the same parameters. The discharges are produced in inert gases and mixtures at pressures 1.5-2 torr and currents in the range 0.5-60 mA. The experimental method is described in detail in a previous paper.[3]

1. The results of measurements obtained with a discharge in one arm of the tube (voltage applied only to one anode) are similar to those observed previously.[1-3] Feedback oscillations at optimum ballast resistance (160 kΩ) disappear at currents above 1.3-1.5 mA. (Numerical values relate to a He — He mixture at a pressure 1.6 torr, ratio He : Ne = 7 : 1.) The frequency of the feedback mode in the initial stage[4] is 300 kHz. The depth of modulation of the discharge current increases with decreasing discharge current, and can reach 10% at appearance of the second harmonic. Striations appear in the positive column at currents 12-14 mA. The frequency generated by the traveling striations falls from 700 to 400 kHz when the discharge current is increased from 12 to 44 mA. The depth of modulation of the discharge current is about 1% and the amplitude of the striations increases with increasing discharge current (in the stated range). The striations are about 9 mm long and become several times more intense the closer they move to the anode. With increasing temperature, especially as the tube is warming up, the frequency at which the current is modulated by the striations increases and the region of existence of the striations is shifted towards higher currents.[5] Cathode oscillations appear when the discharge current is equal to the cathode current, but these are easily suppressed by controlling the cathode heating. No other modes are detected in this tube in operation with a single anode.

2. With discharges simultaneously in both arms of the tube, the current range corresponding to quenched contacts and the modes of the same type in the two discharges interact, with an effect on amplitudes, frequencies and phases. Feedback oscillations affect up to 1.8 mA; increasing the current in one of the arms by an order of magnitude or more does not affect the current at which these oscillations are suppressed; the frequency of the oscillations first increases slightly and then remains unchanged with increasing current. When the currents in both arms are equal the amplitude of the feedback oscillations is smallest. The initial-stage region of feedback oscillations in this tube is small, and the appearance of higher harmonics makes it difficult to investigate the interaction between these oscillations. The striations in the positive column interact over the entire range of currents. Measurements are simultaneously made with two shielded photomultipliers movable along the discharge and with antennas.[1-3] A signal is taken from a resistor connected to the cathode of the discharge tube and led to an SCh-8 spectrum analyzer and an S1-19 oscilloscope. Signals are also taken from both anodes through capacitors and fed to the inputs of an S1-18 dual-beam oscilloscope.

These results can be generalized in the following manner. It is known that traveling striations generate an electromagnetic field and modulate the discharge current. The striations can interact with the field that they themselves produce. The closer the currents in two arms, the more nearly identical become the parameters of the striations in both discharges. This results in a mutual pulling of the

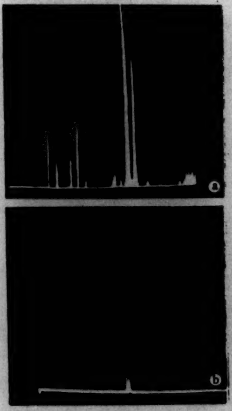

Fig. 1. Spectrum of interacting striations in a tube with two anodes. a) Interaction of striations outside pull-in zone; the two large-amplitude signals (on the right) correspond to striations in separate capillaries, signals of small amplitude are combination frequencies. b) Locking mode; oscillations of discharge current in separate capillaries in antiphase, 100-fold reduction of resultant field.

frequencies and locking (entrainment). When the radiation frequencies are not the same, combination frequencies are observed (Fig. 1a) and the amplitudes vary with varying frequency. In frequency locking the most stable state is one in which the currents in both arms are modulated in antiphase. In this case the amplitude of the restultant field falls sharply by two orders of magnitude compared with the field generated by the striations in a single discharge (Fig. 1b). It is found that the mode amplitudes are not governed by the expression

$$|\mathbf{A}_1+\mathbf{A}_2|=\sqrt{A_1^2+A_2^2+2A_1A_2\cos\varphi} \tag{1}$$

[A_i (i = 1, 2) denote the amplitudes, φ is the phase difference]. Varying the phase by means of the current causes the system to operate in the unstable region adjacent to the locking regime.[6]

In electronic oscillators[6,7] and ring lasers[8,9] the frequencies and amplitudes in the locking zone are described by the following expressions:

$$(\nu^2-\nu_1^2)(\nu_2^2-\nu^2)=\alpha\nu^4\sin\varphi, \tag{2}$$

$$A_1^2-A_2^2=B(\nu_2-\nu_1)+C, \tag{3}$$

where ν_i (i = 1, 2) are the frequencies of the oscillators, ν is the locking frequency, and α, B, and C are parameters.

Regarding our two discharges with traveling striations as two coupled oscillators, we find that their behavior is satisfactorily described by Eqs. (1) and (2). Figure 2 shows the results. The situation is similar to the case in which the difference between the intensities of the oppositely directed waves in a ring laser within the pull-in zone varies linearly with the current through the solenoid of the nonreciprocal element.[10]

As far as we are aware[6-9] locking occurs in the range of phase differences: $\pi/2 \le \varphi \le \pi/2$; the $\varphi = 0$ mode is stable. In the case of the interaction of the fields generated by traveling striations, the phase difference $\varphi = \pi$ is stable, as already mentioned. Symmetry about the stable value of φ is lost. For example, with 15 mA in each arm of the discharge, locking is observed in the phase interval $-0.3\pi \le \varphi \le 0.7\pi$. With increasing current the range of variation of phase within the pull-in zone is reduced. The amplitudes of the striations themselves vary much less when the fields interact in the pull-in zone. As a rule, minimum amplitude of the resultant field corresponds to maximum amplitude of the striations. With striations in a discharge in one arm, striking a discharge in the other arm produces striations at a current below the threshold value required for one arm alone. These striations are induced by the first striations, are phase-shifted relative to the first, are several times smaller in amplitude, and do not exhibit any signs of interaction.

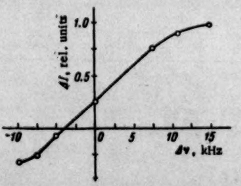

Fig. 2. Variation of intensity difference between fields generated by striations vs detuning ($\nu_1-\nu_2$) within limits of locking zone. Frequency is varied by varying the discharge current, ν_1 and ν_2 denote the frequencies of the radiation of the striations in each discharge separately.

We are unable to say very much concerning how the striations interact. The following can be said concerning the interaction of the fields generated by the traveling striations. Combination frequencies exist, the interaction becomes stronger the more the frequencies approach, and frequency pulling is observed. In the pull-in zone the interaction is determined by the relationships of the amplitudes and phases characteristic for locking. A stable reduction of the resultant amplitude in accordance with (1) is observed for $\varphi = \pi$. Clearly, the incomplete compensation of the fields is determined by the extent to which they are coherent, by the phase relationships, and by the amplitude difference (it should be remembered that the wavelength of this radiation is of the order of hundreds of meters).

Striations (of length 16 mm) appear in the cathode tube only with simultaneous discharges in both arms. This corresponds to a total current in the cathode tube of 30 mA and higher. The frequency is 150-180 kHz; the depth of modulation of the discharge current if 5-10%. The amplitude of the striations in the positive column decreases sharply. The striations in the cathode branch tube can be quenched by varying the heater current and applying a local magnetic field in the cathode region. We propose the following mechanism for the striations. The interaction of the striations in the positive column increases the instability of the discharge and oscillations of the head of the positive column result,[11] which stimulate striations in the branch tube. We note that striations do not appear in the branch tube at a definite total current, but for a definite combination of currents in the arms.

The present work leads to the following conclusions.

1. Modes of the same type interact in a discharge with two anodes (striations interact with striations, feedback oscillations with oscillations).

2. The interaction of the fields generated by the striations in the positive column in the locking zone can lead to the mutual compensation of the fields; it is difficult for the fields to add due to the character of the phase relationships in the locking zone; combination frequencies fixed in the discharge current and in the surrounding space are observed outside the limits of the locking zone.

3. The interaction of the striations in the positive column helps to suppress the striations in the cathode branch tube.

We thank A. A. Zaitsev, L. A. Sen, and L. D. Tsendin for useful discussion.

Theoretical and mathematical physics

Fundamentals of heat-pipe theory and design

M. M. Levitan and T. L. Perel'man
Institute of Heat and Mass Transfer,
Academy of Sciences of the Belorussian SSR, Minsk

(Submitted July 18, 1973; resubmitted November 15, 1973)
Zh. Tekh. Fiz., 44, 1569-1591 (August 1974)

The problem of heat-pipe design is treated rigorously. Heat and mass transfer in the jacket and cavity of a heat pipe are considered. Coupling conditions at the internal surface of the jacket are analyzed in detail. As applied to high-temperature heat pipes in which alkali metals are used as the heat-transfer agent the problem is formulated with the inclusion of chemical transformations of the vapors of those transfer agents. For proper heat-pipe optimization operating conditions are set up which include the reaction of the fluxes of vaporizing and condensing materials at the phase-transition surface.

Many problems of heat transfer which arise in modern technological fields such as atomic power, space technology, etc., cannot be solved without using design principles based on new, high-efficiency structural elements for power systems. One such element is the heat pipe – a device for the transfer of large amounts of thermal energy with minimal temperature drop.[1] Devised in 1963[1)] in connection with certain problems in space power, heat pipes have since attracted the attention of many designers in heat transfer because of their unique properties. For example, a heat pipe can transfer a very large amount of thermal energy with an insignificant drop in temperature over its length, it can bring about the conversion of thermal fluxes, it can create isothermal conditions over relatively large areas, and it can operate under conditions of weightlessness; per unit weight a heat pipe has a thermal conductivity several times greater than any solid heat conductor; depending on the heat-transfer agent, a heat pipe can operate from cryogenic temperatures to 2000°C These properties, in combination with structural simplicity, insignificant weight, absence of moving parts, and total self-regulation, ensure diverse application of heat pipes in atomic power, space technology, experimental technology, etc.

Past experimental and theoretical studies of heat pipes have been directed chiefly toward optimal designs for heat pipes and an explanation of their basic characteristics; successful application of heat pipes is impossible without information about the maximum value of thermal power at the ends of the pipe which is transportable along the pipe, about the temperature drop, and about operating resources.

The problem of heat-pipe theory and design is presently the subject of a considerable number of publications. In the main, however, these papers are qualitative in nature. This fact is evident from the limited assumptions that are used and the resulting incomplete formulation of the problem. Suffice it to say that thus far all results of heat-pipe calculations refer only to long pipes and only to a single kind of condition at the external surface of the heat pipe, where the heat fluxes in the vaporization and condensation zones are constant.

There are two papers[3,4] which are highly important for the clarification of the fundamental principles of heat-pipe design. In the first, an outline of the problem and a method for heat-pipe design are given in general terms; in the second, the operating conditions are given in comparatively clear form. Even in these papers, however, the formulation of the problem is approximate and leaves out a number of real effects, is based on intuitive considerations, and does not yield even in principle an accurate calculation for a heat pipe over a broad range of parameter values and for various modes of operation. This is not to say that individual design elements, for example the calculation of laminar motion of an incompressible vapor in long heat pipes[5] and the calculation of condensate motion along certain types of capillary structures,[6–9] are not useful; the results can indeed be used in calculations within a systematic theory for heat pipes.

Recent experimental data have show that in certain modes of operation heat pipes can have a significant thermal resistance, which cannot be attributed to vapor compressibility. The results of vapor temperature measurements in the cavity of a sodium heat pipe represent a particular case.[10]

To construct a theory that can be used to determine the thermal resistance of a pipe, including short heat pipes, and to describe the heat exchange between a pipe and an external medium with a strong nonuniformity in the longitudinal direction, it is necessary to carry out an analysis in which all the basic processes of heat and mass transfer in the jacket and in the cavity of the pipe are considered together, i.e., a formulation of the "combined" problem in the sense of ref. 11. The construction of a systematic theory for heat pipes and the development of design methods are the subjects of the present paper.

COMBINED DESIGN PROBLEM FOR HEAT PIPES

1. The different modes of heat-pipe operation complicate the construction of a systematic theory for these devices. A change in the operating conditions of a heat pipe can change the nature of the transport processes. For example, depending on thermal load and operating temperature, the vapor motion in the pipe cavity can be laminar or turbulent, and the vapor itself can be compressible or incompressible. Transport in the jacket can be complicated by boiling of the heat-transfer agent in the wick and partial drying of the latter. Hence, it is necessary to delineate the conditions that pertain to a given mode of operation of a heat pipe.

As is well known, the nature of the vapor flow depends on the values of the Reynolds number Re and the Mach number M (Fig. 1). We define these parameters on the basis of the average vapor velocity in the adiabatic zone:

$$\mathrm{Re}=\frac{Q}{\pi R^2}\frac{R}{L\eta_{\mathrm{v}}};\quad \mathrm{M}=\frac{Q}{\pi R^2}\frac{1}{LP_{\mathrm{v}}}\sqrt{\frac{c_{\mathrm{v}}}{c_p}\frac{R^*}{\mu}T_{\mathrm{v}}}, \tag{1}$$

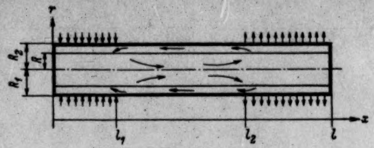

Fig. 1. Diagram of a heat pipe.

where Q is the heat flux transported along the pipe; L is the latent heat of vaporization; η_V is the vapor viscosity; μ is the molecular weight of the vapor; R^* is the universal gas constant; c_p and c_V are the specific heats of the vapor at constant pressure and constant volume; p_V and T_V are the pressure and temperature of the vapor at the end of the vaporization zone. Unfortunately, there is no reliable experimental information in the literature concerning the critical Reynolds number Re_{cr}, for which the transition from laminar flow to turbulent flow occurs in pipes with an inlet and outlet. For this reason, we take Re_{cr} to be the value for flow in an infinitely long pipe, $Re_{cr} = 1250$. With compressibility, matters are somewhat simpler. Since the fundamental quantity needed for heat-pipe calculations is the vapor pressure (see Sec. 3, below) and the ratio between the pressure drop resulting from the motion and the total vapor pressure is proportional to the square of the Mach number M, one can construct some arbitrary boundary by assuming, for example, that motion with $M < 0.1$ is motion of an incompressible vapor.

Using Eq. (1) and the remarks made above with respect to the critical values of Re and M, one can distinguish regions in the thermal-load, temperature plane for a given heat pipe, in which definite modes of vapor flow are realized (Fig. 2).

2. The structure of the combined problem in heat-pipe design does not depend on the mode of operation. The differences appear only in the individual equations, which describe transport processes that undergo a change in the transition to a new mode of operation. We shall discuss the formulation of the combined design problem for heat pipes operating with laminar flow of an incompressible vapor. The generalization of this problem to other modes of operation will be discussed in the second part of this paper.

Thus, the motion of the vapor is described by the system

$$\frac{\partial r v_x}{\partial x}+\frac{\partial r v_r}{\partial r}=0, \tag{2}$$

$$\rho_V v_x \frac{\partial v_x}{\partial x}+\rho_V v_r \frac{\partial v_x}{\partial r}=-\frac{\partial P_V}{\partial x}+\eta_V\left(\frac{\partial^2 v_x}{\partial x^2}+\frac{\partial^2 v_x}{\partial r^2}+\frac{1}{r}\frac{\partial v_x}{\partial r}\right), \tag{3}$$

$$\rho_V v_x \frac{\partial v_r}{\partial x}+\rho_V v_r \frac{\partial v_r}{\partial r}=-\frac{\partial P_V}{\partial r}+\eta_V\left(\frac{\partial^2 v_r}{\partial x^2}+\frac{\partial^2 v_r}{\partial r^2}+\frac{1}{r}\frac{\partial v_r}{\partial r}-\frac{v_r}{r^2}\right), \tag{4}$$

$$\rho_V c_{pV} v_x \frac{\partial T_V}{\partial x}+\rho_V c_{pV} v_r \frac{\partial T_V}{\partial r}=\lambda_V\left(\frac{\partial^2 T_V}{\partial x^2}+\frac{\partial^2 T_V}{\partial r^2}+\frac{1}{r}\frac{\partial T_V}{\partial r}\right), \tag{5}$$

where λ_V is the coefficient of thermal conductivity of the vapor; T_V is the vapor temperature v_x and v_r are the components of the vapor velocity, and ρ_V is the vapor density.

Transport processes in the pipe jacket include heat transport and filtration of the heat-transfer agent through the capillary structure. The pipe jacket consists of two layers: the casing and the capillary structure saturated with the heat-transfer agent. The propagation of heat along the casing of a heat pipe is given by

$$\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial r^2}+\frac{1}{r}\frac{\partial T}{\partial r}=0, \tag{6}$$

where T is the jacket temperature.

Matters are considerably more complicated for the energy transport equation in the capillary structure. This is the case because the temperature of the heat-transfer agent flowing through the pores of the wick can be different from the temperature of the skeleton of the capillary structure; the description of energy transport for this case requires a system of two coupled equations, one for the heat-transfer agent and the other for the skeleton of the capillary structure. However, if the coefficients of thermal conductivity of the heat-transfer agent and the skeleton material are similar, as happens in high-temperature heat pipes, the temperature of the heat-transfer agent is almost the same as the temperature of the skeleton, and the equation for energy transport in the capillary structure can be written

$$\frac{\partial}{\partial x}\left[r\left(\tau_{l_x} h_l-\lambda'_x\frac{\partial T}{\partial x}\right)\right]+\frac{\partial}{\partial r}\left[r\left(\tau_{l_r} h_l-\lambda'_r\frac{\partial T}{\partial r}\right)\right]=0, \tag{7}$$

where λ'_x and λ'_r are the coefficients of thermal conductivity for the capillary structure skeleton and heat-transfer agent system; τ_{l_x} and τ_{l_r} are the components of the flux density vector for the liquid; h_l is the enthalpy of the liquid.

It is convenient to take as a base line for measuring the enthalpy the enthalpy of the condensed heat-transfer agent in the state in which its temperature is equal to the characteristic heat-pipe temperature T_p and its pressure is equal to the pressure of the saturated vapor at the temperature T_p. Then the enthalpies of the vapor and liquid are

$$\left.\begin{aligned} h_V &= L+c_{pV}(T_V-T_p), \\ h_l &= c_{pV}(T-T_p), \end{aligned}\right\} \tag{8}$$

where L is the latent heat of vaporization at the temperature T_p.

The specific form of the filtration equation for the

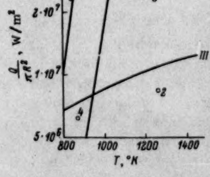

Fig. 2. Regions with various modes of vapor flow in the cavity of a heat pipe (Na, R = 1 cm). 1, 3) Regions of turbulent vapor flow; 2, 4) regions of laminar vapor flow; 1, 2) regions of incompressible vapor; 3, 4) regions of compressible vapor; 5) ultrasonic region. I) M = 1; II) M = 0.1; III) R = 1 cm.

heat-transfer agent depends on the type of capillary structure used in the heat pipe and will be discussed in the second part.

Formulation of the combined problem also implies the formulation of boundary conditions and coupling conditions. The boundary conditions at the external surface of a heat pipe are determined by the specific conditions for heat exchange between the heat pipe and the environment. For definiteness we consider the case in which these reduce to a given heat flux through this surface. If necessary, the formulation of the problem can easily be extended to other conditions. We also assume there is no heat exchange through the ends of the pipe. We denote the heat flux density through the external surface of the heat pipe at $r = R_2$ by $q_2(x)$. With these assumptions a stationary mode of heat pipe operation is possible only when $\int_0^l q_2(x)dx = 0$.

As a rule the thickness of the casing of a heat pipe is considerably smaller than the thickness of the capillary structure, and redistribution of heat along the former can be neglected. In this case, the equation for thermal conductivity in the casing is easily integrated and one obtains the following relation between the thermal fluxes through the external and internal surfaces of the pipe casing, $q_1 = q_2R_2/R_1$. If it is impossible to neglect redistribution of heat along the casing Eqs. (6) and (7) must be solved simultaneously and matched at $r = R_1$.

We now consider conditions at the internal surface of the capillary structure at $r = R$. One can show that for all types of capillary structure the effect of condensate motion at the vapor–liquid interface on vapor motion can be neglected; it can be assumed the vapor velocity component tangential to the surface is zero on the entire surface of the cavity of the heat pipe. Furthermore, conditions must be written for this surface which couple the equations of thermal conductivity in the vapor and in the capillary structure as well as an expression for the vapor velocity component normal to the surface.

It should be noted that at high loading phase transitions in a heat pipe are of a nonequilibrium nature. This is expressed by the fact that the vapor temperature and pressure at the phase transition surface are different from the temperature of the liquid surface and the pressure of saturated vapor at that temperature. The conditions which relate the vapor and liquid parameters in this case are obtained by formulation of the balance equations at the phase transition surface for various moments of the vapor molecule distribution function.[12] For example, by balancing the first moments of the distribution function we obtain an expression for the vaporization rate:

$$\tau = \frac{2\alpha}{2-\alpha}\sqrt{\frac{\mu}{2\pi R^*}}\left[\frac{P_V}{\sqrt{T_V}} - \frac{P(T_0)}{\sqrt{T_0}}\right], \tag{9}$$

where α is the condensation coefficient; T_0 is the temperature of the surface of the liquid; $P(T_0)$ is the saturated vapor pressure at temperature T_0. If a phase transition exists we neglect the transport of energy between the vapor and liquid because of the low-thermal conductivity of the vapor, i.e., we say

$$\left.\frac{\partial T_V}{\partial r}\right|_{r=R} = 0, \tag{10}$$

then the condition for continuity of energy flow through the phase transition surface can then be written as

$$\tau L = -\lambda_r' \left.\frac{\partial T}{\partial r}\right|_{r=R}. \tag{11}$$

Equations (9)-(11) are also the desired conditions for regions of the surface $r = R$, where condensation occurs. Where vaporization occurs Eq. (10) is replaced by a relation which, being a consequence of energy balance and the condition (10), relate directly the temperatures of the vapor and liquid at the vaporization surface. Thus we can take account of the variation along the vaporization zone of the temperature of vapor injected into the cavity of the pipe; this is associated with variation along this zone of the temperature of the surface $r = R$ or of the rate of vaporization. This condition is obtained from the balance for second moments of the distribution function and has the form

$$T_V = T_0\left[1 + \sqrt{\frac{2\pi R^* T_0}{\mu}}\frac{\tau}{8P(T_0)[\alpha + \beta(1-\alpha)]}, \tag{12}$$

where β is the accommodation coefficient.

Although Eq. (12) indicates that $(T_V - T_0)/T_0$ is of the order of the ratio between the vaporization rate and the velocity of sound it should be noted that nevertheless the absolute value of the temperature discontinuity at the phase transition surface, $T_V - T_0$, can amount to a significant part, if not the main part, of the temperature drop between the vaporization and condensation zones of a heat pipe.

Equations (9) and (12) must be refined to apply to phase transitions in heat pipes. Phase transitions do not occur over the entire surface $r = R$, but only over a portion of it equal to the total area of the menisci. We pick out some element of the channel surface. We designate its area by s and the total area of the menisci in this element at which phase transition occurs by s_{tr}; we then introduce the dimensionless quantity $\varepsilon = s_{tr}/s$. Using this definition we can write a complete set of boundary conditions and coupling conditions for (2)-(5) and (7):

$$v_x|_{x=0} = v_r|_{x=0} = v_x|_{x=l} = v_r|_{x=l} = v_x|_{r=R} = 0, \tag{13}$$

$$\left.\frac{\partial T_V}{\partial x}\right|_{x=0} = \left.\frac{\partial T_V}{\partial x}\right|_{x=l} = 0;\ \left.\frac{\partial T}{\partial x}\right|_{x=0} = \left.\frac{\partial T}{\partial x}\right|_{x=l} = 0, \tag{14}$$

$$-\lambda_r' \left.\frac{\partial T}{\partial r}\right|_{r=R_1} = q_1, \tag{15}$$

$$L\tau|_{r=R} = -\lambda_r' \left.\frac{\partial T}{\partial r}\right|_{r=R};\ \tau|_{r=R} = \frac{2\alpha\varepsilon}{2-\alpha}\sqrt{\frac{\mu}{2\pi R^*}}\left[\frac{P_V}{\sqrt{T_V}} - \frac{P(T_0)}{\sqrt{T_0}}\right]_{r=R}, \tag{16}$$

$$T_V|_{r=R} = T_0\left[1 + \sqrt{\frac{2\pi R^* T_0}{\mu}}\frac{\tau}{8\varepsilon P(T_0)[\alpha + \beta(1-\alpha)]} \text{ for } \tau|_{r=R} < 0, \tag{17}$$

$$\left.\frac{\partial T_V}{\partial r}\right|_{r=R} = 0 \qquad \text{for } \tau_{r=R} > 0, \tag{18}$$

$$\lambda_r' \left.\frac{\partial T}{r}\right|_{r=R} = \lambda_V \left.\frac{\partial T_V}{\partial r}\right|_{r=R} \text{ for } \tau|_{r=R} = 0. \tag{19}$$

In this formulation, there is no characteristic value of the temperature and therefore the solution of the problem will be determined except for the value of the temperature at any point of the heat pipe.

We now consider certain limiting cases. If the following two conditions are satisfied: a) the temperature drop along the wick of the thermal pipe is of the same order of magnitude as the drop across it, and b) $R_1 - R \ll l$, heat transport through the heat-pipe jacket can be neglected along the x axis. Then $q_0 = q_2R_2/R$ and the problem reduces to the equation system (2)-(5) with the conditions (13), (14), (16)-(18), where it is assumed, however, that

$$-\lambda_r' \frac{\partial T}{\partial r}\Big|_{r=R} = q_0. \tag{20}$$

For small thermal loading, for which we can neglect the temperature jumps in vaporization and condensation, the problem allows further simplification; Eq. (5) for the thermal conductivity in the vapor need not be included. In this case the problem reduces to the equation system (2)-(4), with the boundary conditions (13) and

$$\tau|_{r=R} = \frac{q_0}{L}. \tag{21}$$

We note that all attempts to calculate vapor motion to date have applied to this problem.

The value of the parameter ε is determined by such factors as the surface porosity of the wick, ε_W, the extent to which it is filled with condensate, the type of capillary structure, etc. In addition, ε can depend on the thermal loading since partial drying of the wick can occur at high loading.[10] Because the phase transition occurs over the entire surface of the channel at r = R in the condensation zone, ε = 1 there. In the vaporization zone, when the capillary structure is completely filled, $\varepsilon = \varepsilon_W$. We note further that with partial drying of the wick, ε in the vaporization zone will be a function of distance along the heat pipe.

3. An arbitrary solution of the combined problem of heat-pipe design formulated in the preceding section is not actually realized in a heat pipe, nor is an exact solution with specific boundary conditions realized. Only that solution is realized which satisfies the operating condition for the heat pipe. By selecting from the multiplicity of all solutions those which are actually realized in the heat pipe the operating condition for heat pipes becomes a fundamental relation for determining the limiting characteristics of heat pipes and for solving the optimization problem. Various versions are encountered[3,4,13] but all are of a qualitative nature. This is evidenced by the fact that while there is a limit on the magnitude of the total pressure drop in the heat pipe, these solutions do not indicate between what points on the phase interface this pressure drop must be determined.

A rigorous operating condition for a heat pipe, free of this deficiency, has been obtained by the present authors[14] in the following manner. The condition for the conservation of the momentum component normal to the vapor–liquid interface with a phase transition present has the form

$$P_v - P_l + \rho_v v_r^2 - \rho_l u_r^2 = \sigma K, \tag{22}$$

where u is the velocity of the liquid; σ is the coefficient of surface tension; K is twice the average curvature of the liquid surface. With the help of Eq. (22), for any two points x_1 and x_2 on the surface of the liquid in the vaporization and condensation zones we can write

$$(P_{v1} - P_{v2}) - (P_{l1} - P_{l2}) + (\rho_{v1}v_{r1}^2 - \rho_{l1}u_{r1}^2) - (\rho_{v2}v_{r2}^2 - \rho_{l2}u_{r2}^2) = \sigma_1 K_1 - \sigma_2 K_2. \tag{23}$$

This relation determines the value of the capillary pressure between the two points needed for the realization of given modes of vapor and liquid flow. It is analogous to a condition given previously.[4]

Normal operation of a heat pipe is possible only when the capillary pressure given by Eq. (23) does not exceed the maximum value of capillary pressure, $P_{K\max}$ created by the heat-pipe wick. Since this requirement must be satisfied for any two points in the vaporization and condensation zones, it must be satisfied for the points at which the left side of Eq. (23) has a maximum. As a result, the operating condition for a heat pipe takes the form

$$\max_{\substack{0\leqslant x_1\leqslant l\\ 0\leqslant x_2\leqslant l}} [(P_{v1} - P_{v2}) - (P_{l1} - P_{l2}) + (\rho_{v1}v_{r1}^2 - \rho_{l1}u_{r1}^2) - (\rho_{v2}v_{r2}^2 - \rho_{l2}u_{r2}^2)] \leqslant P_{K\max}. \tag{24}$$

The points corresponding to the maximum of the left side of inequality (24) considered as a function of the two variables x_1 and x_2 are also points of greatest and least curvature of menisci in the vaporization and condensation zones. Thus, the condition (24) clearly denotes the points for which a pressure balance must be formulated and indicates a procedure for determining their location. It is thus significantly different from the operating condition for a heat-pipe proposed previously[3,4,13] and which resembles Eq. (23). A second property of the condition (24) is that the reaction between the flows of vaporizing and condensing material at the phase transition surface is taken into account. This phenomenon is only significant at very high phase transition rates and for significant transformation of the thermal fluxes through the jacket of the heat pipe in the vaporization and condensation zones. As a rule this effect can be neglected in heat-pipe design. The condition (24) then takes the simpler form

$$\max_{\substack{0\leqslant x_1\leqslant l\\ 0\leqslant x_2\leqslant l}} [(P_{v1} - P_{v2}) - (P_{l1} - P_{l2})] \leqslant P_{K\max}. \tag{25}$$

A first attempt has been made to include the reaction of vaporizing material at the phase transition surface in the analysis of heat-pipe start-up.[15]

The maximum capillary pressure $P_{K\max}$ in condition (24) is determined primarily by the capillary structure and can be determined easily for a given type of structure. For example, in the case of a wick with cylindrical pores of radius *a*, the pressure $P_{K\max}$ is given by (σ is the wetting angle of the edge)

$$P_{K\max} = \frac{2\sigma}{a}\cos\delta - \frac{\sigma}{R}, \tag{26}$$

and for a wick in the form of open channels of width *a* on the internal surface of the casing of the heat pipe, it is given by

$$P_{K\max} = \frac{\sigma}{a}\cos\delta - \frac{\sigma}{R}. \tag{27}$$

NUMERICAL SOLUTION OF THE HEAT-PIPE DESIGN PROBLEM

1. Because of the complicated nonlinear nature of the problem it is necessary to set up an iterative procedure for the numerical solution. The most reasonable iterative procedure would be numerical simulation of the output of a heat pipe in a stationary operating mode. A necessary, but not sufficient, condition for the convergence of this process is the requirement of spatial stability in each iteration. As shown in the course of the calculations, satisfaction of this requirement for simultaneous solution of the entire system of equations describing the processes occurring in a heat pipe is difficult because of the nonlinear coupling conditions.

However, spatial stability can be achieved if the iteration is set up on the principle of sequential solution of the problems of vapor motion in the cavity, heat transport through the heat-pipe jacket, and motion of the heat-transfer agent along the capillary structure. Since all these problems are interrelated, in the solution of each all quantities related to the other problems are taken from their solutions in a previous iteration. Thus, in the solution of the problem of vapor motion in the channel the surface temperature T_0 and the energy flux τh_V through this surface must be taken from the solution in the previous iteraction of the problem of thermal conductivity in the heat-pipe jacket. By sequential solution of the specified problems the demands on the core storage of the computer are reduced considerably and spatial stability is achieved. Further, it is possible to make maximum use of previously published results in solving the problem. We now discuss methods of solution in greater detail. We also describe variations of the problems associated with different modes of heat-pipe operation.

2. Problem of vapor motion in a heat-pipe cavity. For given q_0 and T_0, Eqs. (2)-(4) do not depend on Eq. (5); therefore they can be solved individually. We designate by v_{r_0} a characteristic value for the velocity component v_r in the heat pipe. One can take the quantity $Q/2\pi R l_1 \rho_V$ as v_{r_0}. If we take as a characteristic value of the velocity component $v_{x_0} = v_{r_0} l/R$, the system of equations of motion in the dimensionless variables

$$v'_r=\frac{v_r}{v_{r_0}};\quad v'_x=\frac{v_x}{v_{x_0}};\quad P'=\frac{P}{\rho_V v^2_{x_0}};\quad x'=\frac{x}{l};\quad r'=\frac{r}{R} \tag{28}$$

reduces to the form (primes omitted)

$$\left.\begin{gathered}\frac{\partial r v_x}{\partial x}+\frac{\partial r v_r}{\partial r}=0,\\ v_x\frac{\partial v_x}{\partial r}+v_r\frac{\partial v_x}{\partial r}=-\frac{\partial P}{\partial x}+\frac{\mathrm{Re}_{r_0}}{\mathrm{Re}_0^2}\frac{\partial^2 v_x}{\partial x^2}+\frac{1}{\mathrm{Re}_{r_0}}\left(\frac{\partial^2 v_x}{\partial r^2}+\frac{1}{r}\frac{\partial v_x}{\partial r}\right),\\ \frac{\mathrm{Re}^2_{r_0}}{\mathrm{Re}_0^2}\left(v_x\frac{\partial v_r}{\partial x}+v_r\frac{\partial v_r}{\partial r}\right)=-\frac{\partial P}{\partial r}+\frac{\mathrm{Re}^3_{r_0}}{\mathrm{Re}_0^4}\frac{\partial^2 v_r}{\partial x^2}\\ +\frac{\mathrm{Re}_{r_0}}{\mathrm{Re}_0^2}\left(\frac{\partial^2 v_r}{\partial r^2}+\frac{1}{r}\frac{\partial v_r}{\partial r}-\frac{v_r}{r^2}\right),\end{gathered}\right\} \tag{29}$$

where

$$\mathrm{Re}_0=\frac{v_{x_0}R}{\nu_V},\quad \mathrm{Re}_{r_0}=\frac{v_{r_0}R}{\nu_V}.$$

The boundary conditions for this equation system are

$$v_x|_{x=0}=v_r|_{x=0}=v_x|_{x=1}=v_r|_{x=1}=0, \tag{30}$$

$$v_x|_{r=1}=0;\quad v_r|_{r=1}=\frac{q_0}{L\rho_V v_{r_0}}=\varphi(x). \tag{31}$$

In addition, from symmetry considerations we have

$$\left.\frac{\partial v_x}{\partial r}\right|_{r=0}=0;\quad v_r|_{r=0}=0. \tag{32}$$

The most suitable numerical method for solving the problem (28)-(32) is the method of finite differences. Up until now, it has received rather wide acceptance for the calculation of viscous fluid flow. In the main two-dimensional problems in plane geometry have been solved by this method thus far. The algorithms developed for the solution of these problems can be modified for the solution of problems with cylindrical symmetry. In particular, an algorithm for the solution of the problem (28)-(32) by finite differences has been developed by the present authors. The economy of this algorithm, based on an implicit scheme of variable directions, makes it realizable on the Minsk-22 computer. We cannot discuss this algorithm here in detail because of the lack of space. We only point out that the scheme for solution is similar in many respects to the scheme for the case of Cartesian coordinates.[16] The equation system (29) is written in the form of a system of two equations with respect to the flow function ψ and the vorticity function ξ. The equations for ψ and ξ are solved alternately using approximate boundary conditions[17] for ξ. The equation for ξ is approximated in accordance with the scheme of Allen.[18]

The solution of the problem of vapor motion in long heat pipes by finite differences is difficult because of computational instabilities at large values of 1/R. In addition, to obtain the required accuracy as the length of the heat pipe increases it is necessary to reduce the spatial steps along the x axis and, to a lesser extent, along the r axis. The resulting increase in the number of mesh points is limited by the capacity of computer memory core, the computational labor, and the computing time. Therefore, a need arises for another method of solution of the problem (28)-(32) for the case of long heat pipes.

The entire region of vapor flow in a long pipe can be subdivided into several parts in accordance with the rate of change of the flow characteristics in the x direction. Portions of the cavity near the ends of the pipe, and also near the boundaries l_1, l_2 between zones, are distinguished by a rapid readjustment of the flow. The length of each of these sections is of the order of several radii and the flow in these can be investigated with (29). In other sections of the pipe cavity the nature of the flow varies slowly in the direction of the x axis; in these cases, the vapor flow can be calculated on the basis of the simpler system of equations for a boundary layer. This system is obtained by taking the limit $\mathrm{Re}_0/\mathrm{Re}_{r_0} \to \infty$ in (29) and has the form

$$\frac{\partial r v_x}{\partial x}+\frac{\partial r v_r}{\partial r}=0, \tag{33}$$

$$v_x\frac{\partial v_x}{\partial x}+v_r\frac{\partial v_x}{\partial r}=-\frac{\partial P}{\partial x}+\frac{1}{\mathrm{Re}_{r_0}}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_x}{\partial r}\right), \tag{34}$$

$$\frac{\partial P}{\partial r}=0. \tag{35}$$

Solutions of the system of Navier–Stokes equations in the transition sections of the heat pipe are then matched to solutions of Eqs. (33)-(35) in the other sections of the cavity. As in the case of short heat pipes, the former can be obtained by finite differences. The matching boundary conditions for Eqs. (29) and the boundary-layer equations have been investigated.[19]

An approximate solution of Eqs. (33)-(35) with boundary conditions (31) and (32) can be found through the Karman–Polhausen integral relations. Assuming $v_r|_{r=1} =$ const in Eq. (31), Busse made the first such calculation as applied to heat pipes.[5] Of the earlier work on the calculation of fluid flow in a permeable pipe based on Eqs. (33)-(35), one paper is of particular interest.[20] We extend the results of this work to the case $v_r|_{r=1} = \varphi(x) \neq \text{const}$.

From a comparison of earlier results,[5,20] it follows that in solving Eqs. (33)-(35) by the Karman–Polhausen method the velocity profile v_x must be approximated by a polynomial of at least the sixth power in r. Symmetry considerations dictate that it can only contain even powers of r:

$$v_x(x,\ r) = a_0(x) + a_2(x) r^2 + a_4(x) r^4 + a_6(x) r^6. \tag{36}$$

Since it is impossible to satisfy Eqs. (33)-(35) exactly with the polynomial (36), we only require exact satisfaction of the boundary conditions (31) and (32), of Eqs. (33) and (34) averaged over the cross section of the pipe cavity, and of the relations

$$\left.\frac{\partial P}{\partial x}\right|_{r=0} = \left.\frac{\partial P}{\partial x}\right|_{r=1} = \frac{d\bar{P}}{dx} \tag{37}$$

because of (35), where the derivatives at r = 0 and r = 1 are determined with the help of Eq. (34) and the bar denotes the average:

$$\bar{P} = 2\int_0^1 Pr dr.$$

After some simple transformations we obtain the following system of equations for the coefficients of the polynomial and for P:

$$\left.\begin{aligned}
&a_0 + a_2 + a_4 + a_6 = 0,\\
&\frac{d}{dx}\left(a_0 + \frac{a_2}{2} + \frac{a_4}{3} + \frac{a_6}{4}\right) = -2\varphi(x),\\
&\frac{d}{dx} a_0^2 = 4\varphi(x)(a_2 + 2a_4 + 3a_6) - \frac{8}{\mathrm{Re}_{r_0}}(4a_4 + 9a_6),\\
&\frac{d}{dx}\left[\frac{a_0^2 + 2a_0a_2 + a_0a_6 + a_2a_4}{2} + \frac{2a_0a_4 + a_2^2 + a_4a_6}{3}\right.\\
&\left. + \frac{2a_2a_6 + a_4^2}{5} + \frac{a_6^2}{7}\right] = \frac{4}{\mathrm{Re}_{r_0}}(2a_4 + 3a_6),\\
&\frac{d}{dx}\left[P + \frac{2a_0^2 + 2a_0a_2 + a_0a_6 + a_2a_4}{2}\right.\\
&\left. + \frac{2a_0a_4 + a_2^2 + a_4a_6}{3} + \frac{2a_2a_6 + a_4^2}{5} + \frac{a_6^2}{7}\right] = \frac{4}{\mathrm{Re}_{r_0}}(a_2 + 2a_4 + 3a_6),
\end{aligned}\right\} \tag{38}$$

which makes it possible to calculate the motion of the vapor in the portion of the pipe where the motion is described by the equation system (33)-(35) from the velocity profile, i.e., from the values of the coefficients in the polynomial (36) and from the pressure at the entrance to that portion of the pipe. The initial values of a_i (i = 0, 2, 4, 6) and $\bar{P}$ must be determined from the solution of the complete system of Navier–Stokes equations in the preceding transition section.

With this scheme for the calculation of vapor motion in the cavity of a long heat pipe the demands on the core storage of the computer are reduced sharply since the equations are solved by finite differences only in the transition sections, and they make up a small part of the total cavity of the pipe. We note that sometimes reorganization of vapor flow in the transition sections is generally neglected and the solutions of Eqs. (33)-(35) are matched directly at $x = l_1$ and $x = l_2$ in each of the zones of the heat pipe.[5]

Because of the identical structure of the equations the methods for solving Eqs. (28)-(32) can also be applied to the solution of Eq. (5).

If an increase in the longitudinal vapor velocity in the vaporization zone causes the local Reynolds number to exceed $\mathrm{Re}_{\mathrm{cr}}$ the vapor flow can become turbulent. The transition from laminar flow to turbulent flow takes place over a distance of several channel diameters. The turbulent flow maintains its nature over the extent of the adiabatic zone and into the beginning of the condensation zone. Some stabilization of the flow must occur at the end of the condensation zone, where the vapor motion is decelerated, but the entire flow obviously does not become completely laminar. Analysis of vapor motion in the transition zones of the vaporization and condensation regions is extremely difficult. In the following, therefore, we neglect those zones, assuming that turbulence in the flow occurs immediately at the point in the vaporization zone where $\mathrm{Re} = \mathrm{Re}_{\mathrm{cr}}$ and that the region of turbulent flow extends over the entire condensation zone.

It should be noted that turbulent vapor motion is only possible in long heat pipes. In short heat pipes with high thermal loading a situation can occur in which the Reynolds number reaches $\mathrm{Re}_{\mathrm{cr}}$; however, the laminar flow cannot become turbulent before the beginning of the condensation zone. This circumstance greatly facilitates the analysis of vapor motion, making it possible to use the approximation of a turbulent boundary layer.

If one proceeds on the basis of the requirements of heat-pipe design, one can limit oneself to the determination of flow characteristics averaged over the cross section of the channel. Because of very intense turbulent displacement and the relation $R \ll l$, such vapor parameters as ρ_V and T_V are only weakly dependent on the transverse coordinate r. Assuming them independent of r, we average the equations for a turbulent boundary layer[21] over the cross section of the channel. The averaged equations have the form

$$\left.\begin{aligned}
&\frac{d\rho_V v}{dx} = -\frac{2l}{R}\tau|_{r=R},\\
&\frac{d}{dx}[P_V + \beta\rho_V v^2] = -\frac{2l}{R}\tau_w,\\
&\frac{d}{dx}\left[\rho_V v\left(h_V + \frac{\alpha v^2}{2}\right)\right] = -\frac{2l}{R}(\tau h_V)_{r=R},\\
&P_V = \frac{\rho_V R^* T_V}{\mu_V}.
\end{aligned}\right\} \tag{39}$$

Here a conversion has been made to the dimensionless coordinate x' = x/l (primes omitted) and the notation

$$v=\frac{2}{R^2}\int_0^R v_x r\,dr;\ \beta=\frac{2}{v^2R^2}\int_0^R v_x^2 r\,dr;\ \alpha=\frac{2}{v^3R^2}\int_0^R v_x^3 r\,dr. \tag{40}$$

has been introduced.

Note that the equation system (39) is written with vapor compressibility included.

The equation system (39) is an open system. To solve it, information is needed about the coefficient of momentum flow β, the frictional force τ_ω acting on a unit lateral surface of the channel, and the coefficient α. In the general case the coefficient of friction ζ, which is associated with τ_ω through the relation $\zeta = 8\tau_\omega/\rho_V v^2$, and α and β are functions of the local criteria Re = vR/ν_V and $\mathrm{Re}_r = (v_r(x)|_{r=R}R)/\nu_V$. Experimental data for these coefficients are still very sparse at the present time. Some information about β and ζ is given for the case of uniform injection[22] and extraction.[23] According to this data, starting at a distance of the order of four channel diameters from the entrance to the injection or extraction sections the coefficient β depends very slightly on x and can be assumed to be constant. Obviously, this also holds for a rate of injection or extraction which is a slowly varying quantity along the pipe. Under extraction, the coefficient β is the same as in an impermeable pipe, i.e., close to unity.

Experimental data on the coefficient of friction are very scarce. For injection, it is very small[22] and the inertial term $\beta\rho_V v^2$ in the equation of motion plays the principal role in the distribution of pressure along the flow. Because of this and also because of the absence of reliable experimental data for the coefficient ζ, one can use in the calculations the known laws for resistance to the motion of a fluid in a pipe assuming that they are also satisfied locally with injection. Since the Reynolds number for vapor motion does not exceed 10^5 as a rule, the Blausius equation with local Reynolds number

$$\zeta=\frac{0.3164}{\mathrm{Re}^{1/4}}$$

is suitable for this purpose.

With extraction, the friction force is significant and has a strong effect on the pressure distribution in the pipe. In particular, according to ref. 23, the coefficient of friction when there is extraction is an order of magnitude higher than the coefficient given by the Blasius equation. It turns out in this case that it depends strongly on the extraction coefficient $K_\perp = v_r|_{r=R}/v$ and for the region $0.006 < K_\perp < 0.022$ is given by

$$\zeta=17.5K_\perp.$$

This formula has been checked for two values of Re at the entrance to a porous section: $3.7\cdot10^4$ and $7.9\cdot10^4$.

3. Problem of heat propagation through a capillary structure totally saturated by a heat-transfer agent. Because of the sequence of iterations specified in Sec. 1 for the calculation of a heat-pipe design, the quantities τ_{l_x} and τ_{l_r} as well as $P_V|_{r=R}$ and $T_V|_{r=R}$ are assumed to be known and taken from the solutions of the appropriate problems in the preceding iteration. The propagation of heat through the capillary structure is described by Eq. (7). The boundary conditions take the form

$$\left.\begin{aligned}(\tau h_l)_{r=R}-\left(\lambda'_r\frac{\partial T}{\partial r}\right)_{r=R}&=(\tau h_V)_{r=R},\\ \tau_{l_r}|_{r=R}=\tau_{V_r}|_{r=R}&\equiv\tau,\\ -\left(\lambda'_r\frac{\partial T}{\partial r}\right)_{r=R_1}&=q_1,\end{aligned}\right\} \tag{41}$$

$$\left.\frac{\partial T}{\partial x}\right|_{x=0}=\left.\frac{\partial T}{\partial x}\right|_{x=l}=0. \tag{42}$$

The solution of Eq. (7) under the conditions (41) and (42) is a rather complicated problem because of the nonlinearity of the first of the conditions (41); therefore it is solved approximately. We look for a solution T(x, r) in the form of a polynomial in r requiring satisfaction of the boundary conditions and of the energy equation (7) averaged over the cross section of the capillary structure. For a liquid filtering through the capillary structure, the equation of continuity

$$\frac{\partial r\tau_{l_x}}{\partial x}+\frac{\partial r\tau_{l_r}}{\partial r}=0. \tag{43}$$

must be satisfied.

Taking account of Eq. (43) and the boundary conditions (41) and (42), we write the averaged equation (7) in the form

$$\int_R^{R_1}\tau_{l_x}\frac{\partial rh_l}{\partial x}dr-\lambda'_x\frac{d^2}{dx^2}\int_R^{R_1}Tr\,dr=R\tau(h_V-h_l)_{r=R}$$
$$-R_1q_1-\int_R^{R_1}r\tau_l\frac{\partial h_l}{\partial r}dr. \tag{44}$$

Because of the approximate nature of the solution of the problem of thermal conductivity in the capillary structure of a heat pipe, we assume in Eq. (44) that τ_l does not depend on r but that it is an average of the true value over the cross section of the wick. This assumption is not necessary; however, while having no marked effect on the accuracy of the solution, it permits unification of the calculation for different types of capillary structures and simplifies subsequent calculations significantly. The replacement of τ_{l_x} by $\bar{\tau}_{l_x}$ is justified for wicks of irregular structure, in which the velocity profile of the liquid is almost planar. Using this simplification we write Eq. (44) in the form

$$\frac{d^2\bar{T}}{dx^2}-\frac{\bar{\tau}_{l_x}}{\lambda'_x}\frac{d\bar{h}_l}{dx}=\frac{2R_1q_1}{\lambda'_x(R_1^2-R^2)}-\frac{2R\tau}{\lambda'_x(R_1^2-R^2)}$$
$$\times\left[(h_V-h_l)_{r=R}-\int_R^{R_1}\frac{R_1^2-r^2}{R_1^2-R^2}\frac{\partial h_l}{\partial r}dr\right], \tag{45}$$

where the bar indicates an average over the cross section of the wick.

$$\bar{T}=\frac{2}{R_1^2-R^2}\int_R^{R_1}Tr\,dr.$$

We assume a dependence of the temperature T(x, r) on r in the form of the following polynomial of second degree:

$$T(x, r) = T_0(x) + a_1(x)(r - R) + a_2(x)(r - R)^2. \qquad (46)$$

We determine the coefficients a_1 and a_2 by requiring satisfaction of the boundary conditions (41):

$$a_1(x) = -\frac{1}{\lambda'_r}\tau(h_v - h_l)_{r=R}; \quad a_2(x) = -\frac{q_1 + \lambda'_r a_1(x)}{2\lambda'_r(R_1 - R)}. \qquad (47)$$

We use Eq. (45) to determine the coefficient $T_0(x) \equiv T(x, R)$. After substitution of Eqs. (46) and (47) in Eq. (45), replacement of the variable x by the dimensionless variable $x' = x/l$ (the primes are omitted in the following), and simple transformations, we obtain a nonlinear differential equation with respect to T_0:

$$\frac{d^2\bar{T}}{dx} - \frac{\tau l_x c_{pl} l}{\lambda'_x}\frac{d\bar{T}}{dx} = \frac{2R_1 l^2 q_1}{\lambda'_x(R_1^2 - R^2)} - \frac{2Rl^2\tau}{\lambda'_x(R_1^2 - R^2)}$$
$$\times [L + c_{pv}(T_v - T_p) - c_{pl}(T_0 - T_p) - c_{pl}(a_1 A + B)], \qquad (48)$$

where

$$\bar{T} = T_0 + Aa_1 + B; \quad A = \frac{R_1 - R}{R_1 + R}\left(\frac{5}{12}R_1 + \frac{R}{4}\right);$$

$$B = -\frac{q_1}{4\lambda'_r}\frac{R_1 - R}{R_1 + R}\left(R_1 + \frac{R}{3}\right).$$

We recall that τ is related to T_0 by Eq. (16), and that the enthalpy h_l of the heat-transfer agent and the enthalpy h_v of the vapor at r = R are given by Eq. (8). If $T_v|_{r=R}$ is taken as the vapor temperature in the region of the surface r = R, where condensation occurs, in the calculation of $h_v|_{r=R}$, then the temperature of the vapor at the vaporization surface $T_v|_{r=R}$ must be calculated from Eq. (17) in regions where vaporization occurs.

It is impossible to satisfy (42) exactly with the polynomial (46). Therefore we weaken this condition, requiring only that

$$\left.\frac{\partial\bar{T}}{\partial x}\right|_{x=0} = \left.\frac{\partial\bar{T}}{\partial x}\right|_{x=1} = 0. \qquad (49)$$

Equation (48) with the condition (49) can be solved by the Newton–Kantorovich method. In this case it is not convenient to determine $T_0(x)$ directly from Eq. (48); rather we find the energy flux density through the surface r = R. We designate it by z. Then we determine $T_0(x)$ from

$$\tau h_v|_{r=R} = z \qquad (50)$$

and τ from Eq. (16).

Let the functions $z^n(x)$ and $T_0^n(x)$, which are related through Eq. (50), be the n-th approximation to the desired solution of Eq. (48). We obtain an equation for the correction δz to this approximation by variation of Eq. (48) in the neighborhood of $z^n(x)$. We write each of the expressions in Eq. (48) which depend on z correctly to the linear term in δz in the neighborhood of z^n; T_0^n. For example, $\bar{T}$ can be written in the form $\bar{T} = \bar{T}|_{T_0^n} + F\delta z$, where $F = \partial\bar{T}/\partial z|_{F_0^n, z^n} = \partial\bar{T}/\partial T_0|_{T_0^n}\,\partial T_0/\partial z|_{T_0^n}$. Proceeding in the same way in the other expressions in Eq. (48) and keeping only first-order terms, we obtain the following equation for the correction δz:

$$\frac{d^2F\delta z}{dx^2} - \frac{\tau l_x c_{pl} l}{\lambda'_x}\frac{dF\delta z}{dx} + \frac{2Rl^2\delta z}{\lambda'_x(R_1^2 - R^2)} = -\frac{d^2\bar{T}}{dx^2} + \frac{\tau l_x c_{pl} l}{\lambda'_x}\frac{d\bar{T}}{dx}$$
$$+ \frac{2R_1 q_1 l^2}{\lambda'_x(R_1^2 - R^2)} - \frac{2Rl^2}{\lambda'_x(R_1^2 - R^2)}[z - \tau c_{pl}(T_0 - T_p + a_1 A + B)], \qquad (51)$$

the coefficients and right side of which are calculated for the values $T_0(x) = T_0^n(x)$ and $z(x) = z^n(x)$. The boundary conditions for Eq. (51) are obtained from Eq. (49):

$$\left.\frac{dF\delta z}{dx}\right|_{x=0} = -\left.\frac{d\bar{T}}{dx}\right|_{x=0}; \quad \left.\frac{dF\delta z}{dx}\right|_{x=1} = -\left.\frac{d\bar{T}}{dx}\right|_{x=1}. \qquad (52)$$

A single iteration in the solution of Eq. (48) as the result of which the (n + 1)-th approximations T_0^{n+1}, z^{n+1} are determined from the n-th approximations T_0^n and z^n includes solution of Eq. (51) with respect to δz with the boundary conditions (52), the calculation of the (n + 1)-th approximation z^{n+1} from the expression $z^{n+1} = z^n + \delta z$, and the determination of T_0^{n+1} from Eq. (50) in which we set $z = z^{n+1}$. With the proper choice of the first approximation, this iteration process converges very rapidly. As a rule a few iterations are sufficient. Equation (51) can be solved numerically by finite differences.

4. The calculation of the filtration of the heat-transfer agent depends on the capillary structure and cannot be formulated in a universal fashion. In contrast to the vapor, the great influence exerted by gravity must be taken into account in the calculation of condensate motion. This is comparatively simple. Since gravity represents a potential energy, it is then sufficient to subtract from the pressure of the liquid which is obtained by solving the problem without including gravity a quantity $\rho_l gx\sin\gamma$, where g is the gravitational acceleration and γ is the slope of the heat pipe with respect to the horizontal.

We now consider the filtration of the heat-transfer agent under conditions of weightlessness for three types of capillary structures: a coaxial gap formed by a fine porous screen and the pipe casing, a system of longitudinal grooves on the internal surface of the casing covered by a finely porous screen, and a wick of irregular structure (made of several layers of mesh, dried powder, porous capillary material, etc).

With sufficiently high screen porosity the pressure of the liquid in the gap is due mainly to the average characteristics of the flow and depends only to a limited extent on the details of influx of liquid into the gap and efflux through openings in the screen. We therefore assume that the influx and efflux of liquid does not occur through individual openings in the screen but over the entire surface.

An estimate of the Reynolds number Re_{r_1} for filtration of a heat-transfer agent in a heat pipe yields a value less than unity for alkali metals. This makes it possible to neglect convective terms in the equations of motion and the Stokes approximation is used for calculation of liquid motion along the capillary structure. In this approximation the motion of the liquid along a coaxial gap is described by the system

$$\left.\begin{aligned}&\frac{dru_x}{\partial x}+\frac{l}{R_1}\frac{\partial ru_r}{\partial r}=0,\\&\frac{\eta_l l}{R_1^2}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u_x}{\partial r}\right)=\frac{\partial P_l}{\partial x},\\&\frac{\partial P_l}{\partial r}=0\end{aligned}\right\}\qquad(53)$$

with the boundary conditions

$$u_x|_{r=\alpha}=u_x|_{r=1}=u_r|_{r=1}=0,\qquad(54)$$

$$u_r|_{r=\alpha}=\frac{\tau}{\rho_l}\equiv u_r^*.\qquad(55)$$

Here, we have introduced the dimensionless variables $x' = x/l$, $r' = r/R_1$, and the notation $\alpha = R/R_1$. The primes on the new variables are omitted. The quantity τ in Eq. (55) is determined from a solution of the problem of heat propagation through a capillary structure, Eq. (41).

Integrating Eq. (53), we obtain the following expressions for the velocities u_x and u_y subject to (54):

$$u_x=\frac{R_1^2}{4\eta_l l}\frac{dP_l}{dx}\left[r^2+\frac{1-\alpha^2}{\ln\alpha}\ln r-1\right],\qquad(56)$$

$$u_r=-\frac{R_1^2}{4\eta_l l^2}\frac{d^2P_l}{dx^2}$$

$$\times\left[\frac{r^3}{4}-r\left(\frac{1-\alpha^2}{4\ln\alpha}+\frac{1}{2}\right)+\frac{1-\alpha^2}{2\ln\alpha}r\ln r+\left(\frac{1-\alpha^2}{4\ln\alpha}+\frac{1}{4}\right)\frac{1}{r}\right].\qquad(57)$$

Assuming $r = \alpha$ in Eq. (57) and using Eq. (55), we obtain an equation for the pressure,

$$\frac{d^2P_l}{dx^2}=-\frac{4\eta_l l^2Ru_r^*}{R_1^4\left[\frac{1-\alpha^4}{4}+\frac{(1-\alpha^2)^2}{4\ln\alpha}\right]}.\qquad(58)$$

From Eq. (56) and the requirement that the liquid velocity u_x must vanish at $x = 0$, we obtain a condition for Eq. (58),

$$\left.\frac{dP_l}{dx}\right|_{x=0}=0.\qquad(59)$$

This relation determines the solution of Eq. (58) except for an arbitrary term. However, this ambiguity is unimportant for the heat pipe since the pressure difference between two points in the gap, which is determined unambiguously, appears in the operating condition (24).

The solution of Eq. (58) with condition (59) has the form

$$P_l(x)=P_l(0)-\frac{\nu l}{K}dl^2\int_0^x dx\int_0^x\tau dx,\qquad(60)$$

where

$$K=\frac{R_1^2}{2}\left[\frac{1+\alpha^2}{4}+\frac{1-\alpha^2}{4\ln\alpha}\right],\quad d=\frac{2R}{R_1^2-R^2}.\qquad(61)$$

In Eq. (60) the actual specifications of the capillary structure are taken into account through the coefficients K and d. One can show that the pressure of the liquid along the wick can also be represented in the form (60) for other capillary structures in the Stokes approximation but with different coefficients K and d. In the case of a wick of irregular structure K is determined by the permeability of the wick and d is given by Eq. (61). For a wick in the form of a system of longitudinal grooves covered by a finely porous screen K and d are given by

$$d=\frac{a+b}{ah};\quad K=-\frac{16a^3}{\pi^5h}\sum_{i=0}^{\infty}\frac{1}{(2i+1)^5}\frac{\operatorname{ch}\frac{(2i+1)\pi h}{a}-1}{\operatorname{sh}\frac{(2i+1)\pi h}{a}}$$

$$+\frac{8a^2}{\pi^4}\sum_{i=0}^{\infty}\frac{1}{(2i+1)^4},\qquad(62)$$

where a is the width of a groove, h its depth, and b the spacing between grooves.

5. The capillary pressure created by menisci located in the pores of a wick depends on the radius of the pore and the location of the meniscus. If the capillary structure is such that there are pores of different diameters a situation is possible in which the capillary pressure created by menisci in large pores does not provide transport of the heat-transfer agent while motion of heat-transfer agent along small pores is still possible. In this case, complete or partial drying of the large pores occurs when the condensate does not occupy the entire cross section of a pore. This takes place not over the entire length of a capillary but starting at the point where the difference in vapor and liquid pressures is equal to the maximum surface pressure of the meniscus at this point of the pore. Thus, in operation of a heat pipe under conditions of drying of the capillary structure the extent to which the wick is filled by the heat-transfer agent varies along the pipe. It is completely filled in the condensation zone and is partially dry somewhere at the beginning of the vaporization zone.

Resistance to the motion of the heat-transfer agent, which is characterized by the coefficient of permeability, depends on the degree to which the wick is filled with condensate. Consequently, filtration of the heat-transfer agent is accomplished in this situation under conditions of a varying coefficient of permeability along the pipe, which, in turn, becomes a function of the process of filtration.

With partial drying of the capillary structure vaporization of the condensate takes place within the wick, and the vapor formed in large pores is transported to the surface of the capillary structure and thus arrives in the cavity of the heat pipe. The vapor is heated as the result of heat exchange with the skeleton of the wick in proportion to the amount of travel along large pores. In order to include these processes in the formulation of the problem it is necessary to take as a basis some model of the capillary structure and of the filtration of the condensate through it under conditions of partial drying.[24]

As an assumption with respect to vapor and condensate filtration we may say that the vapor is propagated only across the wick in the r direction and the liquid is propagated along the wick in the x direction. Then we have

$$\tau_{v_x}=\tau_{l_r}=0;\quad\tau_x=\tau_{l_x};\quad\tau_r=\tau_{v_r},$$

$$q_x=\tau_{l_x}h_l-\lambda_x'\frac{\partial T}{\partial x};\quad q_r=\tau_{v_r}h_v-\lambda_r'\frac{\partial T}{\partial r},$$

and the energy and continuity equations become

$$\frac{\partial r\tau_{l_x}}{\partial x}+\frac{\partial r\tau_{v_r}}{\partial r}=0, \tag{63}$$

$$\frac{\partial}{\partial x}\left[r\left(\tau_{l_x}h_l-\lambda'_x\frac{\partial T}{\partial x}\right)\right]+\frac{\partial}{\partial r}\left[r\left(\tau_{l_r}h_l-\lambda'_r\frac{\partial T}{\partial r}\right)\right]=0. \tag{64}$$

As before, the coefficients of thermal conductivity for the heat-transfer agent and the wick skeleton are assumed to be similar and sufficiently large to justify the introduction of the same temperature for them. Taking account of the physical meaning of each of the terms in Eq. (64), it can be rewritten as

$$\tau_{l_x}\frac{\partial h_l}{\partial x}-\frac{\partial}{\partial x}\left(\lambda'_x\frac{\partial T}{\partial x}\right)=-(h_v^{ev}-h_l)\frac{1}{r}\frac{\partial r\tau_{v_r}}{\partial r}+\frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda'_r\frac{\partial T}{\partial r}\right)-\tau_{v_r}\frac{\partial h_v}{\partial r}, \tag{65}$$

where the enthalpy h_v^{ev} created through evaporation of the vapor is taken at the temperature

$$T_v^{ev}=T+\frac{T^{3/2}}{4P(T)}\frac{\alpha}{(2-\alpha)[\alpha+\beta(1-\alpha)]}\left[\frac{P_v}{\sqrt{T_v}}-\frac{P(T)}{\sqrt{T}}\right]. \tag{66}$$

The variation in vapor flow along the r axis, which is reflected by the expression $\partial r\tau_{v,r}/\partial r$ in Eq. (65), is associated with vaporization within the wick. If we designate by ε_1 the total area of the free surface of the liquid per unit volume of the wick, then with the help of Eq. (16) we can write an expression for the rate of vaporization

$$\frac{\partial r\tau_{v_r}}{\partial r}=-\frac{2\alpha}{2-\alpha}\sqrt{\frac{\mu}{2\pi R^*}}\left[\frac{P_v}{\sqrt{T_v}}-\frac{P(T)}{\sqrt{T}}\right]r\varepsilon_1. \tag{67}$$

We take account of heat exchange between the vapor and the skeleton of the capillary structure by means of the coefficient of heat exchange. Then, introducing the porosity ε_r^{dry} of dry pores in a section of the wick normal to the r axis, we write

$$\tau_{v_r}\frac{\partial h_v}{\partial r}=\frac{2\lambda_v \mathrm{Nu} f_1}{a^2}(T-T_v)\varepsilon_r^{dry}, \tag{68}$$

where *a* is the pore radius and f_1 is the sinuosity factor for the pore. Equations (65)-(68) describe the propagation of heat through a capillary structure in regions of partial drying. In those locations where the wick is completely filled with heat-transfer agent the propagation of heat is described by Eq. (7).

To determine the pressure p_l of the liquid and also the quantities ε_1 and ε_r^{dry} appearing in Eqs. (67) and (68), we turn to a wick previously used[10] made of several layers of woven wire mesh. During drying the liquid moves along channels of wedge-shaped cross section formed by the warp wires and the densely packed woof wires,[10] i.e., in a wick of such structure, the number of channels along which the liquid moves and their cross section occupied by heat-transfer agent vary in proportion to the drying. In the case of partial drying the wick under discussion reduces to a stack of capillaries located along the pipe. The permeability of a stack of capillaries is related in the following manner to the average cross sections of the liquid-filled capillaries and their density n:

$$K=fs^2n,$$

where f is a coefficient which is determined by the geometry of the capillaries – the sinuosity and cross-sectional shape.

Using the simple geometric concepts in Fig. 3 we obtain the following approximate expression for the cross section of a wedge-shaped channel: $s=2r_k^2\sqrt{R_{warp}/r_k}$. The permeability of the wick is then

$$K(x)=\begin{cases} f4r_k^3R_{warp}n, & 0\leqslant x\leqslant x_{dry},\\ K_w, & x_{dry}\leqslant x\leqslant l, \end{cases} \tag{69}$$

where K_w is the permeability of a wick completely saturated with liquid; x_{dry} is the point at which drying begins, which is determined from the condition

$$(P_v-P_l)_{x=x_{dry}}=\frac{2\sigma\cos\delta}{a}. \tag{70}$$

The half-width r_k of the channel is determined from the pressure difference p_v-p_l along both sides of the free surface of the liquid:

$$r_k=\frac{\sigma\cos\delta}{P_v-P_l}. \tag{71}$$

Note that Eqs. (70) and (71) are written without inclusion, unimportant as a rule, of the phenomenon of recoil in phase transitions. Thus filtration of the heat-transfer agent is described by the Darcy equation

$$\frac{dP_l}{dx}=-\frac{\nu_l}{K}\tau_{l_x}, \tag{72}$$

in which the permeability of the wick is given by Eqs. (69) and (71). To determine the pressure of the liquid along the wick of a heat pipe by means of Eqs. (69)-(72) it is necessary to give its value at some point in the capillary structure. When the wick dries an excess of heat-transfer agent appears, which is driven back into the condensation zone by vapor flow. Therefore, at the point of minimum curvature of the free surface of the liquid, x_{min}, the latter coincides with the surface of the cavity of the heat pipe, and consequently

$$P_l|_{x_{min}}=P_v|_{x_{min}}-\frac{\sigma}{R}. \tag{73}$$

We determine x_{min} from the condition

$$\frac{d}{dx}[P_v-P_l]_{x_{min}}=0, \tag{74}$$

where dP_l/dx is given by Eq. (72). If there is no root of Eq. (74) in the condensation zone, x_{min} is equal to unity.

Finally, we discuss the quantities ε_1 and ε_r^{dry}. On the basis of the above ideas concerning the heat-transfer agent and the structure of a wick made of woven wire mesh, one can set $\varepsilon_1=2r_kn$ and ε_r^{dry} equal to the porosity

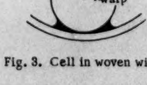

Fig. 3. Cell in woven wire mesh.

of the wick, ε_{WT}. The coefficients of thermal conductivity λ'_x and λ'_r are given approximately by

$$\lambda'_x = \lambda_{TB}(1-\varepsilon_{W.x}); \quad \lambda'_r = \lambda_{TB}(1-\varepsilon_{WT}).$$

With insignificant changes we also apply the method discussed above for approximate solution of Eq. (7) to the present problem of heat propagation through the jacket of a pipe with partial drying of the capillary structure.

SOME RESULTS OF HEAT-PIPE CALCULATIONS

To carry out specific heat-pipe calculations and to compare the results of these calculations with existing experimental data a final development of the computational method at the level of an algorithm and its realization in the form of a computer program has been accomplished. Some of the results obtained in two sets of calculations are discussed below. By mathematical simulation of the appropriate operating conditions for a heat pipe, the nature of the observed significant variations of vapor temperature in the cavity of a heat pipe[10] is clarified in the first set of calculations. The second set is concerned with the question of heat-pipe optimization.

1. The considerable variation in vapor temperature (up to 40°C) observed along the cavity of a heat pipe[10] cannot be interpreted as a manifestation of the effect of vapor compressibility since the Mach number is considerably less than unity under the experimental conditions. Several probable causes for such behavior of vapor temperature have been suggested.

The first possible mechanism is a strong nonuniformity in the jacket temperture created by heat propagation. However, calculations performed on the basis of the combined formulation of the problem of heat-pipe design, in which this phenomenon is automatically included, show that heat propagation along the jacket of the pipe studied[10] is insignificant and does not lead to a change in vapor temperature along the pipe.

Another possible mechanism for the variation in vapor temperature is any process occurring directly in the cavity of the pipe and associated with the fact that vapors of alkali metals are a mixture of chemically reacting molecules with different structures (A_1, A_2, A_3, etc., where A is the designation for a chemical element). The chief chemical reaction is the dimerization reaction

$$A_2 \rightleftarrows 2A_1 \tag{75}$$

with a rather low value for the heat of reaction. Estimates of the rate constant for this reaction in the region of heat-pipe operating temperatures give a value of 10^{10} from the Arrhenius equation. This high value for the rate constant indicates the equilibrium nature of the reaction (75). The existence of an equilibrium chemical reaction in the vapor shows up in its heat capacity. This quantity increases severalfold in comparison with the vapor heat capacity for the freezing reaction. The high value of the vapor heat capacity should prevent a drop in the vapor temperature. However, this tendency can be disturbed by the vaporization process. If conditions are created such that the ratio between the fluxes of vaporizing monatomic and diatomic molecules changes along the vaporization zone, if the phase transition occurs in this case with molecules of different atomicities involved, and if this ratio is different from the molecular ratio in the pipe cavity, then a chemical reaction can occur in the cavity and can cause a drop in vapor temperature. Nonuniformity of conditions along the vaporization zone can be associated with variation in vapor pressure and with the dependence of ε on x.

To check this supposition a combined problem of heat-pipe design has been treated and includes chemical transformations of heat-transfer agent vapors as described by (75). A solution of this problem for various linear functions $\varepsilon(x)$ in the vaporization zone shows that nonuniformity of conditions along the vaporization zone created by variation in vapor pressure and by the $\varepsilon(x)$ dependence has an insignificant effect on the ratio between vaporizing monatomic and diatomic molecules along the vaporization zone and does not lead to a drop in vapor temperature. This calculation also indicates that the vapor produced by vaporization has almost the same composition as the vapor moving along the pipe cavity. As a result, it becomes possible to simplify significantly the calculation for a heat pipe in which alkali metals are used as a heat-transfer agent by eliminating the calculation for chemical transformations of vapors of the heat-transfer agent and by including this phenomenon effectively through a coefficient of heat capacity for the vapor which takes into account chemical reactions.

The consequences of partial drying of the capillary structure have been subsequently studied with this result included on the basis of the model discussed above. The solution of the problem shows that in this case a considerable variation in vapor temperature along the vaporization zone of the heat pipe actually occurs (Fig. 4). It should be noted that there is considerable arbitrariness in the selection of values for the parameters f, f_1, Nu, n, β, and a. One can achieve agreement between the vapor temperature curve and the experimental data[10] by appropriate choice of these parameter values, particularly for the function n(x) in the region of partial drying.

Thus, on the basis of the calculations intended to explain the nature of the observed drop in vapor temperature,[10] one can assert that the drop is caused by partial drying of the capillary structure.

2. With the help of the operating condition (25) for heat pipes, calculations have also been performed to optimize the geometric parameters of heat pipes and to determine the limiting characteristics.

The left side of inequality (25) (denoted by ΔP_{max}) depends on geometric parameters of heat pipes (l, l_1, l_2, R, R_1), the thermal flux Q along the pipe, the operating temperature, and the properties of the capillary struc-

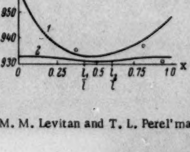

Fig. 4. Variation of vapor temperature along a heat pipe. 1) With partial drying of the capillary structure; 2) with a completely saturated wick; the points are experimental data.[10]

ture and heat-transfer agent. When Q increases $\Delta P_{\max}$ increases monotonically. Therefore the thermal loading for which the equality in (25) is satisfied is the maximum for a given heat pipe. It is obvious that for a given R_1 and with other conditions remaining the same, there is an optimum value for the radius of the heat-pipe cavity R at which the minimum pressure drop must be overcome by the capillary structure. Equating this drop to the maximum value of the capillary pressure $P_{k\max}$ we obtain the following expression for the maximum heat flux $Q_{\max}$ along a pipe:

$$\min_{0<R<R_1} [\Delta P_{\max}(Q_{\max})] = P_{k\max}. \tag{76}$$

Here one should immediately stipulate that Eq. (76) represents a limitation imposed on the quantity Q by the capabilities of the capillary structure. The true value of $Q_{\max}$ can be much smaller because of limitations on the thermal flux density through the pipe jacket in the vaporization zone associated with boiling of the heat-transfer agent and perturbations caused by this type of wick operation.

Shown below are some results for optimization by means of Eq. (76) for heat pipes with a capillary structure in the form of a coaxial gap formed by the pipe casing and a perforated screen. With transfer of maximum heat fluxes along high-temperature heat pipes, the mode of vapor flow is turbulent. Therefore the calculation of the vapor motion is based on the equation system (39). The radius of the screen openings is assumed to be $a = 0.1$ mm, the screen porosity $\varepsilon = 0.5$, and the coefficient of accommodation $\beta = 0.1$. Values for the condensation coefficient are taken from ref. 25.

Shown in Fig. 5 for three pipe lengths with proportional changes in each of the zones ($l_1/l = 0.36$, $l_2/l = 0.5$, $R_1 = 1$ cm) is the temperature dependence of the maximum heat flux density along the pipe for sodium and potassium heat pipes. As is clear from the curves, sodium heat pipes are able to transfer greater heat fluxes than potassium heat pipes at the same temperature, with the difference increasing as the temperature rises.

The dependence of maximum heat load on pipe length for sodium heat pipes at T = 973°K is also shown in Fig. 6. Curves 1, 5, and 6 correspond to a proportional variation of the length of each of the heat-pipe zones. With pipe operation in the vertical position (curve 6), where the vaporization zone is below, $Q_{\max}$ increases very little in comparison with the horizontal case (curve 5). For l somewhat greater than 1 m and T = 973°K, the heat-transfer agent generally cannot be maintained in the gap because of the effect of gravity and the gap dries. In this case return of the heat-transfer agent to the vaporization zone is not accomplished with the help of a capillary structure, as in wickless pipes, but as the result of a flow of condensate film along the internal surface of the pipe casing. It should be pointed out that if there are no differences in vapor pressure between the vaporization and condensation zones to oppose the gravitational force, then the coaxial gap will dry out when $l = 0.5$ m. The thermal pipe being discussed with a screen opening radius $a = 0.1$ mm and a length greater than 0.5 m cannot operate against the force of gravity. The same figure (curve 4) shows the dependence of maximum loading on l when only the length of the adiabatic zone is changed and the vaporization and condensation zones remain fixed. In this case $Q_{\max}$ falls considerably more rapidly with increasing l than with proportional changes in each of the pipe zones. A reduction in heat-pipe radius (curve 1) also leads to a reduction in maximum heat load.

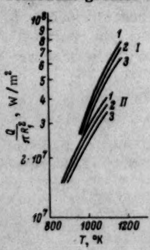

Fig. 5. Temperature dependence of maximum heat load transported along a heat pipe for sodium (I) and potassium (II) heat pipes. $R_1 = 1$ cm, $a = 0.1$ mm, $l_1/l = 0.36$, $l_2/l = 0.5$. l: 1) 0.5; 2) 1; 3) 2 m.

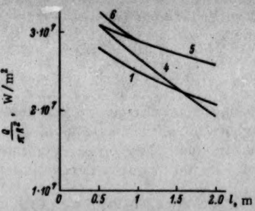

Fig. 6. Dependence of maximum heat load on pipe length for sodium heat pipes at 973°K. 1) $R_1 = 0.5$ cm, $\gamma = 0$; 4) $R_1 = 1$ cm, $\gamma = 0$; 5) $R_1 = 1$ cm, $\gamma = 0$; 6) $R_1 = 1$ cm, $\gamma = \pi/2$.

The optimum width of a coaxial gap for the maximum heat fluxes $Q_{\max}$ along the pipes in Figs. 5 and 6 is plotted in Fig. 7.

Typical distributions of vapor and liquid pressures as well as distributions of vapor temperature T_v, internal surface temperature T_0, and outer surface temperature T_1 of the coaxial gap are shown in Figs. 8 and 9 for maximum heat loads along sodium heat pipes. As is clear from the data, the thermal resistance of heat pipes is made up principally of the thermal resistance of the phase transitions in the vaporization and condensation zones

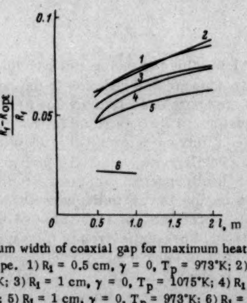

Fig. 7. Optimum width of coaxial gap for maximum heat flux along a sodium heat pipe. 1) $R_1 = 0.5$ cm, $\gamma = 0$, $T_p = 973$°K; 2) $R_1 = 1$ cm, $\gamma = 0$, $T_p = 1175$°K; 3) $R_1 = 1$ cm, $\gamma = 0$, $T_p = 1075$°K; 4) $R_1 = 1$ cm, $\gamma = 0$, $T_p = 973$°K; 5) $R_1 = 1$ cm, $\gamma = 0$, $T_p = 973$°K; 6) $R_1 = 1$ cm, $\gamma = \pi/2$, $T_p = 973$°K.

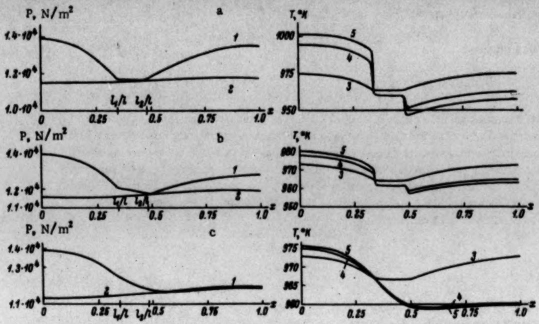

Fig. 8. Variation of vapor pressure P_v (1), liquid pressure P_l(2), vapor temperature T_v (3), internal surface temperature T_0 (4), and external surface temperature T_1 (5) of the coaxial gap along a pipe for transfer of maximum heat loads with Na. T_p = 973°K, $\gamma = 0$; a) R_1 = 1 cm, l = 0.5 m; b) R_1 = 1 cm, l = 2 m; c) R_1 = 0.5 cm, l = 2 m. a, b) x_{min} = 0.48331, x_{max} = 0; c) x_{min} = 0.68331, x_{max} = 0.

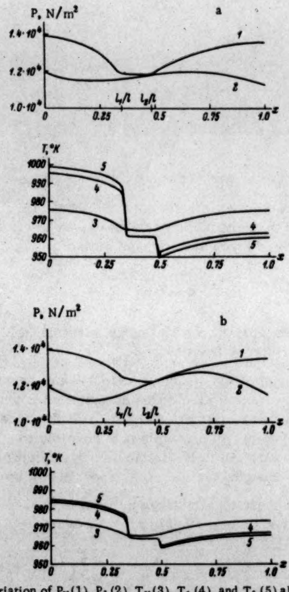

Fig. 9. Variation of P_v(1), P_l (2), T_v(3), T_0 (4), and T_1 (5) along a vertical pipe for transfer of maximum heat loads by Na at 973°K. a) R_1 = 1 cm, l = 0.5 m, x_{min} = 0.48331, x_{max} = 1.0; b) R_1 = 1 cm, l = 1 m, x_{min} = 0.5, x_{max} = 0.13333.

and the thermal resistance of the pipe jacket in the same zones in heat pipe operation at maximum heat loads. In all the cases shown, the points of maximum meniscus curvature, x_{max}, and of minimum meniscus curvature, x_{min}, occupy very different locations; this result confirms the need to use the heat-pipe operating condition in the form (24) or (25) in the calculations.

Design of axisymmetric plasma lenses

A. I. Morozov and S. V. Lebedev

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 1592-1600 (August 1974)

The focusing properties of plasma lenses differ significantly from those of ordinary electromagnetic lenses in the additional focusing or defocusing by the electric fields arising from the space charge in the plasma beam in the lens. For a very low electron temperature ($T_e \to 0$) Laplace's equation ($\Delta\Phi = 0$) for the scalar electric potential is replaced by the equation $\Phi = \Phi(rA_\theta)$, where A_θ is the azimuthal component of the vector potential of the magnetic field. We discuss the focusing properties and methods of designing axisymmetric plasma lenses when $\Phi = \Phi(rA_\theta)$. We calculate focal lengths of plasma lenses for shaping beams close to the axis of symmetry and hollow cylindrical plasma beams.

INTRODUCTION

Plasma lenses are used to focus dense neutralized ion beams. Plasma lenses differ from vacuum lenses[1)] in their ability to focus not only by external electromagnetic fields, but also by the electric field due to the space charge of the beam. Morozov[3] showed the possibility of producing plasma systems with focusing by E and H fields, and experimental confirmation is reported in refs. 4-6. Depending on the beam geometry we can distinguish two types of axisymmetric plasma lenses: axial and annular. Axial lenses focus plasma beams passing close to the axis symmetry. The axis of symmetry in these lenses is the optical axis, and the H field has no azimuthal component $H\varphi$. An example of such an axial plasma lens is given in refs. 4 and 7. Annular lenses operate with hollow cylindrical beams passing close to a certain cylindrical surface r = R, which we call the initial surface. The analog of the optical axis in such lenses is a cylindrical surface, whose generators can have a rather complicated form. We call this the fundamental surface and determine its actual shape later.

For simplicity we limit ourselves to a discussion of paraxial beams. In annular lenses we take the condition for a beam to be paraxial as

$$a \ll R, \tag{1}$$

where R is the radius of the initial surface and *a* is the characteristic width of the beam.

SPECIFICATION OF THE ELECTRIC AND MAGNETIC FIELDS

We specify the magnetic field by using the magnetic flux function ψ, which is related to the magnetic field components by the equations

$$H_r = -\frac{1}{r}\frac{\partial\psi}{\partial z}, \quad H_z = \frac{1}{r}\frac{\partial\psi}{\partial r}. \tag{2}$$

The function ψ satisfies the equation

$$\Delta^*\psi = r\frac{\lambda}{\partial r}\frac{1}{r}\frac{\partial\psi}{\partial r} + \frac{\partial^2\psi}{\partial z^2} = 0, \tag{3}$$

and the line ψ = const is the equation of the projection of the lines of force on the meridian (r, z) planes.

For paraxial beams we can expand ψ in powers of y = r − R (R = 0 for axial lenses), keeping the first terms of the expansion. By taking account of the symmetry about the z axis, for axial lenses we have

$$\psi = \frac{r^2}{2}H_0(z) - \frac{3}{2}\frac{r^4}{4!}H_0(z) + \frac{3\cdot5}{2\cdot4}\frac{r^6}{6!}H_0^{(\mathrm{IV})} + \ldots, \tag{4}$$

where $H_0(z)$ is the magnetic field H_z at r = 0, and the primes denote differentiation with respect to z.

For annular lenses we have

$$\psi = \psi_0(z) + \psi_1(z)\,y + \psi_2(z)\frac{y^2}{2} + \psi_3(z)\frac{y^3}{3!} + \ldots, \tag{5}$$

where by Eqs. (2) and (3)

$$\left.\begin{aligned} &\psi_0 = -R\int_{-\infty}^{z} H_r^0 dz, \quad \psi_1 = RH_z^0, \\ &\psi_2 = -\psi_0'' - \frac{\psi_1}{R}, \quad \psi_3 = -\psi_1'' - \frac{1}{R}\psi_0'', \end{aligned}\right\} \tag{6}$$

H_r^0 and H_z^0 are the projections of H on the initial surface.

For a plasma beam with cold electrons ($T_e \to 0$) the electric and magnetic fields are related by the condition that the lines of force are equipotentials:[3]

$$\Phi = \Phi(\psi). \tag{7}$$

Here, Φ is the scalar potential of the electric field, and $\Phi(\psi)$ is an arbitrary function of ψ.

The electric field distribution in a beam is established either by a system of electrodes at specified potentials,[4] or by conduction mechanisms characteristic of the given particular system. In principle it is possible to produce an arbitrary electric field distribution by a sytem of electrodes, thus changing the focusing properties of the lens.

If the expansions of ψ given by Eqs. (4) and (5) are known, $\Phi(\psi)$ can be expanded in a power series

$$\Phi(\psi) = \Phi(\psi_0) + \left.\frac{d\Phi}{d\psi}\right|_{\psi_0}\psi_1 y + \left(\left.\frac{d\Phi}{d\psi}\right|_{\psi_0}\psi_2 + \left.\frac{d^2\Phi}{d\psi^2}\right|_{\psi_0}\psi_1^2\right)\frac{y^2}{2} + \cdots \tag{8}$$

For axial lenses the coefficients Φ_{2n+1} (n = 0, 1, 2,...) are zero.

EQUATIONS OF MOTION

Taking account of the cyclic nature of the coordinate φ we write the equations of motion in the form[8]

$$M\ddot{r} = -\frac{\partial v}{\partial r} - \frac{l}{c}\dot{z}H_\varphi, \tag{9a}$$

$$M\ddot{z} = -\frac{\partial v}{\partial z} + \frac{l}{c}\dot{r}H_{\varphi}, \tag{9b}$$

$$Mr^2\dot{\varphi} + \frac{e}{c}\psi = D = \text{const}, \tag{9c}$$

where v is the generalized potential

$$v = \frac{\left(D - \frac{l}{c}\psi\right)^2}{2Mr^2} + l\Phi(\psi), \tag{10}$$

and D is the generalized momentum.

Since we are interested in the geometry of ion trajectories it is expedient to change from the variable t to z. As a result, (9a) and (9b) are replaced by

$$r'' + r'\frac{\ddot{z}}{\dot{z}^2} = -\frac{1}{M\dot{z}^2}\frac{\partial v}{\partial r} - \frac{l}{M_e}\frac{H_{\varphi}}{\dot{z}}. \tag{11}$$

The equation for $\dot{z}$ can be obtained from the conservation of energy:

$$\frac{M}{2}\dot{z}^2(1 + r'^2) = -u, \tag{12}$$

where u ≡ v − ε, and ε is the total ion energy.

Eliminating $\ddot{z}$ and $\dot{z}^2$ by using (9b) and (12) we obtain

$$r'' = -\frac{1 + r'^2}{(-2u)}\left(\frac{\partial v}{\partial r} + r'\frac{\partial v}{\partial z}\right) - \left(\frac{eH_{\varphi}}{M_e}\right)^2 \frac{(1 + r'^2)^{3/2}}{\left(-\frac{2u}{M}\right)^{1/2}}. \tag{13}$$

In order to obtain the equation of motion in the paraxial approximation we expand the generalized potential v in a series, substitute it into (13), and retain terms linear in y. For axial systems we obtain

$$u = -\varepsilon + \frac{r^2}{2}v_2 + 0(r^4), \tag{14}$$

where

$$v_2 = \frac{e^2}{M_e^2}\frac{\psi_2^2}{4}, \tag{14a}$$

while for annular systems we have

$$u = -\varepsilon + v_0 + yv_1 + \frac{y^2}{2}v_2, \tag{15}$$

$$v_0 = \frac{\left(D - \frac{l}{c}\psi_0\right)^2}{2MR^2} + e\Phi(\psi_0), \tag{15a}$$

$$v_1 = \frac{\left(D\frac{l}{c}\psi_0\right)^2}{2MR^2} + \frac{l}{M_e}\frac{\psi_1\left(D - \frac{l}{c}\psi_0\right)}{R^2} + e\frac{d\Phi}{d\psi}\Big|_{\psi_1}, \tag{15b}$$

$$v_2 = 3\frac{\left(D - \frac{l}{c}\psi_0\right)^2}{MR^4} + \frac{1}{MR^2}\frac{l^2}{c^2}\psi_1^2 + \frac{l}{c}\frac{D\frac{l}{c}\psi_0}{MR^2}\left(\frac{4\psi_1}{R} - \psi_2\right)$$
$$+ e\left(\frac{d\Phi}{d\psi}\Big|_{\psi_0}\psi_2 + \frac{d^2\Phi}{d\psi^2}\Big|_{\psi_0}\psi_1^2\right). \tag{15c}$$

Substituting Eqs. (15) into (13) and linearizing, we obtain the equation in the paraxial approximation:

$$y'' + ay' + by + c = 0. \tag{16}$$

For annular lenses

$$a = -\frac{1}{M}\frac{v_0'}{\left(-\frac{2}{M}u_0\right)}, \quad b = \frac{1}{M}\frac{1}{\left(-\frac{2}{M}u_0\right)}\left(v_2 - \frac{v_1^2}{u_0}\right)$$
$$+ \left(\frac{eH_{\varphi 0}}{M_e}\right)^2 \frac{1}{\left(-\frac{2u_0}{M}\right)^{1/2}}\left(-\frac{2}{R}\frac{1}{2}\frac{v_1}{u_0}\right); \quad c = \frac{1}{M}\frac{v'}{\left(-\frac{2}{M}u_0\right)} + \frac{\left(\frac{eH_{\varphi 0}}{Mc}\right)^2}{\left(-\frac{2u_0}{M}\right)^{1/2}}, \tag{17}$$

$u_0 = v_0 - \varepsilon$, $H_{\varphi 0} = H_{\varphi}|_{r = R}$. If the lenses are axial, $v_0 = v_1 = 0$, $H_{\varphi} = 0$, $a = 0$, $c = 0$.

GAUSSIAN DIOPTRICS

We consider plasma lenses as analogs of thick optical lenses and describe them from the point of view of Gaussian dioptrics, introducing the cardinal elements – the focal lengths, nodal points etc. For generality we keep annular lenses in mind. The transition to axial lenses is made by letting R → 0.

We write the solution of Eq. (16) in the form

$$y = A_{q_1}(z) + B_{q_2}(z) + y_{\text{med}}, \tag{18}$$

where y_{med} is a particular solution of the inhomogeneous equation in (16), q_1 and q_2 are linearly independent solutions of the homogeneous equation in (16) for c = 0, and A and B are arbitrary constants that depend on the initial conditions.

We choose the boundary conditions of the function y_{med} as follows:

$$y'_{\text{med}}(-\infty) = y'_{\text{med}}(+\infty) = 0. \tag{19a}$$

Then the surface determined by the set of lines y_{med} will be the analog of the optical axis – the fundamental surface.

It is convenient to choose the functions $q_1(z)$ and $q_2(z)$ as basis functions relative to the fundamental surface, setting the boundary conditions equal to

$$q_1(-\infty) = 1, \; q_1'(-\infty) = 0, \; q_2(+\infty) = 1, \; q_2'(+\infty) = 0. \tag{19b}$$

The optical properties of a thick lens are completely determined by the asymptotic forms of the function q_1, q_2, and y_{med}. The starting and focal points in this case are conjugate points in the Gaussian sense, as follows from the linearity of Eq. (16).

If we introduce the focal lengths F_1 and F_2 (Fig. 1) the asymptotic forms of the functions $q_1(z)$ and $q_2(z)$ are

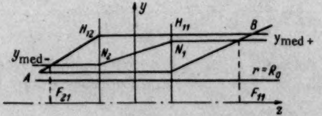

Fig. 1

$$q_1=\begin{cases}1, \\ \alpha_1\left(1-\frac{z}{F_1}\right),\end{cases} \quad q_2=\begin{cases}\beta_1\left(1+\frac{z}{F_2}\right) & (z\ll-\Lambda), \\ 1 & (z\gg\Lambda),\end{cases} \tag{20}$$

Λ is a characteristic dimension of the focusing fields along the initial surface, and F_1 and F_2 are measured from the plane z = 0. If we find d_1, β_1, F_1, and F_2 from (18) it is easy to determine the remaining cardinal elements of the lens. For example, the coordinates of the fundamental planes H_1 and H_2 are

$$H_1(z)=(d_1-1)\frac{F_1}{d_1}, \quad H_2(z)=-(\beta_1-1)\frac{F_2}{\beta_1}. \tag{21}$$

The principal points lie on the intersections of the fundamental planes with the "lines" $y_{\text{med}}(-\infty)$ and $y_{\text{med}}(+\infty)$. The construction of the image in a thick lens using the cardinal elements is shown in Fig. 1. It is frequently more convenient to find the asymptotic forms of the functions $q_1(z)$, $q_2(z)$, and y_{med} rather than F_1, F_2, d_1, and β_1. Then d_1 and β_1 are found by the points of intersection of the lines $q_1(-\infty)$, $q_1(+\infty)$, and $q_2(-\infty)$, $q_2(+\infty)$, and the focal lengths are

$$\frac{1}{F_1}=-\frac{q_1'(-\infty)}{\alpha_1}, \quad \frac{1}{F_2}=-\frac{q_2'(-\infty)}{\beta_1}. \tag{22}$$

WEAK FIELD APPROXIMATION

Since an exact analytic solution of Eq. (18) generally cannot be found, we present a method for finding the approximate form of the functions q_1, q_2, and y_{med}. In this method, the ratio of the change in particle velocity in the lens δv to the total velocity v_0 appears as a small parameter

$$\mu=\frac{\delta v}{v_0}\ll 1. \tag{23}$$

Thus we can seek a solution of Eq. (18) in the form of a series in inverse powers of v_0. For example

$$y=y_0+\frac{1}{v_0}y_1+\frac{1}{v_0^2}y_2+\ldots. \tag{24}$$

We apply the weak field method to determine the functions q_1, q_2, and y_{med}, assuming for simplicity that $H_\varphi = 0$. To do this we expand the coefficients *a*, b, and c in Eq. (17) in powers of v_0^{-2}. Taking account of the fact that

$$\frac{1}{\left(-\frac{2}{M}u\right)}=\frac{1}{v_0^2-\frac{2}{M}v}=\frac{1}{v_0^2}\left(1+\frac{2v}{Mv_0^2}+\cdots\right), \tag{25}$$

we obtain

$$a=\frac{a_1}{v_0^2}+\frac{a_2}{v_0^4}+\cdots=\frac{1}{v_0^2}\left(-\frac{1}{M}\frac{dv_0}{dz}\right)+\frac{1}{v_0^4}\left(-\frac{2v_0}{M^2}v_0'\right)+\ldots, \tag{26a}$$

$$b=\frac{b_1}{v_0^2}+\frac{b_2}{v_0^4}+\ldots+\frac{1}{v_0^2}\left(\frac{v^2}{M}\right)+\frac{1}{v_0^4}\left(\frac{2}{M}(v_1^2+v_0v_2)\right)+\ldots, \tag{26b}$$

$$c=\frac{c_1}{v_0^2}+\frac{c_2}{v_0^4}+\ldots=\frac{1}{v_0^2}\left(\frac{1}{M}v_1\right)+\frac{1}{v_0^4}\left(\frac{2}{M^2}v_1v_0\right)+\ldots. \tag{26c}$$

The functions q_1 and q_2 satisfy the homogeneous equation (18) for c = 0 with boundary conditions (19b):

$$q''+aq'+bq=0. \tag{27}$$

In order to use Eqs. (26) we write (27) in the form

$$q_1=1-\int_{-\infty}^{z}dz_1\int_{-\infty}^{z_1}dz_2\left[\left(\frac{a_1}{v_0^2}+\frac{a^2}{v_0^4}+\ldots\right)q_1'+\left(\frac{b_1}{v_0^2}+\frac{b_2}{v_0^4}+\ldots\right)q_1\right]. \tag{28a}$$

The expression for q_2 is similar except for the limits of integration :

$$q_2=1-\int_{+\infty}^{z}dz_1\int_{+\infty}^{z_1}dz_2\left[\left(\frac{a_1}{v_0^2}+\frac{a}{v_0^4}+\ldots\right)q_2'+\left(\frac{b_1}{v_0^2}+\frac{b_2}{v_0^4}+\ldots\right)q_2\right]. \tag{28b}$$

We seek the solution of (28a) in the form

$$q_1=q_{10}+q_{11}+q_{12}+\ldots. \tag{29}$$

Substituting (29) into (28a) we obtain

$$q_{10}=1, \tag{30a}$$

$$q_{11}=-\frac{1}{v_0^2}\int_{-\infty}^{z}dz\int_{-\infty}^{z}dz_2b_1, \tag{30b}$$

$$q_{12}=-\frac{1}{v_0^4}\left[\int_{-\infty}^{z}dz_1\int_{-\infty}^{z_1}dz_2b_2-\int_{-\infty}^{z}dz_1\int_{-\infty}^{z_1}dz_2a_1\int_{-\infty}^{z_2}dz_3b_1\right.$$
$$\left.-\int_{-\infty}^{z}dz_1\int_{-\infty}^{z_1}dz_2b_1\int_{-\infty}^{z_2}dz_3\int_{-\infty}^{z_3}dz_4b_1\right]. \tag{30c}$$

The expression for q_2 is similar. The function y_{med} differs from q_1 and q_2 by the boundary condition (19a) and therefore cannot be calculated by the Cauchy method, i.e., solution (28) is useless in this case. However, as before this function can be sought in the form of a series

$$y_{\text{med}}=y_{\text{med}\,0}+\varepsilon y_{\text{med}\,1}+\cdots+\varepsilon\sim\frac{1}{v_0^2}, \tag{31}$$

where successive terms of the series decrease rapidly with increasing v_0, and the first term y_{med} can be considered constant.

We again write Eq. (18) in integral form but now take account of the free term c(z). For condition (19a) we obtain

$$y_{\text{med}}=y_{\text{med}}(-\infty)-\int_{-\infty}^{z}dz_1\int_{-\infty}^{z_1}dz_2(ay'_{\text{med}}+by_{\text{med}}+c). \tag{32a}$$

$$y'_{\text{med}}(z)=-\int_{-\infty}^{z}dz_1(ay'_{\text{med}}+by_{\text{med}}+c). \tag{32b}$$

The equation for y'_{med} is obtained by taking account of the fact that a second boundary condition is imposed on this function at $z = -\infty$.

Substituting expansion (31) into (32) and using the fact that[2] y_{med} = const we obtain the equation for this quantity:

$$0=\int_{-\infty}^{+\infty}(b_1y_{\text{med}\,0}+c_1)\,dz. \tag{33a}$$

Hence using (26) we obtain

$$y_{\text{med}} = -\frac{\int\limits_{-\infty}^{+\infty} c_1 dz}{\int\limits_{-\infty}^{+\infty} b_1 dz} = -\frac{\int\limits_{-\infty}^{+\infty}}{\int\limits_{-\infty}^{+\infty} v_2 dz}. \tag{33b}$$

It follows from (33b) that $y_{\text{med}0}$ for $H_\varphi = 0$ does not depend on the mass or the velocity of the particles, i.e., the fundamental surface for a thin lens is an exact analog of the optical axis.

Knowing $y_{\text{med}0}$ and substituting it into (32a) we find the more accurate value $y_{\text{med}1}$:

$$y_{\text{med}\,1} = y_{\text{med}\,1}(-\infty) - \frac{1}{v_0^2}\int\limits_{-\infty}^{z} dz_1 \int\limits_{-\infty}^{z_1} dz_2 (b_1 y_{\text{med}\,0} + c_1)$$

$$\equiv y_{\text{med}\,1}(-\infty) + \tilde{y}_{\text{med}}. \tag{34a}$$

Here $y_{\text{med}1}(-\infty)$ must be determined from the condition

$$y'_{\text{med}\,1}(+\infty) = 0. \tag{35}$$

It is convenient to write $y_{\text{med}1}(-\infty)$ in the form

$$y_{\text{med}\,1}(-\infty) = y_{\text{med}\,0} - \delta y_1. \tag{34b}$$

Substituting (34b) into (32b) and using (35) we obtain

$$\delta y_1 = -\frac{\int\limits_{-\infty}^{+\infty} dz\,(a_1 \tilde{y}'_{\text{med}\,1} + b_1 \tilde{y}_{\text{med}\,1} + c)}{\int\limits_{-\infty}^{+\infty} b_1 dz}. \tag{36}$$

The expressions are simplified for axial lenses since $v_0(z)$ and $v_1(z)$ are identically zero. Therefore in the present case we obtain

$$q_1 = 1 - \frac{1}{Mv_0^2}\int\limits_{-\infty}^{z} dz_1 \int\limits_{-\infty}^{z_1} dz_2 v_2$$

$$-\frac{1}{(Mv_0^2)^2}\int\limits_{-\infty}^{z} dz_1 \int\limits_{-\infty}^{z_1} dz_2 v_2 \int\limits_{-\infty}^{z_2} dz_3 \int\limits_{-\infty}^{z_3} dz_4 v_2, \tag{37a}$$

$$y_{\text{med}0} = 0. \tag{37b}$$

FOCAL LENGTH OF LENSES

The focal length is determined by Eqs. (22), where, in the weak field approximation, the functions $q_1(z)$ and $q_2(z)$ can be found from Eqs. (30). Taking the right-hand focus F_1 for definiteness we find the value of a in this approximation. The equation for a follows from (20) and can be written as

$$a = \lim (q_1 - zq_1'), \quad z \to \infty. \tag{38}$$

Substituting (28a) into (38) we obtain

$$a = 1 + \int\limits_{-\infty}^{0} dz_1 \int\limits_{-\infty}^{z_1} dz_2 f(z_2, q_1) - \int\limits_{0}^{\infty} dz_1 \int\limits_{z_1}^{\infty} dz_2 f(z_2, q_1), \tag{39}$$

where

$$f(z_2, q_1) = \left(\frac{a_1}{v_0^2} + \frac{a_2}{v_0^4} + \dots\right) q_1' + \left(\frac{b_1}{v_0^2} + \frac{b_2}{v_0^4} + \dots\right) q_1.$$

Thus the required quantity F_1 is

$$\frac{1}{F_1} = -\frac{q_1'(+\infty)}{a} =$$

$$-\frac{\int\limits_{-\infty}^{+\infty} dz f(z_1, q_1)}{1 + \int\limits_{-\infty}^{0} dz_1 \int\limits_{-\infty}^{z_1} dz_2 f(z_2, q_1) - \int\limits_{0}^{\infty} dz_1 \int\limits_{z_1}^{\infty} dz_2 f(z_2, q_1)}. \tag{40a}$$

The equation for F_2^0 is similar:

$$\frac{1}{F} = -\frac{q_2'(-\infty)}{b} =$$

$$-\frac{\int\limits_{-\infty}^{+\infty} dz_1 f(z_1, q_2)}{1 + \int\limits_{\infty}^{0} dz_1 \int\limits_{\infty}^{z_1} dz_2 f(z_2, q_2) - \int\limits_{0}^{\infty} dz_1 \int\limits_{\infty}^{0} dz_2 f(z_2, q_2)}. \tag{40b}$$

Substituting into these expressions the explicit form of $f(z, q)$ and collecting terms with the same powers of v_0^2, we obtain expressions for the focal lengths as power series in v_0^2. Thus F_1 has the form

$$\frac{1}{F_1} = \frac{1}{Mv_0^2} W\Big|_{-\infty}^{+\infty} + \frac{1}{(Mv_0^2)^2} A + 0\left(\frac{1}{(Mv_0^2)^3}\right), \tag{41}$$

where

$$W = \int\limits_{-\infty}^{z} v_2 dz, \tag{42a}$$

$$A = 2\int\limits_{-\infty}^{+\infty} v_1^2 dz + 2\,[v_0 W]_{-\infty}^{+\infty} - W\Big|_{-\infty}^{+\infty} \int\limits_{-\infty}^{+\infty} W dz + \int\limits_{-\infty}^{+\infty} W^2 dz$$

$$-\int\limits_{-\infty}^{+\infty} W v_0' dz - W\Big|_{-\infty}^{+\infty}\left[\int\limits_{-\infty}^{0} W dz + \int\limits_{0}^{\infty} dz_1 \int\limits_{z_1}^{\infty} v_2 dz\right]. \tag{42b}$$

For axial lenses F_1 is given by

$$\frac{1}{F} = \frac{1}{Mv_0^2} W\Big|_{-\infty}^{+\infty} - \frac{1}{(Mv_0^2)^2} A_1 + 0\left(\frac{1}{Mv_0^2}\right)^3, \tag{43}$$

where

$$A = \int\limits_{-\infty}^{+\infty} W^2 dz + W\Big|_{-\infty}^{+\infty}\left(\int\limits_{-\infty}^{+\infty} W dz - \int\limits_{-\infty}^{0} W dz + \int\limits_{0}^{\infty} dz_1 \int\limits_{z_1}^{\infty} v_2 dz_2\right). \tag{44}$$

THIN ANNULAR BILENSES

1. Example of a magnetic bilens. As an example we find the focal length and position of the fundamental surface for an annular magnetic bilens. We specify the magnetic field of the bilens in the form

$$\psi_0 = H_0 R \Lambda \sqrt{\frac{e}{2}}\, e^{-z^2/\Lambda^2}, \quad \psi_1 = 0. \tag{45}$$

Here H_0 is a characteristic value of the magnetic field intensity on the initial surface, and Λ is a characteristic length of the field over the initial surface.

We assume that the electric field is zero. We assume that the bilens is thin, i.e., we retain only the first term in expansion (41). Substituting the expression for the magnetic field (45) into Eq. (41) for the focal length and integrating, we find

$$\frac{1}{F_1}=\frac{H_0^2 e_0^2 \Lambda^3}{c^2 (Mv_0)^2 R^3}\frac{e}{2}\sqrt{\frac{\pi}{2}}1+3\frac{\Lambda^2}{R^2}. \tag{46}$$

The position of the fundamental surface is given by Eq. (33b). We obtain

$$y_{\text{med}\,0}=\frac{\Lambda^2}{R}\frac{1}{1+\frac{3\Lambda^2}{R^2}}. \tag{47}$$

The paraxial condition (1) leads to a bound on the value of $y_{\text{med}0}$:

$$y_{\text{med}\,0}\ll R. \tag{48}$$

It follows from this that R must satisfy the inequality

$$\left(\frac{\Lambda}{R}\right)^2\ll 1. \tag{49}$$

As R increases $y_{\text{med}0} \to 0$ and the fundamental surface coincides with the initial surface. It is easy to see that for $\psi_1 = 0$ this is true for any field distribution H_r on the initial surface. Setting $\psi_1 = 0$ and integrating by parts we find for any ψ_0 we have

$$y_{\text{med}\,0}=\frac{\Lambda^2}{R}\frac{\int\limits_{-\infty}^{+\infty}\psi_0^2\,dz}{\int\limits_{-\infty}^{+\infty}\left(\psi_0'^2+3\frac{\Lambda^2}{R^2}\psi_0^2\right)dz}. \tag{50}$$

We note that in such lenses the fundamental surface is always above the initial surface ($y_{\text{med}0} > 0$).

2. Example of an electrostatic bilens. We assume that $H \to 0$ but is large enough to confine the space charge. Then the focusing will be determined by the magnitude and distribution of the electric field, i.e., the lens will be electrostatic. Retaining the shape of the magnetic field as given by (45) we specify the electric field distribution on the initial surface as[3)]

$$E_z=2E_0\frac{z^2}{\Lambda^2}e^{1-2z^2/\Lambda^2}. \tag{51}$$

Then substituting (51) into (42a) we find

$$W=e_0\int\limits_{-\infty}^{z}E_z\frac{1}{H_r}\frac{dH_r}{dz}dz=\frac{e_0E_z}{2}. \tag{52}$$

Since $E_z \big|_{-\infty}^{+\infty} = 0$, Eq. (43) shows that the focal length of the bilens $F_1 \sim v_0^4$. Substituting (52) into (43) we find that

$$\frac{1}{F_1}=\frac{3\sqrt{\pi}}{512}\frac{1}{\left(\frac{Mv_0^2}{2l_0}\right)^2}\frac{e_0^2\Phi_0^2}{\Lambda}, \tag{53}$$

where Φ_0 denotes the value of $E_0\Lambda$.

In order to make an electrostatic plasma bilens with a focal length $F \sim v_0^2$ the electric field must be eliminated from the defocusing parts of the magnetic bilens, e.g., by shortening the electrodes determining the electric field distribution. Thus taking the electric field distribution in the form

$$E_z=\sqrt{2e}E_0\frac{z}{\Lambda}e^{-z^2/\Lambda^2},\quad -\frac{\Lambda}{\sqrt{2}}>z,\quad z>\frac{\Lambda}{\sqrt{2}}, \tag{54a}$$

$$E_z=0,\quad -\frac{\Lambda}{\sqrt{2}}<z<\frac{\Lambda}{\sqrt{2}} \tag{54b}$$

and substituting (54) into (43) we obtain after integrating

$$\frac{1}{F}=\frac{\sqrt{2}}{(Mv_0^2)\,12e_0}\frac{\Phi_0}{\Lambda}. \tag{55}$$

It follows from Eqs. (53) and (55) that by changing the electric field distribution with respect to the magnetic lines of force it is possible to change the velocity dispersion as well as the focal length. We note also that an electrostatic bilens with fields (45) and (54) can be either converging or diverging.

[1)] Lenses which focus tenuous unneutralized charged-particle beams are called vacuum lenses.

[2)] Clearly $y_{\text{med}} = y_{\text{med}0}$ at $\varepsilon = 0$, but in this case $v_0 \to \infty$ and the trajectory is not perturbed.

[3)] Because of condition (7) the electric field distribution is generally arbitrary with respect to the lines of force.

Acousto-electric waves in conducting media

P. A. Andreev

M. I. Kalinin Leningrad Polytechnic Institute

(Submitted September 21, 1973)
Zh. Tekh. Fiz., 44, 1601-1607 (August 1974)

The instability excited by the transmission of an acoustic wave through a conducting medium is investigated. The critical values of the acoustic flux density at which the instability becomes absolute or convective are determined.

An acoustic wave propagating in a medium entrains charge carriers and produces a constant acousto-electric current $\mathbf{j}^{ae}$ or, in the case of an open circuit, a constant acousto-electric field $\mathbf{E}^{ae}$. The acousto-electric field can be represented in the form

$$\mathbf{E}^{ae} = \chi\mathbf{J} + \chi_1[\mathbf{J},\ \mathbf{H}_0] + \chi_2\mathbf{H}_0(\mathbf{J},\ \mathbf{H}_0), \qquad (1)$$

where $\mathbf{J}$ is the energy flux density of the acoustic wave and $\mathbf{H}_0$ is the external magnetic field.

A magnetohydrodynamic (MHD) theory of the acoustic electric effect has been formulated in the single-fluid and two-fluid MHD approximations.[1,2] Expressions have been derived for the coefficients $\varkappa$, $\varkappa_1$, and $\varkappa_2$ in these approximations. It has been shown[2] that acoustic streaming can generate waves and magnetic field structures. In the present paper we investigate the stabilities of the magnetic field (Sec. 1). We also show that an acoustic flux can produce instability in a conducting medium (Sec. 2).

1. ANALYSIS OF INSTABILITIES

We assume that an acoustic wave with an energy flux density J propagates in a conducting medium in the x direction. The external magnetic field $\mathbf{H}_0$ is directed along the y axis. We have previously[2] derived a dispersion relation from the linearized equations for small deviations of the magnetic field $\mathbf{H}'$, the electric field $\acute{E}$, and the current $\mathbf{j}'$ under the stated assumptions. It is assumed that $|\mathbf{k}_H| \ll |\mathbf{k}|$, $\omega_H \ll \omega$ (where $\mathbf{k}_H$ is the wave vector for the generated wave, $\mathbf{k}$ is the wave vector for the transmitted wave, and ω_H, ω are the corresponding wave frequencies). This dispersion relation is extremely cumbersome, so that the nature of the instability is investigated in the same special cases as in ref. 2.

1. $k_H \equiv k_x$. In this case the dispersion relations obtained in ref. 2 can be written in the form

$$\omega_H = c|\chi_1|Jk_H - i\left(\frac{c^2\rho}{4\pi}k_H^2 - 2c\gamma|\chi_1|J\right), \qquad (2)$$

$$\omega_H = c|\chi_1|Jk_H - i\left[\frac{c^2k_H^2}{4\pi}(\rho + \rho_2H_0^2) - 2c\gamma|\chi_1|J\right], \qquad (3)$$

where ρ and ρ_2 are the ordinary and the focused resistivities, γ is the attenuation of the transmitted wave, and $\chi_1 < 0$.

We assume the external magnetic field to be weak, i.e., $\rho/\rho_2H_0^2 \gg 1$. We can then limit the analysis to an instability with the dispersion relation (2). For an acoustic flux density

$$J > \frac{c\rho k_H^2}{8\pi\gamma|\chi_1|} \qquad (4)$$

the frequency ω has a positive imaginary part, indicating an instability. To calculate the character of that instability, following ref. 3, we find the inverse function

$$k_{H_{1,2}}(\omega_H) = -\frac{2\pi|\chi_1|J}{c\rho}i \pm \sqrt{\frac{4\pi}{c\rho}\left(\frac{i\omega}{c} + 2\gamma|\chi_1|J\right) - \left(\frac{2\pi|\chi_1|J}{c\rho}\right)^2}. \qquad (5)$$

The function $k_H(\omega_H)$ has a branch point at the frequency

$$\omega_H = iJ|\chi_1|c\left(2\gamma - \frac{\pi|\chi_1|J}{c\rho}\right). \qquad (6)$$

We consider the contour Ω described by the point ω_H in the complex plane given by Eq. (2) as the real variable k_H varies over the interval $-\infty \leq k_H \leq +\infty$. Putting $\omega_H = \alpha + i\beta$, we obtain the following equation for the portion of Ω that lies in the upper half-plane:

$$\beta = 2\gamma c|\chi_1|J - \frac{\rho}{4\pi}\left(\frac{\alpha}{|\chi_1|J}\right)^2. \qquad (7)$$

At the branch point $\omega_0 = \alpha_0 + i\beta_0$

$$\alpha_0 = 0,\quad \beta_0 = 2\gamma c|\chi_1|J - \frac{\pi}{\rho}(|\chi_1|J)^2, \qquad (8)$$

i.e., in accordance with ref. 3, the instability is convective for $J \geq 2\gamma c\rho/\pi|\chi_1|$ and absolute for $J < 2\gamma c\rho/\pi|\chi_1|$. We note that for (4) to be satisfied it is necessary that $\gamma/k_H > 0.25$ in the case of absolute instability (in the case of convective instability there are no constraints on the ratio γ/k_H). The range corresponding to the absolute instability is very narrow because the analysis is valid for $\gamma/k_H < 1$.

It is evident from an examination of (5) that the following inequalities hold for two waves with wave vectors $k_{H_1}(\omega_H)$ and $k_{H_2}(\omega_H)$ for $\mathrm{Im}\,\omega_H = 0$:

$$\mathrm{Im}\,k_{H_1}(\omega_H) < 0,\quad \mathrm{Im}\,k_{H_2}(\omega_H) < 0,$$

for waves where $\mathrm{Im}\,\omega_H \to \infty$ the appropriate inequalities are

$$\mathrm{Im}\,k_{H_1}(\omega_H) > 0,\quad \mathrm{Im}\,k_{H_2}(\omega_H) < 0.$$

Therefore, according to ref. 3, the solution $k_{H_1}(\omega_H)$ corresponds to wave amplification, and the solution $k_{H_2}(\omega_H)$ to cutoff.

2. $k_H \equiv k_z$ (for $k_H \equiv k_y$, as is shown in ref. 2, periodic field structures are excited). The dispersion relation for this case has the form

$$\omega_H = -2c\frac{|\chi|}{H_0}Jk_H - i\left(\frac{c^2\rho}{4\pi}k_H^2 - 2c\gamma|\chi_1|J\right). \qquad (9)$$

The value of the critical acoustic flux density at which the instability sets in is given by Eq. (2). The only difference is in the frequency of the waves. The instability is analyzed as in case 1. For

$$J < \frac{c\rho\gamma|\chi_1|}{2\pi}\left(\frac{H_0}{|\chi|}\right)^2, \quad \frac{\gamma}{k_H} > \frac{1}{4}\frac{|\chi|}{H_0|\chi_1|}$$

the instability is absolute, and for

$$J \geqslant \frac{c\rho\gamma|\chi_1|}{2\pi}\left(\frac{H_0}{|\chi|}\right)^2$$

it is convective. Note[2] that $|\chi|/H_0|\chi_1| \ll 1$, so that the range corresponding to the absolute instability is now much broader than in case 1.

The inverse of the function (9) has the form

$$k_{H_{1,2}}(\omega_H) = \frac{2\pi|\chi|J}{c\rho H_0}i \pm \sqrt{\frac{4\pi}{c\rho}\left(\frac{i\omega}{c} + 2\gamma|\chi_1|J\right) - \left(\frac{2\pi|\chi|J}{c\rho H_0}\right)^2}. \tag{10}$$

It is evident from an investigation of (10) that the solution $k_{H_1}(\omega_H)$ corresponds to cutoff, and the solution $k_{H_2}(\omega_H)$ to wave amplification.

3. We now consider the case in which the wave vector of the generated wave has two components. The simplest dispersion relations are obtained for $\mathbf{k}_H = (k_x, 0, k_z)$. Hereinafter, so as not to encumber the notation with subscripts, we write k instead of k_H. The dispersion relations now have the form

$$\omega = c|\chi_1|Jk_x - i\left[\frac{c^2k^2}{4\pi}(\rho + \rho_2H_0^2) - 2\gamma c|\chi_1|J\right], \tag{11}$$

$$\omega = cJ\left(|\chi_1|k_x - \frac{2|\chi|}{H_0}k_z\right) - i\left(\frac{c^2\rho}{4\pi}k^2 - 2\gamma c|\chi_1|J\right). \tag{12}$$

An instability arises when

$$J > \frac{ck^2(\rho + \rho_2H_0^2)}{8\pi\gamma|\chi_1|}$$

for the dispersion relation (11) and when

$$J > \frac{c\rho k^2}{8\pi\gamma|\chi_1|}$$

for the dispersion relation (12). Following ref. 4, we determine the character of the resulting instability as follows. If a magnetic field fluctuation occurs at time t = 0, being represented in the form

$$H'(r, 0) = \frac{1}{(2\pi)^3}\int H'(k)e^{i\mathbf{kr}}d^3k, \tag{13}$$

the magnetic field at time t is equal to

$$H'(r, t) = \frac{1}{(2\pi)^3}\int H'(k)e^{i\mathbf{kr} - i\omega(k)t}d^3k. \tag{14}$$

The initial fluctuation is finite in space; therefore the integral in (14) converges. We substitute the frequency given by (11) into (14):

$$H'(r, t) \sim \int H'(k)e^{i\left\{k_x x + k_z z - c|\chi_1|Jk_x t + it\left[\frac{c^2k^2}{4\pi}(\rho+\rho_2H_0^2) - 2c\gamma|\chi_1|J\right]\right\}}dk_x dk_z$$

$$\sim e^{2\gamma c|\chi_1|t - \frac{\pi(c|\chi_1|Jt - x)^2}{c^2(\rho+\rho_2H_0^2)t} - \frac{\pi z^2}{c^2(\rho+\rho_2H_0^2)t}}\int_{-\infty}^{+\infty}H'(\tilde{k})e^{-(\tilde{k}_x^2+\tilde{k}_z^2)}d\tilde{k}_x d\tilde{k}_z, \tag{15}$$

where $\tilde{k}_x$ and $\tilde{k}_z$ depend linearly on k_x and k_z, respectively. The integral in (15) converges. If the magnetic field fluctuation is not to be attenuated it is necessary that the exponent of the exponential function preceding the integral in (15) be nonnegative. This condition is satisfied by points inside the conic surface described by the equation

$$\frac{c^2(\rho + \rho_2H_0^2)}{\pi}\left[2\gamma c|\chi_1|J - \frac{(\pi c|\chi_1|J)^2}{c^2(\rho + \rho_2H_0^2)}\right] - z^2 - x^2 + 2c|\chi_1|Jtx \geqslant 0. \tag{16}$$

We consider the intersection of this cone with the plane z = 0 (Fig. 1). Two cases are possible, depending on the magnitude of J; in the first case (Fig. 1a) condition (16) is satisfied for a particular $x = x_0$ only in a definite time interval, i.e., the resulting magnetic field fluctuation exists at the given point only for a certain time; in the second case (Fig. 1b) condition (16) is satisfied for a particular $x = x_0$ after a time $t = t_1$, i.e., the fluctuation grows at its place of origin. Consequently, in the first case the system is convectively unstable, and in the second case it is absolutely unstable. It is inferred from (16) that the regions in which perturbations can propagate in the case of convective instability correspond to the points

$$|z| \leqslant ct\sqrt{\frac{2\gamma c|\chi_1|J(\rho + \rho_2H_0^2)}{\pi}}.$$

The existence of a convective instability requires that $J > 2c\gamma(\rho + \rho_2H_0^2)/\pi|\chi_1|$, and an absolute instability requires that $J \leq 2c\gamma(\rho + \rho_2H_0^2)/\pi|\chi_1|$ (here, as before, $\gamma/k > 0.25$). To investigate the possibility of wave amplification we find the inverse of the function (11). Inasmuch as $\omega = \omega(k_x, k_z)$, we consider the two inverse functions $k_z = k_z(\omega, k_x)$ and $k_x = k_x(\omega, k_z)$, treating the wave vector component entering into the right-hand sides of the equations as a parameter. The first equation has the form

$$k_{z_{1,2}} = \pm\sqrt{\frac{4\pi(i\omega - ic|\chi_1|Jk_x + 2\gamma c|\chi_1|J)}{c^2(\rho + \rho_2H_0^2)} - k_x^2}. \tag{17}$$

For any k_x we find that the following inequalities hold for two waves with wave vectors $k_{z_1}(\omega, k_x)$ and $k_{z_2}(\omega, k_x)$ when $\operatorname{Im}\omega = 0$ and $\operatorname{Im}\omega \to +\infty$:

$$\operatorname{Im}k_{z_1}(\omega, k_x) > 0, \quad \operatorname{Im}k_{z_2}(\omega, k_x) < 0.$$

Consequently, the system does not transmit waves along the z axis. The second equation is written in the form

$$k_{x_{1,2}} = -\frac{2\pi|\chi_1|i}{c(\rho + \rho_2H_0^2)} \pm$$

$$\pm\sqrt{\frac{4\pi}{c^2(\rho + \rho_2H_0^2)}\left(i\omega + 2\gamma c|\chi_1|J - \frac{\pi|\chi_1|}{\rho + \rho_2H_0^2}\right) - k_z^2}. \tag{18}$$

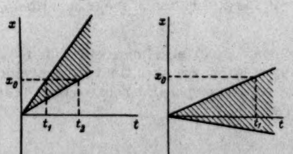

Fig. 1. a) Convective instability; b) absolute instability.

For any k_z, in the limit $\operatorname{Im}\omega \to +\infty$

$$\operatorname{Im} k_{x_1}(\omega, k_z) > 0, \quad \operatorname{Im} k_{x_2}(\omega, k_z) < 0.$$

If k_z is a real number, for $\operatorname{Im}\omega = 0$ we obtain $\operatorname{Im} k_{x_1} \cdot (\omega, k_z) < 0$ $\operatorname{Im} k_{x_2}(\omega, k_z) < 0$ for $k_z^2 < 8\pi\gamma|\chi_1| J/c(\rho + \rho_2 H_0^2)$ and $\operatorname{Im} k_{x_1}(\omega, k_z) > 0$, $\operatorname{Im} k_{x_2}(\omega, k_z) < 0$ for $k_z^2 > 8\pi\gamma|\chi_1| \cdot J/c(\rho + \rho_2 H_0^2)$.

Consequently, for $k_z^2 < 8\pi\gamma|\chi_1|J/c(\rho + \rho_2 H_0^2)$ the solution $k_{x_1}(\omega, k_z)$ corresponds to wave amplification, and the solution $k_{x_2}(\omega, k_z)$ to cutoff; for $k_z^2 > 8\pi\gamma|\chi_1|J/c(\rho + \rho_2 H_0^2)$ the system does not transmit waves along the x axis.

If k_z is imaginary, then for $\operatorname{Im}\omega = 0$

$$\operatorname{Im} k_{x_1}(\omega, k_z) < 0, \quad \operatorname{Im} k_{x_2}(\omega, k_z) < 0.$$

Consequently, the solution $k_{x_1}(\omega, k_z)$ corresponds to amplification, and the solution $k_{x_2}(\omega, k_z)$ to cutoff.

We investigate the character of the instability given by the dispersion relation (12) by the same procedure. The condition for the onset of instability is $J > c\rho k^2/8\pi\gamma \cdot |\chi_1|$.

For the magnetic field fluctuation we obtain the expression

$$H'(r, t) \sim e^{2\gamma c|\chi_1|Jt - \frac{\pi t}{\rho c^3}\left[\left(cJ|\chi_1| - \frac{x}{t}\right)^2 + \left(2cJ\frac{|\chi|}{H_0} + \frac{z}{t}\right)\right]^2} \times \int_0^\infty H'(\bar{k}) e^{-\bar{k}_x^2 - \bar{k}_z^2} d\bar{k}_x d\bar{k}_z. \tag{19}$$

The magnetic field fluctuation is unattenuated for points inside the conic surface (Fig. 2)

$$(x - cJ|\chi_1|t)^2 + \left(z + 2cJ\frac{|\chi|}{H_0}t\right)^2 - \frac{2\gamma c^3|\chi_1|\rho t^2}{\pi} \leqslant 0. \tag{20}$$

The axis of this cone is the line of interaction of the two planes $x = cJ|\chi_1|t$ and $z = -2cJ|\chi|t/H_0$. It is clear that an absolute instability occurs only when the onset conditions along the x axis and along the z axis are satisfied. Considering the intersections of the cone (20) with those planes we obtain the following conditions for the onset of the absolute instability: $J \leq 2\gamma c\rho/\pi|\chi_1|$, $\gamma/k > 0.25$, and for the onset of convective instability: $J > 2\gamma c\rho/\pi|\chi_1|$. The complexity of the dispersion relation (12) prevents us from carrying out a complete instability analysis. We merely note that this dispersion relation implies the existence of waves that are amplified in propagation.

2. EXCITATION OF INSTABILITY OF A MEDIUM

To find the condition for the onset of instability of a conducting medium we use the linearized system of equations for the perturbations of the velocity v', density of the medium ρ', pressure p', current, and magnetic and electric fields:

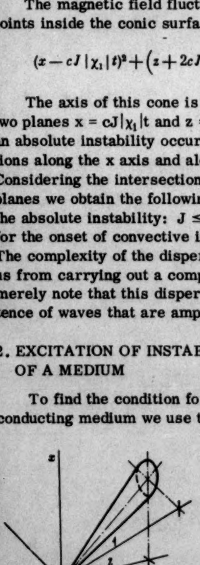

Fig. 2. Cone of instability in a conducting medium. 1) $x = cJ|\chi|t$; 2) $z = -2cJ(|\chi|/H_0)t$.

$$\left.\begin{aligned}
&\operatorname{curl}\mathbf{H}' = \frac{4\pi}{c}\mathbf{j}', \operatorname{curl}\mathbf{E}' = -\frac{1}{c}\frac{\partial\mathbf{H}'}{\partial t},\\
&\frac{\partial\rho'}{\partial t} = -\rho_0 \operatorname{div} v', \ \nabla p = u_0^2\nabla\rho',\\
&\frac{\partial\mathbf{v}'}{\partial t} = -\frac{\nabla p'}{\rho_0} - \frac{1}{4\pi\rho_0}[\mathbf{H}_0, \operatorname{curl}\mathbf{H}'] + \nu\nabla\mathbf{v}',\\
&\sigma\left(\mathbf{E} + \frac{1}{c}[\mathbf{v}', \mathbf{H}_0]\right) = \rho\mathbf{j}' + \rho_1[\mathbf{j}', \mathbf{H}_0] + \rho_2\mathbf{H}_0(\mathbf{j}', \mathbf{H}_0)\\
&\quad + \rho\lambda[\mathbf{J}, \mathbf{H}'] + 2\rho_1\lambda(\mathbf{H}', \mathbf{H}_0)\mathbf{J} - \rho_1\lambda\mathbf{H}_0(\mathbf{H}', \mathbf{J}),
\end{aligned}\right\} \tag{21}$$

where u_0 is the usual acoustic velocity in the medium, ρ_0 is the unperturbed density of the medium, ν is the kinematic viscosity, σ is the conductivity of the medium, and λ is the coefficient in the relation[2] $\mathbf{j}^{ae} = \lambda[\mathbf{J}, \mathbf{H}_0]$. The external magnetic field is perpendicular to the direction of propagation of the acoustic wave. We confine the analysis of the dispersion relation to special cases.

1. $k \equiv k_x$. In addition to the instabilities indicated in Sec. 1 an instability occurs in the medium with the dispersion relation

$$\begin{aligned}
&\omega^3 + [ik^2\nu_m - cJ|\chi_1|(k + 2i\gamma)]\omega^2\\
&- \left[\frac{H_0^2}{4\pi\rho_0} + u_0^2 + \nu\nu_m k^2 + \nu cJ|\chi_1|(2\gamma\right.\\
&\left. - ik)\right]k^2\omega - (i\nu_m k - cJ|\chi_1|)u_0^2 k^3 = 0,
\end{aligned} \tag{22}$$

in which ν_m is the magnetic viscosity. Requiring that $H_0^2/4\pi\rho_0 u_0^2 \ll 1$ and $\nu cJ|\chi_1|k/u_0^2 \ll 1$, we solve (22) by an iteration method.

For the roots $\omega_0 = \pm ku_0$, putting $\omega = \omega_0(1 + \alpha + i\beta)$, we obtain

$$\left.\begin{aligned}
&\alpha = \frac{1}{2(u_0^2 + k^2\nu_m^2)}\left[\frac{H_0^2}{4\pi\rho_0} + cJ|\chi_1|\nu\left(\frac{\nu_m k^3}{\omega_0} - 2\gamma\right)\right],\\
&\beta = \frac{\omega_0}{2(u_0^2 + k^2\nu_m^2)}\left[\nu\frac{cJ|\chi_1|k}{\omega_0}\left(1 + 2\gamma\frac{\nu_m k}{\omega_0}\right)\right.\\
&\qquad \left. - \nu\left(1 + \frac{\nu_m^2 k^4}{\omega_0^2}\right) - \frac{\nu_m k^2 H_0^2}{\omega_0^2 4\pi\rho_0}\right].
\end{aligned}\right\} \tag{23}$$

From (23) we find the following condition for the onset of instability:

$$J > \frac{\nu\left(1 + \frac{\nu_m^2 k^2}{u_0^2}\right) - \frac{\nu_m}{u_0^2}\frac{H_0^2}{4\pi\rho_0}}{\frac{\nu c|\chi_1|}{u_0}\left(1 + 2\gamma\frac{\nu_m}{u_0}\right)}. \tag{24}$$

If $\omega_0 = -u_0 k$, the instability condition assumes the form

$$J > \frac{\nu\left(1 + \frac{\nu_m^2 k^2}{u_0^2}\right) - \frac{\nu_m}{u_0^2}\frac{H_0^2}{4\pi\rho_0}}{\frac{\nu c|\chi_1|}{u_0}\left(2\gamma\frac{\nu_m}{u_0} - 1\right)}. \tag{25}$$

These conditions are compatible with the indicated constraints.

Using the system of equations (21), we can also obtain the ratio of the kinetic energy of the excited medium to the energy of the electromagnetic field:

$$\Gamma = \frac{\rho_0|\mathbf{v}'|^2/2}{|\mathbf{H}'|^2/8\pi} = \frac{1}{4\pi\rho_0}\left(\frac{H_0}{k\nu}\right)^2. \tag{26}$$

An estimate of the ratio Γ shows that in strong fields

$\Gamma \gg 1$, i.e., in transmitting an acoustic wave through a conducting medium we "drive" the medium and not the field.

2. $k \equiv k_y$. The dispersion relation for this case has the form

$$\omega\left(\omega + i\nu_m k^2 - \frac{H_0}{\sqrt{4\pi\rho_0}}k\right)\left(\omega + i\nu_m k^2 - \frac{H_0}{\sqrt{4\pi\rho_0}}k - 2\gamma c|\chi_1| J_i\right) + \frac{c^2\rho_1 H_0}{4\pi}k^2\left(2\gamma\frac{|\chi|}{H_0}J - \frac{c^2\rho_1 H_0}{4\pi}k^2\right) = 0. \tag{27}$$

A simple approximate solution is possible if we let $\omega = \omega_0(1 + \alpha + i\beta)$, where $\omega_0 = \pm H_0 k/\sqrt{4\pi\rho_0}$ is the magnetodynamic wave frequency (the relation $\sqrt{4\pi\rho_0}\,\nu_m k/H_0 \ll 1$ must also be satisfied). Under this assumption we obtain

$$\omega| = \left[\nu_m(\nu_m k^2 - 2\gamma|\chi_1|cJ) - \frac{c^2\rho_1 H_0}{4\pi}\left(\frac{c^2\rho_1 H_0}{4\pi}k^2 - \frac{|\chi|}{H_0}2\gamma cJ\right)\right] \times \frac{k^2}{2}\left(\frac{1}{2\omega_0} + i\frac{k^2}{\omega_0^2}\nu\right). \tag{28}$$

From (28) we obtain the following condition for the onset of instability:

$$J > \frac{ck^2}{8\pi\gamma}\,\frac{\rho_1^2 H_0^2 - \rho^2}{|\chi|\rho_1 - |\chi_1|\rho}. \tag{29}$$

From the system of equations (21) we find the following ratios for the given case:

$$\frac{u'}{w'} = \frac{\rho_1 k c^2}{2}\sqrt{\frac{\rho_0}{4\pi}},\quad \frac{H_z'}{H_x'} = \frac{\rho}{\rho_1 H_0},\quad \frac{v'}{w'} = \frac{H_y'}{H_x'} = 0,\qquad \Gamma = \frac{(H_x'^2 + H_z'^2)/8\pi}{\rho_0(u'^2 + w'^2)/2} = \left(\frac{\rho}{\rho_1 H_0}\right)^2, \tag{30}$$

where u', v', and w' are the velocity components along the x, y, and z axes, respectively. The ratios (30) have orders of magnitude far greater than unity.

3. $k \equiv k_z$. In this case we have the dispersion relation

$$\omega^3 + i\left[\nu_m k^2 - cJ\left(2\gamma|\chi_1| + ik\frac{|\chi|}{H_0}\right)\right]\omega^2 - \left\{\frac{H_0^2}{4\pi\rho_0} + u_0^2 + \nu\left[\nu_m k^2 - cJ\left(2\gamma|\chi_1| + ik\frac{|\chi|}{H_0}\right)\right]\right\}k^2\omega - iu_0^2 k^2\left[\nu_m k^2 - cJ\left(2\gamma|\chi_1| + ik\frac{|\chi|}{H_0}\right)\right] = 0. \tag{31}$$

As in case 1 of this section, we use the iteration method (assuming $\omega_0 = \pm u_0 k$) to obtain

$$\left.\begin{aligned}\alpha &= \frac{1}{2(u_0^2 + k^2\nu_m^2)}\left[\frac{H_0^2}{4\pi\rho_0} - \nu cJ\left(2\gamma|\chi_1| + \frac{\nu_m k^3}{\omega_0}\frac{|\chi|}{H_0}\right)\right],\\ \beta &= \frac{\omega_0}{2(u_0^2 + k^2\nu_m^2)}\left[\nu\frac{k}{\omega_0}cJ\left(\frac{2\gamma k\nu_m}{\omega_0}|\chi_1| - \frac{|\chi|}{H_0}\right) - \nu_m\frac{H_0^2}{4\pi\rho_0 u_0^2} - \nu\left(1 + \frac{\nu_m^2 k^2}{u_0^2}\right)\right].\end{aligned}\right\} \tag{32}$$

From (32) we find the instability condition

$$J > \frac{\nu\left(1 + \frac{\nu_m^2 k^2}{u_0^2}\right) + \frac{\nu_m}{u_0^2}\frac{H_0^2}{4\pi\rho_0}}{\frac{\nu ck}{\omega_0}\left(\frac{\nu_m k}{\omega_0}2\gamma|\chi_1| - \frac{|\chi|}{H_0}\right)}. \tag{33}$$

From (21) we obtain Γ, which turns out to be equal to the ratio (26).

I wish to thank I. V. Ioffe for valuable comments.

Equilibrium in a tokamak with noncircular cross section

L. E. Zakharov

(Submitted November 19, 1973)
Zh. Tekh. Fiz., 44, 1608-1613 (August 1974)

A general method is proposed for calculating the equilibrium in a toroidal configuration with noncircular cross section. Illustrative calculations are carried out for the equilibrium of a plasma in a chamber with cross section extended along the symmetry axis and in external fields.

In this work we describe a numerical method for solving problems dealing with the equilibrium of a plasma in an axisymmetric toroidal configuration. Interest in such problems has been revived because of experimental studies of plasma confinement in systems in which the plasma has a noncircular cross section (e.g., the "napkin ring" tokamak[1] in the USSR, the Ohkawa doublet[2] in the USA, and the belt-pinch[3] in the German Federal Republic) and because of the development of various axisymmetric diverters.[4] In the course of these studies problems related to the plasma equilibrium have arisen: producing a plasma with a specified cross section by means of a conducting wall or by a system of control windings and monitoring this cross section during the discharge.

Several numerical methods for analyzing plasma equilibrium in configurations in which the plasma has a noncircular cross section have now been reported. The most versatile of these methods appears to be that proposed by Hagenov and Lackner,[5] in which a solution is sought for the (generally nonlinear) equilibrium equation as an expansion in orthogonal polynomials. The simple iterative procedure used by Hagenov and Lackner converges well. This method can be used to analyze the equilibrium of a plasma both in a conducting wall and in an external field, without any restrictions on the cross-sectional shape of the plasma, the current distribution, or the pressure distribution.

Dnestrovskii et al.[6] based their analysis of the equilibrium in an ideally conducting wall on the time-dependent MHD equations incorporating an artificial dissipation. Their method has yielded several solutions for a toroidal plasma with elliptical cross section. However, this method is restricted to a certain class of analytically selected initial conditions, so that it cannot be used to solve equilibrium problems of a general nature.

We have developed a different method for studying the equilibrium in a tokamak with noncircular cross section; the method is based on the equilibrium equation written in integral form. An interative procedure which converges rapidly is used to solve this equation; on the BÉSM-6 computer a typical calculation requires only a few seconds. This integral-equation method is a general method and, in practice, is much simpler than the method of ref. 6. It does not seem to have any advantages over the method of ref. 5, but since it is an independent method and has already been used to study the equilibrium in a tokamak with noncircular cross section[7] we felt it worthwhile to report it.

1. EQUILIBRIUM EQUATIONS IN INTEGRAL FORM

We recall that the equilibrium equations for a plasma in an axisymmetric configuration reduce to a single equation for the flux function $\Psi(r, z)$, which is associated with the equilibrium poloidal field $\mathbf{B}(r, z)$ (ref. 8) (r, z, φ are the cylindrical coordinates; $\partial/\partial\varphi = 0$, $\mathbf{B} = (1/2\pi r)[\nabla\Psi \mathbf{e}_\varphi]$):

$$L\Psi = \frac{1}{r}\frac{\partial^2\Psi}{\partial r^2} - \frac{1}{r^2}\frac{\partial\Psi}{\partial r} + \frac{1}{r}\frac{\partial^2\Psi}{\partial z^2} = -\frac{8\pi^2}{c} j_\varphi$$

$$= -\frac{8\pi^2}{c}\left[A(\Psi) r + B(\Psi)\frac{1}{r}\right],$$

$$j_\varphi = j_\varphi(\Psi, r) = A(\Psi) r + B(\Psi)\frac{1}{r}. \tag{1}$$

The functions $A(\Psi)$ and $B(\Psi)$ are related to the pressure distribution $p(\Psi)$ and the distribution of the poloidal field, $I(\Psi)$, over the magnetic surfaces:

$$A(\Psi) = 2\pi c\frac{dp}{d\Psi}, \quad B(\Psi) = \frac{1}{c}\frac{dI^2}{d\Psi}. \tag{2}$$

We denote by $\Psi_0(r, z; r', z')$ and $b(r, z; r', z')$ the flux function and the magnetic field of a unit ring current at point (r', z') (we will use these functions below):

$$\left.\begin{aligned}
\Psi_0(r, z; r', z') &= \frac{8\pi}{c}\sqrt{\frac{rr'}{k^2}}\left[\left(1 - \frac{k^2}{2}\right)K(k) - E(k)\right],\\
b_r(r, z; r', z') &= \frac{2}{c}\frac{z}{\sqrt{(r + r')^2 + (z - z')^2}}\Big[-K(k)\\
&\quad + \frac{r'^2 + r^2 + (z - z')^2}{(r - r')^2 + (z - z')^2}E(k)\Big],\\
b_z(r, z; r', z') &= \frac{2}{c}\frac{1}{\sqrt{(r + r')^2 + (z - z')^2}}\Big[K(k)\\
&\quad + \frac{r'^2 - r^2 - (z - z')^2}{(r - r')^2 + (z - z')^2}E(k)\Big],\\
k^2 &= \frac{4rr'}{(r + r')^2 + (z - z')^2}.
\end{aligned}\right\} \tag{3}$$

Here and below the semicolon separates the coordinates of the observation point from the current coordinates.

a) Integral equation for the problem with an external field. We denote by Ψ_e the specified flux function of the external (confining) field, and we denote by Ψ_c the flux of the field produced by the plasma current j_φ. Then we have

$$\Psi_c(r, z) = \iint\limits_S \Psi_0(r, z; r', z')\, j_\varphi(\Psi_e + \Psi_c, r')\, dr'dz', \tag{4}$$

where j_φ is given by Eq. (1). Here, the integral is evaluated over the plasma cross section. The current density outside some magnetic surface Ψ_p corresponding to the plasma boundary must vanish:

$$j_\varphi(\Psi_e + \Psi_c, r) = 0 \text{ for } \Psi_e + \Psi_c \leqslant \Psi_p. \tag{5}$$

b) Integral equation for the equilibrium problem of a plasma in an ideally conducting wall. In this case the wall is a magnetic surface, and we can use $\Psi|_\Gamma = 0$ as a boundary condition (Γ is the contour of the wall cross section).

We denote by $\Psi_f(r, z; r', z')$ the fundamental solution of the problem

$$L_{r,z}\Psi_f(r,\ z;\ r',\ z') = -\frac{8\pi^2}{c}\delta(r-r')\delta(z-z'), \tag{6}$$

$$\Psi_f|_\Gamma = 0.$$

Then we can write the equilibrium equation for a plasma in a conducting wall as the nonlinear integral equation

$$\Psi(r,\ z) = \iint_S \Psi_f(r,\ z;\ r',\ z')\, j_\varphi(\Psi,\ r')\, dr'dz'. \tag{7}$$

Below we offer a different derivation of this equation, which yields an algorithm for calculating the kernel Ψ_f.

At the equilibrium of a plasma in an ideally conducting wall, the confining field is produced by the surface current of the wall i_φ, so that the flux function of the equilibrium field is the sum

$$\Psi = \Psi_c + \Psi_e, \tag{8}$$

where Ψ_c is given by (4) and where

$$\Psi_e(r,\ z) = \oint_\Gamma \Psi_0(r,\ z;\ l)\, i_\varphi(l)\, dl. \tag{9}$$

The current i_φ satisfies

$$\frac{2\pi}{c} i_\varphi(l) + \oint_\Gamma b_\tau(l;\ l')\, i_\varphi(l')\, dl' = -\iint_S b_\tau(l;\ r',\ z')\, j_\varphi(r',\ z')\, dr'dz', \tag{10}$$

$$b_\tau(l;\ r',\ z') = \mathbf{b}(l;\ r',\ z')[\mathbf{e}_\varphi \cdot \mathbf{n}(l)]$$

(**n** is the outward unit vector normal to the wall). Here, the left-hand side is the tangential component of the field of surface current i_φ at the outer side of Γ, and the right-hand side is equal in magnitude but opposite in sign to the tangential component of the field of the plasma current j_φ. Equation (10) must hold since there is no magnetic field outside the wall.

We denote by $\oint_\Gamma dl'K(l,\ l')$ the operator which is the inverse of that on the left-hand side of Eq. (10). It can be calculated on a computer by a standard method. Using this operator we find a linear relationship between the currents i_φ and j_φ:

$$i_\varphi(l) = -\oint_\Gamma dl'K(l,\ l') \iint_S b_\tau(l';\ r',\ z')\, j_\varphi(r',\ z')\, dr'dz'. \tag{11}$$

Equation (8) can be rewritten as

$$\Psi(r,\ z) = \iint_S \Psi_0(r,\ z;\ r',\ z')\, j_\varphi(\Psi,\ r')\, dr'dz'$$

$$-\oint_\Gamma dl\Psi_0(r,\ z;\ l) \oint_\Gamma dl'K(l,\ l') \iint_S b_\tau(l';\ r',\ z')\, j_\varphi(\Psi,\ r')\, dr'dz'. \tag{12}$$

Comparing with Eq. (7), we find an explicit equation for the kernel Ψ_f:

$$\Psi_f(r,\ z;\ r',\ z') = \Psi_0(r,\ z;\ r',\ z') - \oint_\Gamma\oint_\Gamma dl\,dl'\Psi_0(r,\ z;\ l)\, K(l,\ l')\, b_\tau(l';\ r',\ z'). \tag{13}$$

Since the magnetic field vanishes outside the wall, the boundary condition $\Psi_f|_\Gamma = 0$ is satisfied automatically.

We note that the kernel of Eq. (8), like that of (4), is a function of the geometry alone, so that once it is calculated for a specific geometry it can be used to analyze equilibrium situations with various current and pressure distributions. Despite the singularities of the kernels Ψ_f and Ψ_0 at r = r' and z = z', there is no difficulty in computer evaluation since these singularities are integrable. For a mesh containing ~ 120 internal mesh points and ~ 50 mesh points at the jacket surface, the calculation of Ψ_f requires 1.5 min on a BÉSM-6 computer.

c) Iteration scheme. In Secs. 2 and 3 below we illustrate the equilibrium calculations for a plasma in a jacket and in an external field. We describe the method for solving Eq. (8); with the obvious changes, this method can also be applied to Eq. (4).

We write the functional dependence of the current on Ψ in the form

$$j_\varphi(\Psi,\ r) = A\left(\frac{\Psi}{\Psi_{\max}}\right) r + B\left(\frac{\Psi}{\Psi_{\max}}\right)\frac{1}{r}. \tag{14}$$

where $\Psi_{\max}$ is the value of Ψ at the elliptical magnetic axis.

To solve Eq. (8) we use two iterative procedures,

$$1.\ \Psi_{n+1} = \iint \Psi_f j_\varphi(\Psi_n,\ r')\, dr'dz',$$

$$2.\ \Psi_{n+1} = \Psi_n + \delta\Psi,$$

determining δΨ from

$$\delta\Psi - \iint \Psi_f \frac{\partial j_\varphi}{\partial \Psi}\delta\Psi\, dr'dz' = \iint \Psi_f j_\varphi(\Psi_n,\ r')\, dr'dz' - \Psi_n.$$

In the course of the iteration the functions A and B can be assumed fixed or normalized in such a manner that the total current is conserved. The quantity $\Psi_{\max}$ serves as an eigenvalue. The initial current distribution is taken to be a homogeneous distribution or a distribution concentrated at a single point.

Procedure 1 requires ~ 30 iterations instead of the 2-10 iterations required in procedure 2, but less computer time is required.

2. Plasma equilibrium in an ideally conducting jacket.

As an example we consider the equilibrium of a force-free (∇p = 0) plasma in a wall with a racetrack cross section. Then the function A(Ψ) in Eq. (14) vanishes, and we choose the function B(Ψ) as follows (Fig. 1): for $\Psi < \Psi_p$ we have B(Ψ) = 0, and elsewhere this function is part of a parabola. We recall that the magnetic surface Ψ = 0 coincides with the wall, while the surface $\Psi = \Psi_{\max}$ coincides with the magnetic axis. The surface $\Psi = \Psi_p$ is the plasma boundary.

Figure 2 shows the results of the equilibrium calculation corresponding to three functions B(Ψ). In the first case the current fills the entire cross section of the wall, but in the second and third cases (Fig. 2a) there is a current-free region between the plasma and the wall. Figures

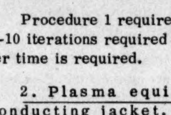

Fig. 1. Functional dependence of the current, $j_\varphi = B(\Psi)(1/r)$.

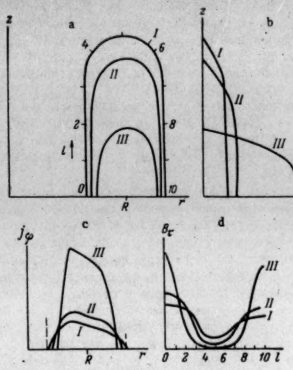

Fig. 2. Equilibrium in a conducting wall. a) Plasma cross sections; b) current distribution along z at r = R; c) current distribution along r at z = 0; d) distribution of the poloidal field at the inner surface of the wall.

2b and 2c show the current distributions j_ψ along z at r = R and along r at z = 0 corresponding to these cases. When the current is concentrated near the magnetic axis the ratio of the vertical dimension to the horizontal dimension decreases.

The problem of determining the characteristic parameters of a plasma cross section from measurements of the magnetic field outside the plasma has been discussed previously.[9] Figure 2d shows the distribution of the equilibrium field at the inner surface of the wall corresponding to the three cases under consideration here (the total current is the same in each case). The explicit functional dependence of the field distribution on the dimensions of the region through which the current flows is available so that we can determine the basic dimensions of the plasma for systems having an extended plasma cross section by means of simple probe measurements.

3. Equilibrium of a plasma in an external field. In systems designed for prolonged plasma confinement the equilibrium must be maintained by a system of control windings. Even in systems with walls these coils are required to maintain the extended shape of the plasma cross section.

The first question which arises in connection with the confinement of a plasma by external fields is that of the magnitudes of the currents in the control windings. Figure 3 shows the equilibrium force-free configuration in the field of three coils calculated on the basis of Eq. (4). In this calculation we assume a parabolic functional dependence $B(\Psi)$ and choose Ψ_p so that the plasma has the specified height. The current distribution in the plasma is shown in the same figure.

We see from these results that the currents in the coils used to extend the plasma cross section are no higher than the plasma current in this arrangement.

Figure 4 also shows a configuration which is not force-free, but with $\beta_p = 1$ (there are no poloidal currents in the plasma). Here we have $B(\Psi) = 0$, and $A(\Psi)$ is chosen to be parabolic. We choose the function Ψ_p so that the plasma has the same vertical dimension as in the preceding case. To balance the forces due to the pressure we are forced to increase the current in the third coil. Under these conditions both the position and shape of the plasma remain essentially unchanged. The current-density maximum in the case of a plasma with pressure is displaced outward from the symmetry axis.

This calculation shows that comparatively low currents are required to compensate for the plasma extension due to the pressure change; with $\beta_p \sim 1$, the currents required are of the order of 10% of the plasma current.

CONCLUSION

We have outlined a general method for solving fundamental problems dealing with plasma equilibrium in ax-

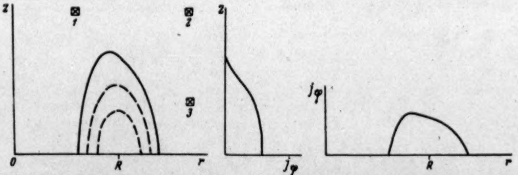

Fig. 3. Equilibrium of a force-free plasma in the field produced by three turns. $I_p = 1$, $I_1 = 0.75$, $I_2 = -0.15$, $I_3 = -0.175$, $\beta_p = 0$.

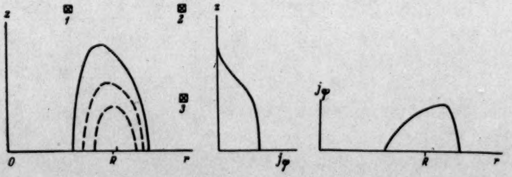

Fig. 4. Equilibrium of a plasma with $\beta_p = 1$ in the field produced by three turns. $I_p = 1$, $I_1 = 0.75$, $I_2 = -0.15$, $I_3 = -0.25$.

isymmetric toroidal configurations. By comparing the results found in equilibrium calculations for specific systems such as the tokamak with noncircular cross section with the experimental distribution of the magnetic field outside the plasma we can determine the dimensions of the region in which the current is concentrated. A comparison of this kind is reported in ref. 7. Calculations show that the functional dependence of the distribution of the poloidal field on the pressure is weak in the case $\beta_p \lesssim 1$. This functional dependence is evidently not a suitable basis for determining parameters such as β_J and β_p.

This method can be used to find the currents required in the control windings in order to produce a plasma cross section of the specified shape. We have shown that, for a particular arrangement, the currents in the windings required are no higher than the plasma current.

The author thanks V. D. Shafranov for his interest.

(Submitted September 19, 1973)
Zh. Tekh. Fiz., 44, 1614-1618 (August 1974)

The acceleration of a piston in a semiinfinite tube filled with a conducting gas is investigated in the presence of crossed electric and magnetic fields. The effects of the initial conditions on the distribution of the gas dynamic parameters behind the piston and on piston acceleration have been investigated. It is shown that the electromagnetic forces increase the piston velocity by a factor of one and a half as compared with the case of a nonconducting gas.

1. FORMULATION OF PROBLEM AND INITIAL EQUATIONS

The Lagrange problem in magnetohydrodynamics is formulated as follows: There is a semiinfinite tube in which a piston of mass M is placed at a distance L from the back wall. The space between the back wall and the piston is filled with a gas of mass m at pressure p_0, density ρ_0, temperature T_0, and conductivity σ_0. We assume that there is a vacuum to the right of the piston. If we take the x axis along the tube axis, and the external electric field E_0 (initially the current is distributed uniformly with density j_0) and the magnetic field H_0, respectively, along the y and z axes, then as a result of the pressure differential and the action of the electromagnetic forces the gas will move with velocity V and the piston will accelerate in the tube.

This problem is considered in ref. 1 for the case $\sigma = \infty$, and in refs. 2-4 for the case $\sigma = \text{const}$. The most interesting results based on the distribution of gasdynamic parameters and magnetic field in the space behind the piston are obtained in ref. 4. However, the functional dependence of the piston velocity is not treated. Moreover, the effect of a number of initial parameters on the acceleration of the piston, in particular the parameter $\mu = m/M$, has not been investigated.

In the present work we consider the case of variable gas conductivity and investigate the effect of all initial parameters.

We introduce the Lagrangians for the coordinate t and $\xi = \rho_0 x_0$ (x_0 is the initial coordinate of a particle) and the dimensionless variables

$$\left.\begin{aligned}&\mu=\frac{m}{M},\ t=\frac{a_0 t}{M}\left(a_0^2=\gamma\frac{p_0}{\rho_0}\right),\ x=\frac{\xi}{L\rho},\\ &V=\frac{U}{a_0},\ d=\frac{p}{\gamma p_0},\ D=\frac{1}{\gamma p_0}\left(p+\frac{H^2}{8\pi}\right)=d+\frac{h^2}{2},\\ &\nu=\frac{c^2}{4\pi\sigma a_0 L},\ r=\frac{\rho}{\rho_0},\ h^2=\frac{H^2}{4\pi\rho_0 a_0^2},\\ &h_0^2=\frac{H_0^2}{4\pi\rho_0 a_0^2},\ i=\sqrt{\frac{4\pi}{\rho_0}}\frac{L}{ca_0}j.\end{aligned}\right\} \tag{1.1}$$

Then, according to refs. 4 and 5, the initial equations, and the initial and boundary conditions, are written (dropping the bars over the dimensionless quantities):

$$\frac{\partial V}{\partial t}+\frac{\partial D}{\partial x}=0, \tag{1.2}$$

$$\frac{\partial}{\partial t}\left(\frac{1}{r}\right)=\frac{\partial V}{\partial x}, \tag{1.3}$$

$$\frac{\partial}{\partial t}(r^{-\gamma}d)=(\gamma-1)r^{2-\gamma}\nu i^2,\ i=-r\frac{\partial h}{\partial x}, \tag{1.4}$$

$$\frac{\partial}{\partial t}\left(\frac{h}{r}\right)=\frac{\partial}{\partial x}\left(\nu r\frac{\partial h}{\partial x}\right). \tag{1.5}$$

For t = 0, 0 ≤ x ≤ 1

$$h(0,\ x)=h_0+i_0(1-x),\ d=\frac{1}{\gamma},\ r=1,\ V=0. \tag{1.6}$$

For t > 0, x = 0

$$h-\frac{a_0 r\nu}{c}\frac{\partial h}{\partial x}=h_0-\frac{a_0\nu}{c}i_0,\ V=0, \tag{1.7}$$

for x = 1

$$\left(1-\frac{a_0\nu}{c}\right)h+\frac{a_0 r\nu}{c}\frac{\partial h}{\partial x}=h_0-\frac{a_0\nu}{c}i_0,\ \frac{\partial V}{\partial t}=\mu d. \tag{1.8}$$

Thus, the problem reduces to the solution of the system (1.2)-(1.8), in which the gas conductivity is a function of temperature and pressure (or density).

2. DETERMINATION OF GAS CONDUCTIVITY

The exact calculation of the conductivity of a partially ionized gas is rather complicated; therefore, we use the approximate relation[6]

$$\frac{1}{\sigma}=\frac{1}{\sigma_p}+\frac{1}{\sigma_s}, \tag{2.1}$$

where σ_p is the conductivity of a fully ionized plasma with singly charged ions[7]

$$\sigma_p=\frac{0.591\,(\pi\varepsilon)^2(kT)^{3/2}}{m^{1/2}e^2\ln\left[\frac{12\,\pi\varepsilon kT}{e^2}\sqrt{\frac{\varepsilon kT}{n_e e^2}}\right]}\ (\Omega\cdot\text{m}^{-1}), \tag{2.2}$$

and σ_s is the conductivity of a weakly ionized plasma[8]

$$\sigma_s=\frac{3\sqrt{2}}{2}\sqrt{\frac{kT}{\pi m_e}}\frac{e^2}{(n_e Q_e+n_a Q_{en})}. \tag{2.3}$$

Here, ε is the dielectric constant of the plasma; m_e and n_e are the mass and density of electrons, respectively; k is the Boltzmann constant; Q_e is the Coulomb cross section for the interaction of charged particles

$$Q_e=0.8\left(\frac{e^2}{4\pi\varepsilon kT}\right)^2\ln\left[\frac{12\pi\varepsilon kT}{e^2}\sqrt{\frac{\varepsilon kT}{n_e e^2}}\right], \tag{2.4}$$

Q_{en} is the cross section for the interaction of electrons

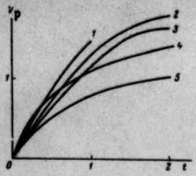

Fig. 1. Profiles of dimensionless piston velocities V_p as a function of dimensionless time t for given current i_0 ($i_0 = 1.0$, $\mu = 3$) and different initial magnetic fields. h_0: 1) 1.1, 2) 0.22, 3) 0; 4) $\sigma = \infty$, 5) $\sigma = 0$.

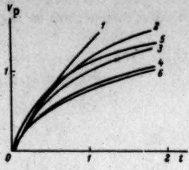

Fig. 2. Profiles of dimensionless piston velocities V_p as a function of dimensionless time t for given magnetic field h_0 ($h_0 = 0.8$, $\mu = 3$) and different initial currents. i_0: 1) 1.0, 2) 0.8, 3) 0.5, 4) 0.2; 5) $\sigma = \infty$, 6) $\sigma = 0$.

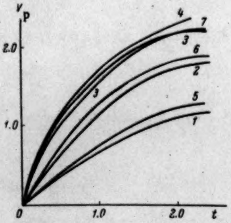

Fig. 3. Profiles of dimensionless piston velocities V_p as a function of dimensionless time t for given current i_0 ($i_0 = 1.0$) and different initial magnetic fields h_0 ($h_0 = 0.22$ and 0.55) and ratio of mass of gas to mass of piston. μ: 1, 5) 1; 2, 6) 3; 3, 7) 7; 4) 10. 1-4) $h_0 = 0.22$, 5-7) $h_0 = 0.55$.

with neutrals. The values of Q_{en} for different gases are given, e.g., in ref. 9. In particular, for helium, which is widely used in light-gas guns, in the range $5.5 \cdot 10^3 \le T \le 2.2 \cdot 10^4$, the quantity Q_{en} is well approximated by a polynomial[10] of third degree in T.

3. CALCULATION RESULTS

Several schemes have been developed[4,11-13] for the numerical solution of one-dimensional nonstationary problems of magnetohydrodynamics. In the calculations we have approximated the "gasdynamic" equations according to the scheme of Courant, Isaacson, and Rees[11] with first-order accuracy, and we have approximated the equations of magnetic induction by an implicit scheme of second-order accuracy, and solved them by a pivotal method.[4] The corresponding boundary conditions were also approximated with the same order of accuracy. All the calculations are carried out on a BÉSM-4 computer for helium for $L = 10^2$ cm, $T_0 = 10^4$°K, and $p_0 = 10^3$ atm.

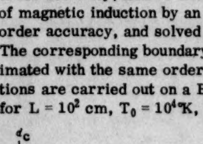

Fig. 4. Profiles of dimensionless values of pressure of gas on bottom of chamber d_c as a function of dimensionless time t for given current i_0 ($i_0 = 1.0$, $\mu = 3$) and different initial magnetic fields. h_0: 1) 1.1, 2) 0.22, 3) 0.

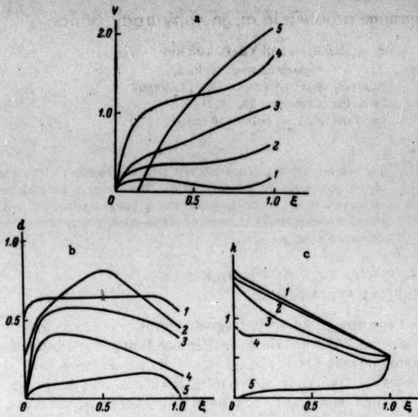

Fig. 5. Profiles of dimensionless values of velocity $V(\xi)$ (a) in the space behind the piston ($0 \le \xi \le 1$) at different dimensionless time t for given current i_0 and magnetic field h_0 ($i_0 = 1.0$, $h_0 = 0.55$), gas pressure $d(\xi)$(b), magnetic field $h(\xi)$ (c). t: 1) 0, 2) 0.4, 3) 0.8, 4) 1.6, 5) 3.2.

In order to investigate the effect of the initial parameters on the flow picture we carry out three series of calculations. In the first series we determine the effect of the initial magnetic field h_0 ($0.22 \le h_0 \le 1.1$; $3.15 \cdot 10^4$ Oe $\le H_0 \le 1.57 \cdot 10^5$ Oe; $0.04\, p_0 \le H_0^2/8\pi \le p_0$) for $\mu = 3$, $i_0 = 1.0$ ($j_0 = 3.44 \cdot 10^{12}\, 2^{1/2}$ cm$^{-1/2}$ sec^{-1}). In the second series we consider the dependence of the parameters on the initial current i_0($0.2 \le i_0 \le 1.0$) for $h_0 = 0.8$, $\mu = 3$. In the third series we study the effect of the quantity μ (μ = 1-10) for $h_0 = 0.22$, 0.55, and $i_0 = 1$. The principal results of the calculations are given in Figs. 1-5.

Figures 1-3 represent profiles of dimensionless piston velocities V_p as a function of time. For comparison we give the $V_p(t)$ profiles for $\sigma = \infty$($h_0 = 0.5$) and $\sigma = 0$.

Figure 4 gives profiles of dimensionless values of gas pressure on the bottom of the chamber $d_c(t)$ for different h_0 (for fixed i_0). Similar $d_c(t)$ profiles are obtained for different i_0 and fixed h_0.

Figure 5 represents the distributions of dimensionless velocities $V(\xi)$, gas pressure $d(\xi)$, and magnetic field $h(\xi)$ in the space behind the piston at different times for $h_0 = 0.55$ and $i_0 = 1$. Similar profiles of $V(\xi)$, $d(\xi)$, and $h(\xi)$ hold also for other values of h_0 and i_0.

The calculation results show that for a conducting gas we can obtain a piston velocity 1.5 times greater than for a nonconducting gas.

It is interesting to note that for the case $\sigma = \infty$ the piston velocity first increases more rapidly than for the case of finite conductivity, but then, more slowly (Figs. 1 and 2). This is explained as follows: With $\sigma = \infty$ the piston is first subject to a pressure $p_0 + H_0^2/8\pi$, and it is greater than for $\sigma = \infty$. With time, however, as the piston moves, the gas expands, and the gas pressure and magnetic field fall, (since the field is frozen in), and this fall occurs more strongly than for the case of finite conductivity; in the latter case the gas is still heated owing to the generation of Joule heat.

The dependence of $V_p(t)$ on μ, falls with increasing μ (Fig. 3) as for a nonconducting gas. Therefore, for practical purposes it is sufficient to take $\mu = 6$–7. Any further increase in μ leads to a small increase in piston velocity, but requires an expenditure of energy proportional to μ for the heating.

It follows from Fig. 5, a and b, that the distribution of velocity and pressure in the space behind the piston (unlike the case of a nonconducting gas) has a clearly nonmonotonic character. In time the magnetic field and velocity can change sign; reverse flows arise in the gas due to the retarding effect of the magnetic field and the generation of Joule heat. In a certain sense, a similar result (the presence of a zone with negative velocity on the bottom of the chamber) is obtained in ref. 14, where the acceleration of a piston by a nonconducting gas is considered, but with the introduction of heat. The profile of pressure has a maximum, the position and shape of which varies with time: At first, it is smeared out; then it becomes more sharply defined, and then it is displaced from the bottom of the chamber to the bottom of the piston.

(Submitted June 1, 1973)
Zh. Tekh. Fiz., 44, 1619-1624 (August 1974)

The electrohydrodynamic effect is considered for nematic crystals in parallel electric and magnetic fields, for piezoelectric nematic crystals, and for type C smectic crystals in an electric field. The critical fields are determined. It is shown that the effect is oscillational in piezoelectric crystals.

I. In this paper the electrohydrodynamic effect (EHDE) is investigated in nematic crystals in parallel electric and magnetic fields $\mathbf{E}_0$ and $\mathbf{H}_0$, and in piezoelectric nematic crystals and type C smectic crystals[1] in an electric field. The author knows of no other work concerned with EHDE in these cases. We present the results before turning to the calculations.

1. It is well known[2] that a homogeneous magnetic field exceeding a critical value H_c gives rise to the formation of domains in nematic crystals. A field $H_0 \leq H_c$ is considered here. It turns out that the critical electric field E_c for which the EHDE arises can be written in the form

$$E_c = E_c^0 \left[1 - \frac{H_0^2}{H_c^2}\right]^{1/2}, \tag{1}$$

when $\mathbf{E}_0 \parallel \mathbf{H}_0$, where E_c^0 is the field which gives rise to EHDE when $H_0 = 0$ and which is determined, for example in ref. 3. If we neglect the drift velocity of current carriers,[3,4] the EHDE also develops aperiodically when $H_0 \neq 0$. The amplitude of the hydrodynamic velocity $\mathbf{v}$ decreases as H_0 increases from zero to H_c with $\mathbf{v} = 0$ when $H_0 = H_c$. An EHDE is also not possible in nonconducting crystals when $H_0 = 0$; only the formation of "electric" domains similar to the magnetic domains[2] is possible. The critical fields required for the formation of electric domains when $H_0 = 0$ and $H_0 \neq 0$ are also related through Eq. (1).

2. In piezoelectric nematic crystals, one ordinarily assumes[5,6] a dependence on a single coordinate for the components of the vector $\mathbf{n}$, which leads to the appearance of piezoelectric domains. If $\mathbf{n}$ depends on two coordinates and the electric field is greater than some critical field, the EHDE is possible. It is significant that the EHDE is possible in piezoelectric crystals in the absence of a conductivity even with an isotropic dielectric constant. The point is that even for the approximation used in refs. 5 and 6, when it is assumed that the relation $\beta_2 = -\beta_1 = \beta$ holds between the coefficients in the piezoelectric portion of the free energy density

$$F_\beta = -\beta_1 (\mathbf{E}\mathbf{n}) \operatorname{div} \mathbf{n} - \beta_2 (\mathbf{E}(\mathbf{n}\nabla)\mathbf{n}), \tag{2}$$

the curl of the piezoelectric force acting on the crystal is nonzero when $\mathbf{n} \neq \text{const}$. Therefore, for zero conductivity and, consequently, zero charge q, and with an isotropic dielectric constant with consequent absence of a fluctuation potential of the electric field φ, the creation of a fluctuation angle of rotation θ in the vector leads to motion of the liquid. This motion creates a frictional moment which gives rise, in turn, to the appearance of an angular moment proportional to θ. Since the piezoelectric force increases as the field increases, the fluctuation deflection is not damped for some field.

The critical electric field is

$$E_1 = \sqrt{\frac{K}{\rho}} \frac{\alpha}{\beta} k, \tag{3}$$

where K is the value of the elastic constant in the usual expansion of the free energy density in the Oseen–Frank approximation;[7,8] ρ is the density; α is a characteristic value for the coefficients of viscosity in the Navier–Stokes equation and the moment equations (the viscosity coefficients are much the same[3,9,10]); k is the wave vector for the fluctuation.

In piezoelectric crystals the EHDE is oscillational. The frequency of the oscillations is

$$\omega = \omega_0 = \frac{\beta k E_0}{\alpha}. \tag{4}$$

Assume that in the dielectric constant,

$$\varepsilon_{ik} = \varepsilon_\perp \delta_{ik} + (\varepsilon_\parallel - \varepsilon_\perp) n_i n_k \tag{5}$$

the anisotropic part $\varepsilon_a = \varepsilon_\parallel - \varepsilon_\perp \neq 0$; then Eq. (3) holds for the critical field only when $\beta > \alpha \sqrt{\varepsilon_a / 4\pi\rho}$. In the other limit ($E_c \simeq E_c^0$) the oscillatory EHDE arises at a frequency ω_0 given by Eq. (4).

When $\beta_+ = \beta_1 + \beta_2 \neq 0$, the EHDE is also possible in nonconducting crystals.[10]

Three cases should be distinguished. If $\beta_+ < \alpha/\sqrt{\rho}$, the EHDE is oscillatory at a frequency ω_0. The critical field is equal to E_c^0 when $\beta_2 < \alpha\sqrt{\varepsilon_a/4\pi\rho}$ and is

$$E_c \simeq \frac{\alpha k}{\sqrt{\rho}} \frac{\sqrt{K + \beta_+^2}}{\beta_2}$$

when $\beta_2 > \alpha\sqrt{\varepsilon_a/4\pi\rho}$.

If $\beta_2, \beta_+ > \alpha/\sqrt{\rho}$, the frequency is $\alpha k^2/\rho$ and

$$E_c \simeq \frac{\alpha k}{\sqrt{\rho}}.$$

In conducting piezoelectric crystals we confine ourselves to the cases in which the conductivity σ is considerably greater than all frequencies encountered in the problem. Then the results given above remain valid.

3. In type C smectic crystals the EHDE occurs only for finite conductivity. As usual,[11,12] we assume the free energy density is a function of the variation along the k axis of the angle of rotation Ω_i around the i axis: $d\Omega_i/dx_k$. Similarly, we expand the dielectric constant (conductivity) in a series[12] Ω_i:

$$\varepsilon_{ik}=\varepsilon_{ik}^0+\varepsilon_{ikl}\Omega_l+\varepsilon_{iklm}\Omega_l\Omega_m. \qquad (6)$$

The appearance of Ω_l leads to a change in ε_{ik} and σ_{ik} which leads to the appearance, in an external electric field, of a charge and fluctuation field in the same way that ε_a, $\sigma_a=\sigma_\parallel-\sigma_\perp$ leads to q, $\psi\neq 0$ in nematic crystals. The EHDE is therefore possible in this case also. It is aperiodic and the critical field is $\sqrt{a/\varepsilon k}$, where a is the constant in the expansion of the free energy density over $\Omega_{i,k}=\partial\Omega_i/\partial x_k$.

Only the linear theory in constant homogeneous fields is considered here. Everywhere in the calculations the problem is discussed without consideration of boundary conditions; all fluctuation quantities are taken as $\sim\exp[i\cdot(kr-\omega t)]$. The values of the components of the wave vector k are taken to be of the same order of magnitude except where specifically stated otherwise.

II. Let $E_0\parallel H_0\parallel Ox$. Assuming $k=k_x, 0, k_n$, we write a linearized system of equations for the EHDE. Since the effect is aperiodic, $\partial/\partial t\equiv 0$ and for

$$\sigma_{ik}=\sigma_\perp\delta_{ik}+\sigma_a n_i n_k, \qquad (7)$$

$$n_x=\sin\theta\simeq\theta,\ n_z=\cos\theta\simeq 1 \qquad (8)$$

we have the continuity equation for the current

$$\sigma_a(\mathbf{E}_0\nabla)\theta-\sigma_\parallel\frac{\partial^2\varphi}{\partial x^2}=\sigma_\perp\frac{\partial^2\varphi}{\partial z^2}=0, \qquad (9)$$

the Poisson equation

$$\varepsilon_a(\mathbf{E}_0\nabla)\theta-\varepsilon_\parallel\frac{\partial^2\varphi}{\partial x^2}-\varepsilon_\perp\frac{\partial^2\varphi}{\partial z^2}=4\pi q, \qquad (10)$$

the incompressibility equation

$$\frac{\partial v_x}{\partial x}+\frac{\partial v_z}{\partial z}=0, \qquad (11)$$

the equation for moment equilibrium

$$\frac{\varepsilon_a E_0\left(E_0\theta-\frac{\partial\varphi}{\partial x}\right)+\chi_a H_0[H_0\theta+H'_x]}{4\pi}-K\Delta\theta+\alpha_1\frac{\partial v_x}{\partial z}+\alpha_2\frac{\partial v_z}{\partial x}=0, \qquad (12)$$

the projection of the curl of the Navier–Stokes equation

$$E_0\frac{\partial q}{\partial z}+\sigma_\perp\left[\frac{H_0^2}{c^2}\frac{\partial v_x}{\partial z}-\frac{j_0H_0}{Nec^2}\frac{\partial H'_x}{\partial z}\right]+\alpha_3\frac{\partial^3 v_x}{\partial z^3}$$

$$+\alpha_4\frac{\partial^3 v_k}{\partial z\partial x^2}+\alpha_5\frac{\partial^3 v_z}{\partial x^3}+\alpha_6\frac{\partial^3 v_r}{\partial x\partial z^2}=0, \qquad (13)$$

$$E_0H_0\sigma_a\frac{\partial\theta}{\partial z}-H_0\sigma_\parallel\frac{\partial^2\varphi}{\partial x\partial z}-j_0\frac{\partial H'_x}{\partial z}=0 \qquad (14)$$

and the equation

$$\chi_\perp\frac{\partial H'_z}{\partial z}+\chi_\parallel\frac{\partial H'_x}{\partial x}+\chi_a H_0\frac{\partial\theta}{\partial x}=0. \qquad (15)$$

Here, j_0 is the stationary current; $\chi_a=\chi_\parallel-\chi_\perp$; $\sigma H_0/Nec\ll 1$,

$$\chi_{ik}=\chi_\perp\delta_{ik}+\chi_a n_i n_k \qquad (16)$$

is the magnetic susceptibility; N is the number of carriers.

It is clear from Eqs. (9)-(15) that when $\sigma_{ik}=0$ and $E_0=0$, it is possible that $\theta\neq 0$ for

$$H_0=H_c=\sqrt{\frac{4\pi K}{\chi_a}}\,k. \qquad (17)$$

Furthermore $H'_x=H'_z=v_x=v_z=\varphi=0$. Electric domains are possible if $H_0=0$, $E_0\neq 0$. For $\sigma_{ik}\neq 0$, we set $\mathbf{v}$, φ, θ, and $H'\sim\exp i(k_x x+k_z z)$, $k_x\simeq k_z\simeq k$, and assume that the quantity $K\sigma/\alpha c^2\ll 1$. Then, setting the determinant of the system (9)-(15) equal to zero, we obtain Eq. (1). When $E=E_c$

$$\frac{H'_x}{H_0}=-\frac{\sigma_a}{\sigma}\theta;\quad \frac{H'_z}{H_0}=\left(\frac{\chi_\parallel}{\chi_\perp}\frac{\sigma_a}{\sigma}-\frac{\chi_a}{\chi_\perp}\right)\theta$$

(everywhere, except for ε_a, σ_a, and χ_a, it is assumed $\varepsilon_\parallel=\varepsilon_\perp=\varepsilon$ etc.). The ratio $|H'/H_0|/|E'/E_0|\simeq|(\chi_a/\chi)(\varepsilon/\varepsilon_a)|\simeq 1$. Thus a magnetic field parallel to the electric field does not change the possibilities of the planar EHDE (depending only on x and z) or its aperiodic nature.

III. Using Eq. (2) in a piezoelectric crystal we find that the linearized system of equations consists of

$$\varepsilon_a(\mathbf{E}_0\nabla)\theta-\varepsilon_\parallel\frac{\partial^2\varphi}{\partial x^2}-\varepsilon_\perp\frac{\partial^2\varphi}{\partial z^2}+4\pi(\beta_1+\beta_2)\frac{\partial^2\theta}{\partial x\partial z}=4\pi q, \qquad (18)$$

$$\frac{\partial q}{\partial t}+\sigma_a(\mathbf{E}_0\nabla)\theta-\sigma_\parallel\frac{\partial^2\varphi}{\partial x^2}-\sigma_\perp\frac{\partial^2\varphi}{\partial z^2}=0, \qquad (19)$$

$$J\frac{\partial^2\theta}{\partial t^2}+\alpha_0\frac{\partial\theta}{\partial t}-K\Delta\theta+\alpha_1\frac{\partial v_x}{\partial z}+\alpha_2\frac{\partial v_z}{\partial x}+\frac{\varepsilon_a E_0}{4\pi}\left(E_0\theta-\frac{\partial\varphi}{\partial x}\right)$$

$$+(\beta_1+\beta_2)\left(E_0\frac{\partial\theta}{\partial z}-\frac{\partial^2\varphi}{\partial x\partial z}\right)=0, \qquad (20)$$

$$\frac{\partial^2 v_x}{\partial t\partial z}-\frac{\partial^2 v_z}{\partial t\partial x}+\alpha_3\frac{\partial^3 v_x}{\partial z^3}+\alpha_4\frac{\partial^3 v_x}{\partial z\partial x^2}+\alpha_5\frac{\partial^3 v_z}{\partial x^3}$$

$$+\alpha_6\frac{\partial^3 v_z}{\partial x\partial z^2}+E_0\frac{\partial q}{\partial z}+\beta_2E_0\frac{\partial^3\theta}{\partial x\partial z^2}=0 \qquad (21)$$

and the incompressibility equation (11).

We set $\mathbf{v}$, φ, θ, and $q\sim\exp i(k_x x+k_z z-\omega t)$. We are interested only in $\mathrm{Re}\,\omega$ and E_c, for which $\mathrm{Im}\,\omega=0$. Using the same approximations as in Sec. II we find an equation for the determination of the frequency in the case $\beta_+=\beta_1+\beta_2=0$ and $\sigma_{ik}=0$,

$$\omega^3-\left[\frac{\alpha^2k^2}{J\rho}+\frac{Kk^2}{J}-\frac{\varepsilon_a\varepsilon_\perp k^2E_0^2}{4\pi(\varepsilon_\parallel k_x^2+\varepsilon_\perp k_z^2)}\right]\omega-\frac{\beta_2\alpha E_0k^3}{J\rho}=0. \qquad (22)$$

We assume $k^2J/\rho\simeq(kl)^2\ll 1$ (l is the length of a molecule of the nematic crystal material), $\alpha^2\gg K\rho$, $\alpha k>E_0\sqrt{\rho}$ up to fields of the order of 3 kV/cm. Then the only real root of Eq. (22) is

$$\omega=\omega_0=\beta_2\frac{kE_0}{\alpha}.$$

Substituting this frequency value into the equation for the determination of E_c we have

$$\rho\omega^2-Kk^4+\frac{\varepsilon_a\varepsilon_\perp k^4E_0^2}{4\pi(\varepsilon_\parallel k_x^2+\varepsilon_\perp k_z^2)}=0. \qquad (23)$$

It is clear that for

$$\beta_2<\alpha\sqrt{\frac{\varepsilon_a\varepsilon_\perp k^2}{4\pi\rho\,[\varepsilon_\parallel k_x^2+\varepsilon_\perp k_z^2]}}\equiv\beta$$

one can neglect the term $\sim\omega^2$ and $E_c \simeq E_c^0$. For the opposite sign in the inequality

$$E_c=E_1=\frac{\beta}{\beta_2}E_c^0<E_c^0.$$

When $E_c = E_1$, $\omega \simeq \sqrt{K/\rho}\,k$. If $K \simeq 10^{-6}$ erg/cm and $k \simeq 10^3$ cm^{-1}, $\omega \simeq 1$ Hz. Note that if $\beta = 0$ but $\varepsilon_a \neq 0$, domains develop when $E = E_c^0$ in which θ and φ are nonzero but $\mathbf{v} \equiv 0$. When $\beta_2 < \bar{\beta}$ and $E \simeq E_c^0$, $\mathbf{v} \neq 0$ and EHDE occurs.

We turn to the case where $|\beta_+| \simeq |\beta_2|$.

The equation analogous to Eq. (22) is

$$\omega^3-\left[\frac{\alpha^2k^2}{J\rho}+\frac{Kk^2}{J}+\frac{\beta^2+k^2}{J}-\frac{\varepsilon_a\varepsilon_\perp k^2E_0^2}{4\pi(\varepsilon_\parallel k_x^2+\varepsilon_\perp k_z^2)}\right]\omega-\frac{\alpha\beta_2E_0k^3}{J\rho}=0. \qquad (24)$$

The ratio $\beta_+\sqrt{\rho}/\alpha$ is important. If it is smaller than unity and $\beta_2 > \alpha\sqrt{\varepsilon_a/4\pi\rho}$, then $\omega = \omega_0$ and

$$E_c\simeq\frac{\alpha k}{\beta_2}\sqrt{\frac{K+\beta_+^2}{\rho}}.$$

When $\beta_2 < \alpha\sqrt{\varepsilon_a/4\pi\rho}$, $\omega = \omega_0$ and

$$E_c=E_c^0\sqrt{\frac{K+\beta_+^2}{K}}.$$

For the case $\beta_+ > \alpha/\sqrt{\rho}$ we find a real root of Eq. (24),

$$\omega=\frac{\alpha k}{\rho}\frac{\beta_2}{\beta_+^2}E_0.$$

Substituting this value in the equation

$$\omega^2-\frac{(K+\beta_+^2)k^4}{J\rho}+\frac{\varepsilon_a\varepsilon_\perp k^2E_0^2}{4\pi(\varepsilon_\parallel k_x^2+\varepsilon_\perp k_z^2)}\frac{1}{J\rho}+\frac{\beta kE\omega}{\alpha}=0, \qquad (25)$$

we find that the EHDE at a frequency $\omega = \alpha k^2/\rho$ is possible when $E_0 > k\beta_+^2/\beta_2$. Since $|\beta_+| \simeq |\beta_2|$ by assumption and $\beta > \alpha/\sqrt{\rho}$, the required $E_0 > \alpha k/\sqrt{\rho}$. In this case, the frequency $\omega \simeq \alpha k^2/\rho$. If $\alpha \simeq 10^{-2}$ g/cm · sec and $k \simeq 10^3$ cm^{-1} $E_c \simeq$ kV/cm [sic] $\omega \simeq 10^4$ sec^{-1}. The inhibition of the EHDE with increasing β_+ is reasonable if one recalls that piezoelectric domains form more easily when $\beta_+ = 0$ (generally, there are no domains when $\beta_1 = \beta_2$). When $\sigma \neq 0$ we limit our considerations to $\sigma \gg \alpha/J$, $E/\sqrt{J}$, $k\beta/\sqrt{J}$; then $\sigma \gg \omega$, as shown by calculation.

In this case we find that the equations for the determination of frequency and E_c agree with Eqs. (22)-(25) when ε_a is replaced by $(\varepsilon_\parallel\sigma_\perp - \varepsilon_\perp\sigma_\parallel)(k^2)/(\sigma_\parallel k_x^2 + \sigma_\perp k_z^2)$. Therefore the results obtained above are also valid for this case.

IV. In smectic type C crystals, we use the usual axial directions.[11,12] Then the nonzero coefficients a_{iklm} in the expression for the elastic portion of the free energy density,

$$F_{el}=\frac{a_{iklm}}{2}\Omega_{i,k}\Omega_{e,m} \qquad (26)$$

are known.[11,12] Assuming that $\sigma_{xy}^0 = \sigma_{zy}^0 = \varepsilon_{xy}^0 = \varepsilon_{zy}^0 = 0$, we determine the nonzero values of $\varepsilon_{ikl}(\sigma_{ikl})$ and ε_{iklm} · (σ_{iklm}) which appear in Eq. (6) and in the electric portion of the free energy density,

$$F_E=\frac{1}{8\pi}\left\{\varepsilon_{iklm}E_iE_k\Omega_l\Omega_m-\varepsilon_{ikl}\left(E_i\frac{\partial\varphi}{\partial x_k}+E_k\frac{\partial\varphi}{\partial x_i}\right)\Omega_l\right\}, \qquad (27)$$

$$\begin{gathered}
\varepsilon_{zxy}=-\varepsilon_{xzy}=-2\varepsilon_{xz}^0;\ \varepsilon_{xyx}=\varepsilon_{yxx}=-\varepsilon_{xz}^0,\\
\varepsilon_{xyz}=\varepsilon_{yxz}=\varepsilon_{xx}^0-\varepsilon_{yy}^0;\ \varepsilon_{zzy}=\varepsilon_{zxy}=\varepsilon_{xx}^0-\varepsilon_{zz}^0,\\
\varepsilon_{yxz}=\varepsilon_{zyx}=\varepsilon_{yy}^0-\varepsilon_{zz}^0;\ \varepsilon_{zyz}=\varepsilon_{yzz}=\varepsilon_{xz}^0,\\
\varepsilon_{xxxz}=-\varepsilon_{xx}^0;\ \varepsilon_{yyxz}=-\varepsilon_{yy}^0;\ \varepsilon_{zzxz}=-\varepsilon_{zz}^0,\\
\varepsilon_{xxzz}=\varepsilon_{yyxz}=\varepsilon_{zz}^0-\varepsilon_{yy}^0,\\
\varepsilon_{xxyy}=-\varepsilon_{zzxx}=\varepsilon_{zz}^0-\varepsilon_{xx}^0,\\
\varepsilon_{zxxz}=\varepsilon_{xxzx}=\varepsilon_{yyzz}=\varepsilon_{yyzx}=\varepsilon_{zzxz}=\varepsilon_{zzzx}=2\varepsilon_{xz}^0,\\
\varepsilon_{xzxz}=\varepsilon_{xzzx}=\varepsilon_{zxxz}=\varepsilon_{zxzx}=\varepsilon_{xyxy}=\varepsilon_{xyyx}\\
=\varepsilon_{yxyx}=\varepsilon_{yxxy}=\varepsilon_{yzyz}=\varepsilon_{yzzy}\\
=\varepsilon_{zyzy}=\varepsilon_{zyyz}=\varepsilon_{xx}^0+\varepsilon_{yy}^0+\varepsilon_{zz}^0,\\
\varepsilon_{yzyx}=\varepsilon_{zyyx}=\varepsilon_{yzxy}=\varepsilon_{zyxy}=\varepsilon_{xz}^0,\\
\varepsilon_{yzxz}=\varepsilon_{zyxz}=\varepsilon_{yzzx}=\varepsilon_{zyzx}=\varepsilon_{xx}^0.
\end{gathered} \qquad (28)$$

The calculation shows that the EHDE is aperiodic in smectic type C crystals. Then, following refs. 9-12, we write the moment of the viscous stresses and the moment of the viscous forces in the forms

$$\pi_{ik}=\alpha_{iklm}^{(1)}\left[\frac{\partial v_l}{\partial x_m}+\frac{\partial v_m}{\partial x_l}\right]+\alpha_{iklm}^{(2)}e_l[\operatorname{curl}\mathbf{v}\cdot\mathbf{e}]_m+\alpha_{iklm}^{(3)}e_m[\operatorname{curl}\mathbf{v}\cdot\mathbf{e}]_l, \qquad (29)$$

$$\Gamma_i=\alpha_1\operatorname{curl}\mathbf{v}+\alpha_2e_{i\,np}e_k\left(e_m,\frac{\partial v_m}{\partial x_p}+\frac{\partial v_p}{\partial x_m}\right)+\alpha_3e_i(\mathbf{e}\operatorname{curl}\mathbf{v}) \qquad (30)$$

(e_i is a unit vector along the i axis; $e_{i\,cr}$ is a unit antisymmetric tensor).

Considering Eqs. (26)-(30), the system of equations describing EHDE in smectic type C crystals consists of the equation for moment equilibrium

$$-\frac{\partial}{\partial\Omega_i}(F_{el}+F_E)+\Gamma_i=0, \qquad (31)$$

the equation of continuity

$$\sigma_{ik}\frac{\partial^2\varphi}{\partial x_i\partial x_k}-\sigma_{i\,cr}E_k\Omega_{p,i}=0, \qquad (32)$$

the Poisson equation

$$\varepsilon_{ik}\frac{\partial^2\varphi}{\partial x_i\partial x_k}-\varepsilon_{i\,cr}E_k^0\Omega_{p,i}+4\pi q=0, \qquad (33)$$

the incompressibility equation

$$\operatorname{div}\mathbf{v}=0 \qquad (34)$$

and the curl of the Navier–Stokes equation

$$[E_i\nabla q] + \operatorname{curl}\frac{\partial \pi_{ik}}{\partial x_k} = 0. \tag{35}$$

Assuming φ, Ω_i, v, and $q \sim e^{ikr}$ and equating the determinant of the system (31)-(35) to zero, we obtain an equation for the determination of the critical field,

$$(ak^2)^3 + b_1 (ak^2)^2 E_c^2 + b_2 ak^2 E_c^4 + b_3 E_c^6 = 0, \tag{36}$$

where a is a quantity of the order of a_{iklm} and $b_{1,2,3}$ are complicated quantities which are determined by the coefficients of viscosity and by the quantities $\varepsilon_{ik}(\sigma_{ik})$, $\varepsilon_{ikl}\cdot(\sigma_{ikl})$, and $\varepsilon_{iklm}(\sigma_{iklm})$. In order of magnitude, the quantities $b_{1,2,3} \simeq 1$. A solution of Eq. (36), if it exists, is of the form $E_c^2 \simeq ak^2b$. We shall show that a solution exists; for this, we consider the case $E^0 = E_z^0$, $k = k_x$, $v = v$, $\Omega_z = \Omega_y$. Then for $\varepsilon_{xx}, \varepsilon_{zz} \gg \varepsilon_{xz}$ and $\sigma_{xx}, \sigma_{zz} > \sigma_{xz}$, we find from Eqs, (26)-(35)

$$E_c^2 = a_{yxyx} k^2 \frac{\sigma_{xx}}{(\varepsilon_{xx}^0 - \varepsilon_{zz}^0)(\sigma_{zz}^0 - \sigma_{xx}^0)}$$

and EHDE is possible when $(\varepsilon_{xx}^0 - \varepsilon_{zz}^0)(\sigma_{zz}^0 - \sigma_{xx}^0) > 0$.

Assuming $a \simeq 10^{-6}$ erg · cm^{-1} and $k \simeq 10^3$ cm^{-1}, we find $E_c \simeq 10^2$ V/cm.

Effect of temperature-dependent conductivity on electromagnetic field, current, temperature, and impedance in a plane conductor. I

R. S. Kuznetskii

(Submitted May 10, 1973; resubmitted August 6, 1973)
Zh. Tekh. Fiz., 44, 1625-1632 (August 1974)

First-order corrections to the monochromatic electromagnetic field, the current density, and the distribution of the steady-state temperature in a plane conductor due to a linear temperature dependence of the conductivity are obtained in analytic form. The corrections are analyzed in detail, and curves are given.

INITIAL EQUATIONS

A monochromatic high-frequency electromagnetic field $\mathbf{E} = \mathbf{e}(z)\exp(i\omega\tau)$, $\mathbf{H} = \mathbf{h}(z)\exp(i\omega\tau)$, and the steady-state temperature t(z) due to the surface outflow of heat in a conducting plane layer (a slab) $|z| \leq a$, on the surface of which the tangential electric field $\mathbf{e}^0\exp(i\omega\tau)$ ($\mathbf{e}^0 = \mathrm{const}$, $\mathrm{Im}\,\mathbf{e}^0 = 0$) and the constant temperature [from which we calculate t(z)] are given, satisfy the following equations:[1,2]

$$e'' = i\mu\omega\sigma e, \quad t'' = -\frac{\sigma}{2\lambda}|e|^2, \tag{1}$$

where $h = i/\mu\omega e'$, and the current density $j = \sigma e = -h'$. The boundary conditions are $e(a) = e^0$, $t(a) = 0$, $e'(0) = 0$, $t'(0) = 0$. Here and below the monochromatically varying quantities are represented by their complex amplitudes: μ, λ and σ are the magnetic permeability, the thermal conductivity, and the conductivity of the conductor, respectively. The electric field (and the current density) are parallel to $\mathbf{e}^0$, and the magnetic field is perpendicular to $\mathbf{e}^0$ and parallel to the surfaces of the layer.[2,3]

We consider an extended conductor, one of the dimensions of which is small compared with the two others. If the formulation of the problem is physically associated with electromagnetic waves incident on a conductor we assume two plane waves with the same linearly polarized electric vector normally incident (the electric field, current, and temperature distribution in the conductor are symmetric, while the magnetic field distribution is asymmetric with respect to the central plane z = 0); $\mathbf{e}^0$ represents the total electric vector at the boundary. It should be noted, however, that there is generally no dependence on $\mathbf{e}^0$ in the above distributions (i.e., in the components of the complex surface impedance). The assumed constancy with time of the steady-state temperature of the conductor for high-frequency currents is provided by thermal inertia. The absolute temperature of the conductor surface can be found first by using the equation for heat balance between the conductor and the external medium (or by direct experimental measurement); it depends on the nature of the external surface heat exchange. This procedure does not present any difficulties, and will not be specifically considered in this communication, which is devoted purely to the internal problem.

We assume that the conductivity $\sigma(t)$ always depends on temperature with constant thermal conductivity $\lambda = \mathrm{const}$ (the case in which there is also a temperature dependence of thermal conductivity can, in principle, be reduced to the case considered in refs. 4 and 5). In this case Eq. (1) is nonlinear. We then have the problem of nonlinear macroscopic electrodynamics of a conducting solid,[6] which has not been considered in general form. The corresponding microscopic equations with a self-consistent $\sigma(t)$ have been studied in semiconductors.[7]

Equation (1) is solved in quadratures[8] for a steady-state boundary field ($\omega = 0$), and in finite analytic form for a constant conductivity ($\sigma = \mathrm{const}$, the "degenerate" linear case).[3] In more general cases Eq. (1) cannot be solved in quadratures. An approximate analytic solution (the first correction to the solution for $\sigma = \mathrm{const}$), similar to that given below, has been obtained for a semiinfinite conductor with plane boundaries ($a \to \infty$ with one of its surfaces fixed).[2] A similar problem has also been solved for a cylindrical conductor with constant[9] and monochromatic[10,11] boundary fields.

We introduce the following dimensionless quantities:

$$\left.\begin{aligned} z_* = \frac{z}{a}, \quad e_* = \frac{e}{e^0}, \quad h_* = \frac{a\mu\omega}{e^0}h, \quad j_* = \frac{j}{\sigma^0 e^0}, \\ t_* = \frac{2\lambda}{\sigma^0 (ae^0)^2}, \quad \sigma_* = \frac{\sigma}{\sigma^0}, \quad l^2 = a^2\frac{\sigma^0\mu\omega}{2}, \end{aligned}\right\} \tag{2}$$

where $\sigma^0 \equiv \sigma(0)$ and l is the ratio of a to the skin depth of the conductor $z \leq a$ for $\sigma \equiv \sigma^0$. The asterisks will be omitted below.

Equation (1) and the boundary conditions now take the form

$$e'' = 2il^2\sigma e, \quad t'' = -\sigma|e|^2, \tag{3}$$

$$e(1) = 1, \quad t(1) = e'(0) = t'(0) = 0, \quad 0 \leqslant z \leqslant 1, \tag{4}$$

where $h = ie'$, $h(0) = 0$; $j = \sigma e = -h'/2l^2$, $j(1) = 1$, $j'(0) = 0$. The dimensionless distributions of the electric and magnetic fields, the current, and the temperature in a plane conductor are determined below.

EXPRESSIONS FOR THE FIELDS AND THE TEMPERATURE IN THE FORM OF SERIES

We consider the linear dependence of the conductivity on temperature

$$\sigma = 1 - kt, \quad k \equiv \frac{\sigma^0 (ae^0)^2}{2\lambda}\alpha, \tag{5}$$

where $\alpha > 0$ is the temperature coefficient of conductivity. Hence, the frequency factor l and the dimensionless temperature coefficient of conductivity k [a measure of the degree of nonlinearity of the system of Eqs. (1) or (3)] are defining parameters in terms of the theory of similitude.

Assuming k to be a small parameter, and representing the solutions of Eqs. (3), h, and j in the form of series

$$e=\sum_{\rho=0} k^{\rho} e_{\rho}, \quad h=\sum_{\rho=0} k^{\rho} h_{\rho}, \quad j=\sum_{\rho=0} k^{\rho} j_{\rho}, \quad t=\sum_{\rho=0} k^{\rho} t_{\rho}, \tag{6}$$

we obtain the following linear differential equations for the coefficients:

$$\frac{i}{2l^2} e_s'' + e_s = p_s(z), \quad t_s'' = q_s(z) \tag{7}$$

(where $h_s = ie_s'$, $j_s = -h_s'/2l^2$), the right side of which,

$$p_s(z)=\sum_{\rho=0}^{s-1} t_\rho e_{s-\rho-1}, \quad q_s(z)=\sum_{m=0}^{s} e_m^* \left(\sum_{\rho=0}^{s} e_\rho t_{s-\rho-m-1} - e_{s-m}\right) \tag{8}$$

are defined by recursion relations in terms of the preceding coéfficients. The boundary conditions for e_s and t_s, which are identical with Eq. (4) for s = 0, vanish for s ≥ 1.

The solution of Eq. (7) is

$$e_s = C_s \operatorname{ch}(1+i) lz + \int_{\zeta=0}^{\zeta=z} p_s(\zeta)\, d \operatorname{ch}(1+i) l (\zeta - z), \quad j_s = p_s(z) + e_s, \tag{9}$$

$$h_s = (i-1) l \left[C_s \operatorname{sh}(1+i) lz + \int_{\zeta=0}^{\zeta=z} p_s(\zeta)\, d \operatorname{sh}(1+i) l (z-\zeta) \right], \tag{10}$$

$$t_s = \int_1^z d\zeta \int_0^{\zeta} q_s(\xi)\, d\xi, \tag{11}$$

the constant of integration being determined by the value of $e_s(1) = \delta_{0s}$:

$$C_s = \operatorname{ch}^{-1}(1+i) l \left[\delta_{0s} + \int_{\zeta=0}^{\zeta=1} p_s(1-\zeta)\, d \operatorname{ch}(1+i) l\zeta \right]. \tag{12}$$

In the zeroth approximation (s = 0) the quantities (9)–(11) take the well-known form[3]

$$e_0 = j_0 = \frac{\operatorname{ch}(1+i) lz}{\operatorname{ch}(1+i) l}, \quad h_0 = (i-1) l \frac{\operatorname{sh}(1+i) lz}{\operatorname{ch}(1+i) l},$$
$$t_0 = \frac{c_2(n) - c_2(nz)}{n^2 c_1(n)}. \tag{13}$$

In the same way[3] we have

$$n \equiv 2l, \quad c_{1,2}(\xi) = \operatorname{ch}\xi \pm \cos\xi, \quad s_{1,2}(\xi) = \operatorname{sh}\xi \pm \sin\xi. \tag{14}$$

For s ≥ 1 (9) and (10) take the form

$$e_s = \int_{\zeta=0}^{\zeta=z} p_s(\zeta)\, d \operatorname{ch}(1+i) l(\zeta - z)$$
$$+ \frac{\operatorname{ch}(1+i) lz}{\operatorname{ch}(1+i) l} \int_{\zeta=0}^{\zeta=1} p_s(1-\zeta)\, d \operatorname{ch}(1+i) l\zeta, \tag{15}$$

$$h_s = 2l^2 \left[\int_0^z p_s(\zeta) \operatorname{ch}(1+i) l(z-\zeta)\, d\zeta \right.$$
$$\left. - \frac{\operatorname{sh}(1+i) lz}{\operatorname{ch}(1+i) l} \int_0^1 p_s(1-\zeta) \operatorname{sh}(1+i) l\zeta\, d\zeta \right]. \tag{16}$$

In particular, in the median plane and on the surfaces of the plane layer we have

$$e_s(0) = \operatorname{ch}^{-1}(1+i) l \int_{\zeta=0}^{\zeta=1} p_s(1-\zeta)\, d \operatorname{ch}(1+i) l\zeta,$$
$$j_s(0) = p_s(0) + e_s(0), \tag{17}$$

$$h_s(0) = e_s(1) = j_s(1) = 0,$$
$$h_s(1) = 2l^2 \operatorname{ch}(1+i) l \int_0^1 p_s(\zeta) \operatorname{ch}(1+i) l\zeta\, d\zeta. \tag{18}$$

FIRST-ORDER CORRECTIONS TO THE FIELD, CURRENT, AND TEMPERATURE

We now obtain the first correction $(s = 1)$ to the zeroth approximation (13), proportional to k. Using the Puzyrevskii–Krylov functions

$$f_1(\xi) = \operatorname{ch}\xi \cos\xi, \quad f_{2,4}(\xi) = \operatorname{ch}\xi \sin\xi \pm \operatorname{sh}\xi \cos\xi, \quad f_3(\xi) = \operatorname{sh}\xi \sin\xi \tag{19}$$

and bilinear combinations

$$f^{\pm}_{abcd} \equiv f^{\pm}_{abcd}(l, z) = f_a(l) f_b(lz) \pm f_c(l) f_d(lz) \quad (f^{\pm}_{abcd} = \pm f^{\pm}_{cdab}) \tag{20}$$

from Eqs. (15), (16), and (11), we have

$$2n^2 c_1^2(n) \operatorname{Re} e_1 = [c_2(n) nz - s_2(nz)] f^-_{1433}$$
$$+ \frac{nc_2(n) - s_2(n)}{c_1(n)} \{f_3(n) f^-_{2143} - [f_1(n) + 1] f^+_{2341}\}$$
$$+ \frac{1}{5} \left\{ \left[12 \frac{f_1(n)+1}{c_1(n)} - c_1(n) + c_1(nz) \right] f^-_{1331} + 3 [c_2(n) - c_2(nz)] f^+_{1133} \right\},$$
$$2n^2 c_1^2(n) \operatorname{Im} e_1 = -[c_2(n) nz - s_2(nz)] f^+_{1234} \tag{21}$$

$$+ \frac{nc_2(n) - s_2(n)}{c_1(n)} \{f_3(n) f^+_{2341} + [f_1(n) + 1] f^-_{2143}\}$$
$$+ \frac{1}{5} \left\{ 3 \left[c_2(n) - c_2(nz) - 4 \frac{f_3(n)}{c_1(n)} \right] f^-_{1331} + [c_1(n) - c_1(nz)] f^+_{1133} \right\}, \tag{22}$$

$$4nc_1^2(n) \operatorname{Re} h_1 = 2 \left[c_2(n) nz - \frac{4}{5} s_2(nz) \right] f^+_{1133}$$
$$+ \frac{nc_2(n) - s_2(n)}{c_1(n)} \{[f_1(n) + 1] f^+_{2442} + f_3(n) f^-_{4422}\}$$
$$+ \frac{1}{5} \left\{ [c_1(n) - c_1(nz)] f^-_{1432} + 6 s_1(nz) f^-_{1331} \right.$$
$$\left. + \left\{ 12 \frac{f_3(n)}{c_1(n)} + 7 [c_2(n) - c_2(nz)] \right\} f^+_{1234} \right\}, \tag{23}$$

$$4nc_1^2(n) \operatorname{Im} h_1 = 2 \left[c_2(n) nz - \frac{4}{5} s_2(nz) \right] f^-_{1331}$$
$$+ \frac{nc_2(n) - s_2(n)}{c_1(n)} \{[f_1(n) + 1] f^-_{4422} - f_3(n) f^+_{2442}\}$$
$$+ \frac{1}{5} \left\{ 7 [c_2(n) - c_2(nz)] f^-_{1432} \right.$$
$$\left. + \left[12 \frac{f_1(n)+1}{c_1(n)} - c_1(n) + c_1(nz) \right] f^+_{1234} - 6 s_1(nz) f^+_{1133} \right\}, \tag{24}$$

$$j_1 = e_1 - e_0 t_0 = e_1 - \frac{c_2(n) - c_2(nz)}{2l^2 c_1^2(n)} (f^+_{1133} + i f^-_{1331}), \tag{25}$$

$$2n^4 c_1^2(n) t_1 = \left\{ \frac{nc_2(n) - s_2(n)}{2c_1^2(n)} [s_2(2n) - 2f_4(n)] \right.$$
$$\left. - \frac{1}{5} \left[6 \frac{f_3(n)}{c_1(n)} + 7c_2(n) \right] + 2c_2(n) \right\} [c_2(n) - c_2(nz)]$$
$$+ \frac{1}{10} \{4 [f_1(n) - f_1(nz)] + 3 [c_1(2n) - c_1(2nz)]\}$$
$$- nc_2(n) [s_1(n) - zs_1(nz)]. \tag{26}$$

The moduli $|e_1|$, $|h_1|$, $|j_1|$ and phases $\varphi_e = \arg e_1$, $\varphi_h = \arg h_1$, $\varphi_j = \arg j_1$ of the quantities e_1, h_1, j_1, and the temperature t_1 are shown in Fig. 1 for various values of the parameter l. In particular, on the surfaces of the plane layer of the quantities in Eqs. (21)-(26) only h_1 is nonzero:

$$4nc_1^2(n)\operatorname{Re}h_1(1)=[nc_2(n)-s_2(n)]\left[c_1(n)+\frac{5-3c_1(2n)+f_1(2n)}{8c_1(n)}\right]$$
$$+\frac{1}{5}\left[c_1(n)\,s_2(n)+6f_3(n)\frac{s_1(n)}{c_1(n)}\right], \tag{27}$$

$$4nc_1^2(n)\operatorname{Im}h_1(1)=\frac{3}{5}s_1(n)\left[2\frac{f_1(n)+1}{c_1(n)}-c_1(n)\right]$$
$$-\frac{nc_2(n)-s_2(n)}{2c_1(n)}f_3(n)[f_1(n)+3]. \tag{28}$$

For $l \ll 1$ (a thin layer, at low frequencies) we have

$$|e_1|\simeq\operatorname{Im}e_1\simeq\frac{l^2}{12}(1-z^2)(5-z^2),\quad \varphi_e\simeq\frac{\pi}{2}-\frac{l^2}{15}\frac{127-38z^2+7z^4}{5-z^2}, \tag{29}$$

$$|h_1|\simeq\operatorname{Re}h_1\simeq\frac{l^2}{3}z(3-z^2),\quad \varphi_h\simeq-\frac{l^2}{10}\frac{55-30z^2+7z^4}{3-z^2}, \tag{30}$$

$$|j_1|\simeq-\operatorname{Re}j_1\simeq t_0\operatorname{Re}e_0\simeq\frac{1}{2}(1-z^2),\quad \varphi_j\simeq\pi-\frac{l^2}{6}(11-7z^2), \tag{31}$$

$$t_1\simeq-\frac{1}{24}(1-z^2)\left[5-z^2-\frac{4}{525}l^4(1717-208z^2-33z^4+72z^6)\right]. \tag{32}$$

The ratios of the corrections to the corresponding quantities in the zeroth approximation, i.e.,[3]

$$|e_0|=|j_0|\simeq1,\quad |h_0|\simeq2l^2z,\quad t_0\simeq\frac{1}{2}(1-z^2), \tag{33}$$

are

$$\left|\frac{e_1}{e_0}\right|\simeq\left|\frac{j_1}{j_0}\right|\simeq|e_1|\simeq|j_1|,\quad \left|\frac{h_1}{h_0}\right|\simeq\frac{1}{6}(3-z^2),$$
$$\frac{t_1}{t_0}\simeq-\frac{1}{12}(5-z^2). \tag{34}$$

The limiting values of the corrections and their phases are

$$\lim_{l\to0}e_1=\lim_{l\to0}h_1=0,\quad \lim_{l\to0}\varphi_e=\frac{\pi}{2},\quad \lim_{l\to0}\varphi_h=0,\quad \lim_{l\to0}\varphi_j=\pi.$$

For $l \gg 1$ for a large part of the cross section of the lay-

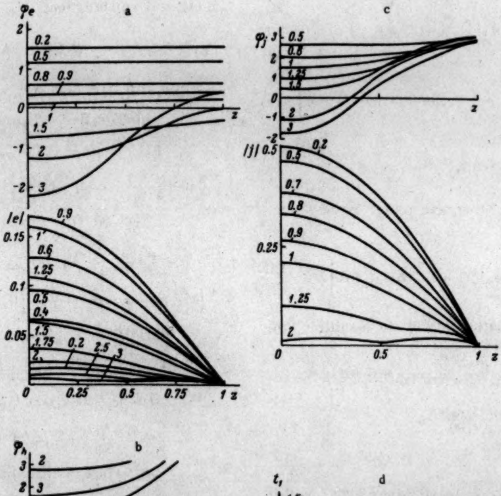

Fig. 1. Moduli and phases of e_1 (a), h_1 (b), j_1 (c), and t_1 (d) as a function of z, for various values of l.

er, for which $l \min(z, 1-z) \gg 1$, we have

$$\operatorname{Re} e_1 \simeq \operatorname{Re} j_1 \simeq \frac{\exp[-l(1-z)]}{4l}\left\{\sin\left(n-\frac{\pi}{4}\right)\sin\left[l(1-z)-\frac{\pi}{4}\right] - \frac{z}{\sqrt{2}}\sin\left[l(1-z)+\frac{\pi}{4}\right]\right\}, \tag{36}$$

$$\operatorname{Im} e_1 \simeq \operatorname{Im} j_1 \simeq \frac{\exp[-l(1-z)]}{4l}\left\{\sin\left(n+\frac{\pi}{4}\right)\sin\left[l(1+z)-\frac{\pi}{4}\right] + \frac{z}{\sqrt{2}}\sin\left[l(1-z)-\frac{\pi}{4}\right]\right\}, \tag{37}$$

$$\operatorname{Re} h_1 \simeq \frac{1}{4}\exp[-l(1-z)]\left\{\cos n \sin\left[l(1+z)-\frac{\pi}{4}\right] - \sin n \sin l(1+z) + z\cos l(1-z)\right\}, \tag{38}$$

$$\operatorname{Im} h_1 \simeq \frac{1}{4}\exp[-l(1-z)](1-z)\sin l(1-z), \tag{39}$$

$$t_1 \simeq \frac{3}{80 l^4}. \tag{40}$$

For the field and the current the main, exponentially small factor, which determines the order of e_1, j_1, and h_1, is the same as in the zeroth approximation, (30), i.e., of the quantities[3]

$$|e_0| = |j_0| \simeq \exp[-l(1-z)], \quad |h_0| \simeq l\sqrt{2}\exp[-l(1-z)] \tag{41}$$

$|e_1|$, $|j_1|$, and $|h_1|$ are approximately damped oscillations (and their ratios to $|e_0|$ and $|h_0|$ are approximately undamped oscillations) with period $\Delta z = 2\pi/l$. The correction to the temperature is positive; everywhere, in addition to a small region near the surface, it is constant and proportional to l^{-4}; its ratio to $t_0 = 1/(4l^2)$ is $t_1/t_0 \simeq 3/(20 l^2)$ (see ref. 3). The limiting values are

$$\left.\begin{aligned} &\lim_{l\to\infty} e_1 = \lim_{l\to\infty} h_1 = \lim_{l\to\infty} j_1 = \lim_{l\to\infty} t_1 = 0,\\ &\lim_{l\to\infty}\frac{e_1}{e_0} = \lim_{l\to\infty}\frac{h_1}{h_0} = \lim_{l\to\infty}\frac{j_1}{j_0} = \lim_{l\to\infty}\frac{t_1}{t_0} = 0. \end{aligned}\right\} \tag{42}$$

The quantities $|e_1|$, $|h_1|$, and $|j_1|$ are functions which decrease for $l \leq \pi$ with a maximum at $z = 0$, increase for $l \leq 1$ with a maximum at $z = 1$, and decrease for $l < \pi/2$, with a maximum at $z = 0$. For large l they have additional extrema, the first of which is reached for smaller values of z, the larger the value of l; $|e_1|$ and $|h_1|$ as functions of l have maxima for $l \simeq 0.9008$ and 0.8045 respectively; $|j_1|$ decreases monotonically as a function of l.

The phases φ_e, φ_h, and φ_j $(-\pi < \varphi \leq \pi)$ are increasing functions of $z = 0$ and a maximum at $z = 1$. For $l < \pi$, $l < \pi/2$, and $l < \pi$ respectively they are continuous; in the opposite case, for values which are multiples of π, the phases have discontinuities with jumps of -2π (the number of which for φ_e, in particular, is $[l/\pi]$). The range of variation of the phases and their closeness to a linear relationship is the greater the smaller the value of l.

The value of t_1 for small values of l is negative and decreases in absolute value as l increases, and for $l \simeq 1.198$ becomes zero (for smaller values of l, t_1 is an increasing function of z with a minimum at $z = 0$, and for larger values of l is a decreasing function with a maximum at $z = 0$). When l is increased further, t_1, while remaining positive, continues to increase, and for $l \simeq 1.381$ reaches a maximum and then tends to zero monotonically in accordance with the asymptotic equation (40).

For $t_1 < 0$ the overall temperature profile in the conductor is less convex and flatter than for constant conductivity ($k = 0$), and for $t_1 > 0$ the reverse is true.

CONDITION UNDER WHICH THE APPROXIMATION IS VALID

The above approximation [beginning with Eqs. (6) and (7)] is valid when the initial set of equations (3) are weakly nonlinear, i.e., when

$$k t_0(0) \ll 1 \quad \text{or} \quad k \ll n^2 \frac{c_1(n)}{c_2(n)}. \tag{43}$$

In addition to this an essential physical requirement is the condition that the maximum absolute temperature of the conductor (for $z = 0$) must remain below the melting point. Together with Eq. (43), this requirement leads to a system of two equalities of the same sense:

$$\frac{(e^0)^2}{4\lambda\mu\omega}\frac{c_2(n)}{c_1(n)}\begin{cases} < \delta t,\\ \ll \alpha^{-1}\end{cases} \tag{44}$$

(δt is the difference between the melting point and the temperature of the surface of the conductor), which answers the question of the condition of applicability of the approximation considered. The system (44) can be regarded as a limitation on the allowed amplitude of the electric field at the boundary.

In the limiting cases with respect to n, condition (44) can be written in a form which does not contain transcendental functions and which is thus more suitable from the practical point of view. For a weak skin effect ($n \ll 2$) Eq. (44) is replaced by

$$\sigma^0 a^2\begin{cases} < \dfrac{4\lambda}{(e^0)^2}\delta t,\\ \ll \min\left[\dfrac{4\lambda}{(e^0)^2\alpha}, \ \dfrac{1}{2\mu\omega}\right],\end{cases} \tag{45}$$

and for a strong skin effect ($n \gg 2$),

$$\mu\omega\begin{cases} > \dfrac{(e^0)^2}{4\lambda\delta t},\\ \gg \max\left[\dfrac{(e^0)^2}{4\lambda}\alpha, \ \dfrac{1}{2\sigma^0 a^2}\right].\end{cases} \tag{46}$$

(Submitted July 25, 1973; resubmitted November 22, 1973)
Zh. Tekh. Fiz., 44, 1633-1640 (August 1974)

A method is proposed for the exact numerical calculation, in the hydrodynamic approximation, of the interaction of a charged particle beam with a periodic waveguide. Typical numerical calculations are given and the results are compared with approximate calculations based on conventional methods. It is shown that there are significant discrepancies in certain cases.

INTRODUCTION

The study of plasma instabilities (space-charge) waves in periodic structures is of both practical and theoretical interest. Examples of periodic structures might be: a waveguide with a periodically modulated conducting surface;[1] a waveguide filled with a stratified medium;[1-3] a uniform waveguide with a premodulated current density.[4] Another example of a periodic system is a waveguide with a plasma whose density is acoustically modulated so that in a coordinate system moving with the phase velocity of the sound wave the plasma can be regarded as a dielectric medium with a permittivity $\varepsilon(z) = [1-\omega_p^2(z)/\omega^2]$, $\mu \equiv 1$ with $\varepsilon(z+\lambda) \equiv \varepsilon(z)$, where λ is the acoustic wavelength. A plasma with a density of 10^8-10^{14} cm^{-3} is transparent to a beam of particles but would at the same time cause retardation of electromagnetic waves[5,6] in the range 3m to 3 mm.

We consider here an exact method of investigating the behavior of a beam of charged particles in periodic systems, using a linearized hydrodynamic model. It is shown below that this method leads to quantitative, and in some cases, qualitative differences from approximate methods. Our method is based on the formulation of the problem in the equivalent variational statement and the subsequent reduction to a system of normal differential equations in the auxiliary unknowns which characterize the self-consistent distribution of the wave field and beam current density.

FORMULATION OF THE PROBLEM[1)]

We assume that the system has axial symmetry and is bounded by the conducting surface of the waveguide $r = \Pi(z)$. Assume that a beam of charged particles with radius r_e moves along the z axis of the system. We assume that the velocity of all the particles in the beam is directed along the z axis. We use the hydrodynamic approximation and introduce the following notation: $e(n_0+n)$ is the spatial charge density, $(v_0 = v)\mathbf{e}_z$ is the velocity of the particles and $(j_0 + j)\mathbf{e}_z$ is the current density. Here, n_0, v_0 and $j_0 = en_0v_0$ are constant in time and space and the terms n, v and j are small and vary with time as $\sim e^{-i\omega t}$.

From the linearized equations of motion $(e/m)\mathcal{E}_z = \partial v/\partial t + v_0(\partial v/\partial z)$, the equation of continuity $\partial j/\partial z = -e(\partial n \cdot dt^{-1})$, the relationship $j = e(n_0v + nv_0)$, the Maxwell equation $-i\omega\mathcal{E} = \operatorname{curl}\mathcal{H} - (4\pi/c)\mathbf{j}$ and the fact that only axially symmetric TM waves (for which $\mathcal{H} = \mathcal{H}\mathbf{e}_\varphi$) are excited, we get

$$\left[\frac{\partial^2}{\partial z^2} - 2i\beta_e\frac{\partial}{\partial z} - (\beta_e^2 - \beta_p^2)\right]j = \frac{c}{4\pi}\beta_p^2\left[\frac{\partial}{\partial r} + \frac{1}{r}\right]\mathcal{H}. \tag{1}$$

Here, we have introduced the notation:

$$\beta_e = \frac{\omega}{v_0} = \frac{k}{\beta}, \quad k = \frac{\omega}{c}, \quad \beta = \frac{v_0}{c}; \quad \beta_p = \frac{\omega_p}{v_0}, \quad \omega_p = \left(\frac{4\pi}{\varepsilon}\frac{e^2}{m}n_0\right)^{1/2}.$$

Equation (1) relates the complex amplitudes of the field $\mathcal{H} = \mu^{-1}B$ excited in the system to the varying component of the beam current density j.

We can get a second equation relating $\mathcal{H}$ and j from the condition

$$\delta_{\mathcal{H}_0} J(\mathcal{H}, \mathcal{H}_0, \mathbf{j}) = 0 \quad \text{for} \quad \delta\mathcal{H}_0[S(z_{1,2})] = 0. \tag{2}$$

Here

$$J(\mathcal{H}, \mathcal{H}_0, \mathbf{j}) = \iiint\limits_W \Big[\varepsilon^{-1}(\operatorname{curl}\mathcal{H}, \operatorname{curl}\mathcal{H}_0) - k^2\mu(\mathcal{H}, \mathcal{H}_0) - \frac{4\pi}{c}(\operatorname{curl}\varepsilon^{-1}\mathbf{j}, \mathcal{H}_0)\Big]dv - ik\iint\limits_\Pi w(\mathcal{H}_\tau, \mathcal{H}_{0\tau})\,d\sigma,$$

W is the region bounded by the conducting surface Π and the cross section planes S(z) normal to the z axis at $z = z_1$, and $z = z_2$ $(z_1 < z_2)$; $\mathbf{n}$ is the external normal to Π. It is evident that the stationarity condition (2) is equivalent, inside the region W, to the equation

$$\operatorname{curl}[\varepsilon^{-1}\operatorname{curl}\mathcal{H}] - k^2\mu\mathcal{H} = \frac{4\pi}{c}\operatorname{curl}\varepsilon^{-1}\mathbf{j},$$

and on the conducting boundary Π to the Leontovich boundary condition

$$\{(\operatorname{curl}\mathcal{H})_\tau + ikw[\varepsilon\mathcal{H}, \mathbf{n}]\}_\Pi = 0.$$

Remembering that $= \mathcal{H}\mathbf{e}_\varphi$, $\mathbf{j} = j\mathbf{e}_z$ and taking $\mathcal{H}_0 = \mathcal{H}_0\mathbf{e}_\varphi$, we can put

$$\mathcal{H} = \sum_n e_n(r, z)f_n(z); \quad \mathcal{H}_0 = \sum_n e_n(r, z)v_n(z); \quad j = \sum_k \eta_k(r)j_k(z). \tag{3}$$

Here $\{e_n\}$ and $\{\eta_k\}$ are systems of basis functions. In the approximation of order (N, N_1) we assume that the sum over n in (3) contains N terms $(n = 1, 2, \ldots, N)$ and the sum over k has N_1 terms $(k = 1, 2, \ldots, N_1)$.

Substituting (3) first into (1) with the application of the Galerkin method and then into (2) where we use $\delta v_n(z_1) = \delta v_n(z_2) = 0$, we obtain the following two systems of equations:

$$T\left[\frac{d^2}{dz^2}\mathbf{f}_1 - 2i\beta_e\frac{d}{dz}\mathbf{f}_1 - (\beta_e^2 - \beta_p^2)\mathbf{f}_1\right] = \frac{c}{4\pi}\beta_p^2\Phi\mathbf{f}_0,$$

$$\frac{d}{dz}\left[G(z)\frac{d\mathbf{f}_0}{dz} + Q(z)\mathbf{f}_0\right] - Q^\tau(z)\frac{d\mathbf{f}_0}{dz} + P(z)\mathbf{f}_0 = \frac{4\pi}{c}\mathcal{T}\mathbf{f}_1,$$

in which $\mathbf{f}_0 = (f_1, \ldots, f_N)^T$, $\mathbf{f}_1 = (j_1, \ldots, j_{N_1})^T$ and the elements of the matrices T, Φ, $\mathscr{F}$, G, Q, and P are the following integrals:

$$T_{ns} = \iint\limits_{S(z)} \eta_s \eta_n dS; \quad \Phi_{ns} = \iint\limits_{S(z)} \left(\frac{\partial e_s}{\partial r} + \frac{1}{r} e_s\right) \eta_n dS;$$

$$\mathscr{F}_{ns} = \iint\limits_{S(z)} \frac{\partial}{\partial r} (\varepsilon^{-1} \eta_s) \bar{e}_n dS,$$

$$G_{ns} = \iint\limits_{S(z)} \varepsilon^{-1} e_s \bar{e}_n dS; \quad Q_{ns} = \iint\limits_{S(z)} \varepsilon^{-1} \frac{\partial e_s}{\partial z} \bar{e}_n dS,$$

$$P_{ns} = k^2 \iint\limits_{S(z)} \mu e_s \bar{e}_n dS - \iint\limits_{S(z)} \varepsilon^{-1} \left[\frac{\partial e_s}{\partial z} \frac{\partial \bar{e}_n}{\partial z} + \frac{1}{r^2} \frac{\partial (r e_s)}{\partial r} \frac{\partial (r \bar{e}_n)}{\partial r}\right] dS$$

$$+ ik\Pi \sqrt{1 + \left(\frac{d\Pi}{dz}\right)^2} \int\limits_0^{2\pi} w e_s \bar{e}_n d\varphi.$$

This system of two vector equations (in the unknowns $\mathbf{f}_0$ and $\mathbf{f}_1$) describes in a self-consistent way the interaction of a cylindrical plasma beam with a nonuniform system and can be written as the single vector equation

$$\frac{d}{dz}\left[\tilde{G} \frac{d\mathbf{f}}{dz} + \tilde{Q}\mathbf{f}\right] - \tilde{R} \frac{d\mathbf{f}}{dz} + \tilde{P}\mathbf{f} = 0, \qquad (4)$$

in which

$$\mathbf{f} = \begin{pmatrix} \mathbf{f}_0 \\ \mathbf{f}_1 \end{pmatrix}, \quad \tilde{G} = \left(\begin{array}{c|c} G & 0 \\ \hline 0 & T \end{array}\right), \quad \tilde{Q} = \left(\begin{array}{c|c} Q & 0 \\ \hline 0 & -i\beta_e T \end{array}\right), \quad \tilde{R} = \left(\begin{array}{c|c} Q^* & 0 \\ \hline 0 & i\beta_e T \end{array}\right)$$

$$\tilde{P} = \left(\begin{array}{c|c} P & -\frac{4\pi}{c} F \\ \hline -\frac{c}{4\pi} \beta_p^2 \Phi & (\beta_p^2 - \beta_e^2) T \end{array}\right).$$

Taking

$$\tilde{\mathbf{f}}(z) = \tilde{G} \frac{d\mathbf{f}}{dz} + \tilde{Q}\mathbf{f} = \begin{pmatrix} \tilde{\mathbf{f}}_0 \\ \tilde{\mathbf{f}}_1 \end{pmatrix} \text{ and } \mathbf{g}(z) = \begin{pmatrix} \mathbf{f} \\ \tilde{\mathbf{f}} \end{pmatrix},$$

we write (4) in the form of a first-order vector differential equation

$$\frac{d\mathbf{g}}{dz} = A(z)\mathbf{g}, \quad A(z) = \left(\begin{array}{c|c} -\tilde{G}^{-1}\tilde{Q} & \tilde{G}^{-1} \\ \hline -\tilde{P} - \tilde{R}\tilde{G}^{-1}\tilde{Q} & \tilde{R}\tilde{G}^{-1} \end{array}\right). \qquad (5)$$

In the following calculations we take the basis functions appearing in (3) as:

$$e_n(r, z) = \frac{J_0'\left(\nu_n \frac{r}{\Pi(z)}\right)}{\sqrt{\pi} J_1(\nu_n)}, \quad \eta_k(r) = \frac{J_0\left(\mu_{k-1} \frac{r}{r_e}\right)}{\sqrt{\pi} r_e J_0(\mu_{k-1})} \theta(r_e - r). \qquad (6)$$

Here ν_n and μ_n are the positive roots of the Bessel function $J_0(x)$ and its derivative $J_0'(x)$ respectively (n = 1, 2, ...), $\mu_0 = 0$, $\theta(x) = 1$ for $x \geq 0$ and 0 for $x < 0$. Physically this choice of $\{e_n\}$ means that we represent the field at each cross section by the superposition of the TM_0 modes of a cylindrical waveguide of the same cross section. With this choice of $\{\eta_k\}$ the first term of the sum for j in (3) corresponds to the approximation of a current density uniformly distributed over the cross section of the beam.

The expressions for the matrix elements in (4) are given in Appendix (1) for the basis defined by (6).

In the statement of the problem we have given there is no unique solution if only because under the stationarity condition (2) no restrictions are placed on the values of the unknown field $\mathscr{H}$ in the cross sections $S(z_1)$ and $S(z_2)$. Therefore Eq. (4) or the equivalent form (5) must be considered with auxiliary initial or boundary conditions depending on which process is in fact modulated. Putting, for example,

$$\mathbf{g}(z_1) = (\mathbf{f}_0^{\tau}(z_1),\ \mathbf{0}_{N_1}^{\tau},\ \tilde{\mathbf{f}}_0^{\tau}(z_1),\ \mathbf{0}_{N_1}^{\tau})^{\tau}, \qquad (7)$$

we get a model of a traveling-wave tube where there is no velocity or current density modulation at the input ($z = z_1$). Problem (5), (7) is a normal initial value problem and a numerical solution does not present any difficulties. It is just as simple to construct a model for a backward-wave tube; here it is necessary to use two-point type conditions $\mathbf{f}_1(z_1) = \tilde{\mathbf{f}}_1(z_1) = \mathbf{0}_{N_1}$, $\mathbf{f}_0(z) = \tilde{\mathbf{f}}_0(z_2) = \mathbf{0}_N$, which denote the absence of density and velocity modulation of the beam at the input ($z = z_1$) and the fact that the transverse field components are zero at the output ($z = z$).

PERIODIC SYSTEMS

We consider the particularly interesting case of a beam in a periodic waveguide where the shape of the boundary and the medium filling the waveguide vary periodically (period D) with the z coordinate along the axis [$\Pi(z + D) \equiv \Pi(z)$, $\varepsilon(z + D) \equiv \varepsilon(z)$ and $\mu(z + D) \equiv \mu(z)$]. The matrix coefficient A(z) in (5) is then periodic in z with period D and we may therefore consider solutions (5) which satisfy the Floquet boundary condition

$$\mathbf{g}(z) = e^{ihz}\mathbf{u}(z), \ \mathbf{u}(z + D) \equiv \mathbf{u}(z). \qquad (8)$$

Solutions of type (8) always exist and in many cases have the property of completeness. The set of solutions of type (8) (normal modes[7]) is conveniently divided into two groups: One is the group of normal modes of a periodic waveguide, excited as it were by the particle beam, and the other represents space-charge waves.[8]

We note that in certain cases the set of normal modes (5), (8) does not possess the property of completeness (points of nondiagonalizable multiplicity of the cell operator); in order to maintain completeness in this case we have to consider in addition to the normal modes the adjoint modes[9] which differ from (8) in the presence of a secular factor (polynomials in z). This general case is covered by the matrix formulation of the Floquet theorem on the structure of the fundamental matrix Y(z) of the system (5) with $A(z + D) \equiv A(z)$

$$Y(z) = U(z)e^{iBz}.$$

Here, U(z) is a matrix function which is periodic with the period D, and B is a constant matrix. The propagation constants h in (8) are the eigenvalues of B to an accuracy of $2\pi n/D$ ($n = 0, \pm 1, \ldots$). If to some h_j in the Jordan form $\tilde{B}$ of the matrix B ($B = C^{-1}\tilde{B}C$) there corresponds some cell of dimension $n_j \geq 1$, then to this cell there corresponds n_j columns of the fundamental matrix $\tilde{Y}(z) =$

$CY(z)C^{-1}$, one of which is the normal wave and the remaining $(n_j - 1)$ are the adjoint waves.

We limit ourselves to a consideration of the normal modes. We seek the approximate solutions of (4) which satisfy the Floquet condition (8) in the form of a finite sum of $(2q+1)$ terms $(q = 0, 1, 2, \ldots)$

$$\mathbf{f}(z) \simeq \mathbf{f}_q(z) = \sum_{m=-q}^{q} e^{ih_{(m)}z}\mathbf{c}^{(m)}, \quad h_{(m)} = h + \frac{2\pi}{D}m. \qquad (9)$$

After substitution of (9) into (4), multiplication of the resultant equation by $e^{-ih_{(p)}z}$ $(p = 0, \pm 1, \ldots, \pm q)$ and integration with respect to z over the period D we obtain a system of $(2q+1)$ equations in the unknown vectors $\mathbf{c}^{(m)}$

$$\sum_{m=-q}^{q} [-h_{(m)}h_{(p)}\tilde{G}^{(p-m)} + ih_{(p)}\tilde{Q}^{(p-m)} - ih_{(m)}\tilde{R}^{(p-m)} + \tilde{P}^{(p-m)}]\mathbf{c}^{(m)} = 0. \qquad (10)$$

Here, $A^{(m)}$ is the matrix coefficient of the Fourier series

$$A(z) = \sum_{m} A^{(m)} \exp\left(i\frac{2\pi m}{D}z\right),$$

where A(z) is any of the matrices $\tilde{G}$, $\tilde{Q}$, $\tilde{R}$ and $\tilde{P}$. The unknown vectors $\mathbf{c}^{(m)} = \begin{pmatrix}\mathbf{f}_0^{(m)}\\ \mathbf{f}_1^{(m)}\end{pmatrix}$ have dimension $(N + N_1)$ so that the system (10) contains $(N+N_1)(2q+1)$ unknowns $c_n^{(m)} = f_n^{(m)}$ for $1 \le n \le N$ and $j_n^{(m)}$ for $N+1 \le n \le N+N_1$.

After introducing new notation and eliminating $\mathbf{J}_1 = -\beta_p^2 K^{-1}(h)M\mathbf{J}_0$, we can write (10) in the form

$$[B(h) - \beta_p^2 FK^{-1}(h)M]\mathbf{J}_0 = 0, \qquad (11)$$

where B, K, M and F are block matrices with elements

$$B^{lm} = -h_{(m)}h_{(l)}G^{(l-m)} + ih_{(l)}Q^{(l-m)} - ih_{(m)}Q^{*(l-m)} + P^{(l-m)},$$
$$K^{lm} = [\beta_p^2 - (h_{(m)} - \beta_l)^2] I_{N_1}\delta_{lm},$$
$$M^{lm} = \Phi^{(l-m)}, \quad F^{lm} = F^{(l-m)} = -\frac{1}{\varepsilon}\Phi^{*(l-m)},$$

and the matrices G, Q, P and Φ are given in the Appendix (1).

The condition

$$\det[B(h) - \beta_p^2 FK^{-1}(h)M] = 0 \qquad (12)$$

is the dispersion equation. This equation can be expanded in powers of a small parameter (the amplitude of the periodic modulation, for example) and if terms of second order are neglected we get approximate dispersion equations[1,4] which give a useful qualitative picture. Here, however, we consider exact solutions of the dispersion equation (12) obtained by means of a computer.

SOLUTION OF THE DISPERSION EQUATION

We now give the results of calculations for a waveguide bounded by the surface $\Pi(z) = a[1 + \varkappa\cos(2\pi/D)z]$, with $\varepsilon = \mu = 1$ and a perfectly conducting boundary $(w = 0)$. The greatest interest is in the cases where the phase constants of the lower-type space-charge waves[8] are close to the phase constants of the waveguide waves.

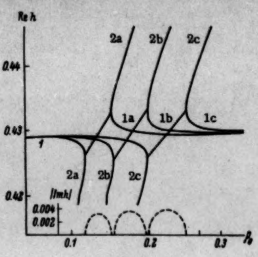

Fig. 1

The following parameter values are chosen for the calculations: $a = 4.315$ cm, $D = 3.333$ cm, $r_e = 0.500$ cm. The calculations apply for an electron beam.

Figure 1 shows the way the phase constant h (8) depends on the density of the space charge $\rho_0 = en_0$ in cgs esu near the resonance of the direct wave of the system with the slow space-charge wave ($\varkappa = 0.25$, $k_0 = \omega/c = 0.660\ \mathrm{cm}^{-1}$) for various values of the relative particle velocity $\beta = v_0/c$ (c is the velocity of light in vacuum). The indices a, b and c correspond respectively to the values $\beta = 0.298$, 0.300 and 0.302. The numbers in Fig. 1 denote: 1) the direct waveguide wave (i.e., the direct wave of the periodic system excited by the particle beam); 2) the slow space-charge wave. This division of the waves is arbitrary and loses its meaning very close to the resonance parameter values where the dispersion curve 1 goes over to curve 2. The continuous lines in Fig. 1 (and also in Fig. 2) give the values of $|\mathrm{Re}\,h|$ (cm^{-1}) and the dashed lines the values of $|\mathrm{Im}\,h|$ (cm^{-1}) in the complex h region. It can be seen from Fig. 1 that there is a region of values of ρ_0 for which h is complex. It can be established from refs. 10 and 11 that convective instability exists and one of the system waves is amplified. It is evident from the dispersion curves that as β is increased the region of complex h moves towards higher space charge densities and the width of the instability region increases together with the value of max $|\mathrm{Im}\,h|$.

Figure 2 shows the way that the propagation constant h in (8) depends on $\beta = v_0/c$ for $\varkappa = 0.5$ and $k_0 = \omega/c = 0.6131\ \mathrm{cm}^{-1}$ near the same resonance (the direct waveguide wave corresponds to 1 and the slow space-charge wave to 2) for space-charge density values $\rho_0 = 0.09$ cgs esu

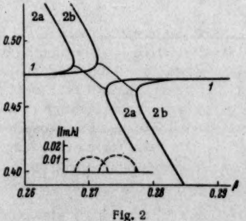

Fig. 2

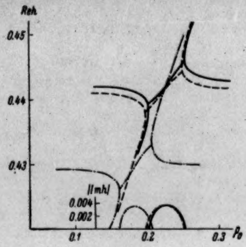

Fig. 3

(letter a) and $\rho_0 = 0.18$ cgs esu (letter b). The beam instability shown in Fig. 2 is convective as in Fig. 1. The results given in Figs. 1 and 2 correspond to the approximation $N = N_1 = 3$, $q = 1$.

We have made a numerical study of the rate at which this method of calculation converges. The nature of the approximations is defined by the choice of the values of the three indices N, N_1, and q. The convergence over N is similar to that of the normal method of calculating nonregular waveguides without particle beams according to the Galerkin technique studied in ref. 12. From physical considerations the convergence over N_1 must be similar to that over N. It is therefore of most interest to consider the convergence over q. The results of some calculations are given in Fig. 3 for $\varkappa = 0.25$, $k_0 = \omega/c = 0.6600$ cm^{-1}, $\beta = v_0/c = 0.300$; the axes represent the values of h (cm^{-1}) and ρ_0 in cgs esu. The calculations are for $N = N_1 = 3$ and $q = 1$ (dashed dotted lines), $q = 2$ (dashed lines) and $q = 3$ (continuous lines).

For the system we have considered here the dispersion equation is known but it is difficult to use it for actual calculations because it contains the unknown amplitude distributions of the spatial harmonics (see, for example, refs. 13 and 14). This equation reduces approximately to a fourth-order algebraic equation with coefficients K_c (coupling factor) and T (depression coefficient) which depend on the unknown propagation constant and the unknown field distribution in a cross section. In the calculation of these coefficients approximate use is made of the values of the high-frequency characteristics of the system in the absence of a beam and it is assumed that the effect of the beam is small. It has been noted in refs. 13 and 14 that even in this approximation the determination of the system characteristics in the absence of a beam is in itself a rather difficult problem, especially in a structure with a complex geometry. We also note that this approach, which is based on the use of a characteristic fourth-order equation with coefficients which are calculated only approximately without beam effects taken into account, leads to large errors near the boundary between the real and significantly complex values of h. The reason is that the coefficients of the characteristic equation contain in the energy flux the denominator; in the absence of a beam this quantity vanishes at the edge of the passband. This was in fact used in ref. 15 as the basis of the idea that the transverse instability would be suppressed in the high intensity beam of a linear accelerator under conditions where the parasitic wave responsible for the growth of the instability was excited near the edge of the passband of a system without a beam. This idea, which is based on the use of the above-mentioned characteristic equation, is not valid, as has been shown experimentally[16] and theoretically.[17,18]

We now give a comparison of the results of calculations of the growth rate Im h near resonance for the direct waveguide wave and the slow space-charge wave; we use the example described above with $\varkappa = 0.25$, $k_0 = 0.660$ cm^{-1}, $\beta = 0.300$ and $\rho_0 = 0.2295$ cgs esu. From the fourth-order characteristic equation we get $|\mathrm{Im}\, h| = 0.448 \cdot 10^{-2}$ cm^{-1}. For the model used in ref. 19, an approximate calculation[13] gives $\Gamma = 1$ and in our notation we have for k_c that

$$k_c = \frac{c}{8\pi\mathscr{P}} \frac{[\beta_p^2 - (h_s - \beta_e)^2]^2}{h_s k} \frac{(FK^{-1}M\mathbf{j}_0, \mathbf{j}_0)^2}{\left|\sum\limits_m \Phi^{(s-m)} \mathbf{f}^{(m)}\right|^2},$$

where $h_{(s)}$, $\mathbf{j}_0$, and $\mathscr{P}$ are the values calculated in the absence of a beam for the propagation constant of the spatial harmonic which is synchronous with the beam ($s = 1$ here), of the vector $\mathbf{j}_0$ from (11) and the energy flux $\mathscr{P}$ through a cross section. The expression for $\mathscr{P}$ in given in the Appendix (2).

A numerical calculation from the dispersion equation (12) in the approximation $N = N_1 = q = 3$, which produces results to three significant figures, gives $|\mathrm{Im}\, h| = 0.368 \cdot 10^{-2}$ cm^{-1}. The discrepancy might be a result of the fact that the effect of the higher modes and of the nonresonant spatial harmonics ($\Gamma = 1$) has not been taken into account and also of the approximate nature of the calculation of k_c which has used the values of h_s, J_0 and $\mathscr{P}$ for a "cold" system.

The authors are grateful to A. A. Rukhadze for discussion.

APPENDIX

1. We give the expressions for the elements of the matrices G, Q, P, T, and Φ in the basis (6)

$$G_{ns} = \varepsilon^{-1}\Pi^2(z)\delta_{ns};\ Q_{ns} = \varepsilon^{-1} q_{ns} \frac{d}{dz}(\Pi^2),$$

$$q_{ns} = \frac{\nu_s^2}{\nu_n^2 - \nu_s^2} \text{ for } n \neq s,\ q_{nn} = 0,$$

$$P_{ns} = \left\{\mu [k\Pi]^2 - \frac{\nu_n^2}{\varepsilon}\right\}\delta_{ns} + \varepsilon^{-1}\left(\frac{d\Pi}{dz}\right)^2 p_{ns} + 2ik\omega\Pi\sqrt{1 + \left(\frac{d\Pi}{dz}\right)^2},$$

$$p_{ns} = 2 - \frac{8\nu_n^2\nu_s^2}{(\nu_n^2 - \nu_s^2)^2} \text{ for } n \neq s,\ p_{nn} = \frac{5 - \nu_n^2}{3},$$

$$T_{ns} = \delta_{ns};\ \Phi_{ns}' = -\frac{2(\nu_s r_e)^2}{J_1(\nu_s)} \frac{J_1\left(\nu_s \frac{r_l}{\Pi(z)}\right)}{(\nu_s r_e)^2 - [\mu_{n-1}\Pi(z)]^2}.$$

2. The electromagnetic energy flux through a cross section averaged over the hf period is defined for $\mathbf{j} = 0$ by

$$\mathscr{P}(z) = \frac{c}{8\pi k} \mathrm{Im} \iint\limits_{S(z)} \varepsilon^{-1}([\mathbf{e}_z, \mathrm{curl}\,\mathscr{H}], \mathscr{H})\, dS.$$

Using (3), we get

$$\mathscr{P}(z)=\frac{c}{8\pi k}\operatorname{Im}\left(G\frac{d\mathbf{f}}{dz}+Q\mathbf{f},\ \mathbf{f}\right).$$

Since in the absence of losses and for a system without a beam $\mathscr{P}(z) = \text{const}$, then $\mathscr{P} = 1/D\int\limits_{-D/2}^{D/2}\mathscr{P}dz$.

Remembering that $\mathbf{f} = \sum\limits_{m} e^{ih(m)z}\mathbf{f}(m)$, we get

$$\mathscr{P}=\frac{c}{8\pi kD}\operatorname{Im}\sum_{p,\,m=-q}^{q}\left([ih_{(m)}G^{(p-m)}+Q^{(p-m)}]\mathbf{f}^{(m)},\ \mathbf{f}^{(p)}\right).$$

[1)] In this section the structure is not assumed to be periodic and the problem is formulated for the general case.

Computer calculation of quasistationary pulsed magnetic fields

V. I. Yurchenko

Institute of Nuclear Physics, Siberian Branch,
Academy of Sciences of the USSR, Novosibirsk

(Submitted March 17, 1973)
Zh. Tekh. Fiz., 44, 1641-1649 (August 1974)

A procedure for calculating two-dimensional magnetic fields (plane-parallel or with rotational symmetry) is described. The skin effect is taken into account. The procedure is based on the replacement of a differential equation by a system of difference equations relating the values of the vector potential at different points of a rectangular grid at two different times. Two iteration methods, a longitudinal—transverse method and an upper-relaxation method, are used to solve the difference equations. The calculation procedure is illustrated for the case of a pulsed magnet. The calculation is carried out for a δ-function excitation. In this form, the results can be used in a simple manner to determine the field for any functional dependence of the excitation on time. The procedure for calculating the field is described for the case in which a capacitor discharges into a magnet of unit length.

Various physics research experiments use pulsed magnets, in which the skin effect is important. Such magnets are used, e.g., in the production of ultrastrong fields[1] and, with a thin skin, in the production of the desired field configuration in a gap.[2,3] Optimization of the parameters of these magnets requires an effective method for calculating magnetic fields with the skin effect taken into account.

Appropriate calculations have been carried out on the basis of the integral form of the field equations.[4-7] This is not the only possible approach; in the magnetostatic case, e.g., the equation for the vector potential can be solved by a difference method.[8,9] The same method can be used to solve the quasisteady-state problem. The difference method has the advantage of simplicity; also, it can be used in nonlinear problems, in which the relative permeability of the magnet, μ, is a function of the induction, or in problems in which the conductivity varies as a function of the time because the conductors are heated. The latter case is important, e.g., in producing ultrastrong fields.[1]

Our purpose here is to examine the practical usefulness of the difference method for solving the two-dimensional problem (in which the field is plane-parallel or has rotational symmetry) in the linear, quasistationary case. The use of this method is illustrated by the calculation of the field in an iron-free magnet with zero gradient in which the ratio of the height of the conductors to separation is 2 : 1.

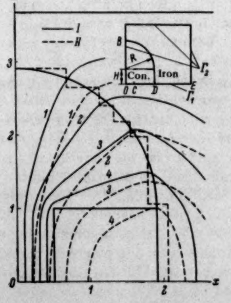

Fig. 1. H = 1, R = 1.91, δ-shaped voltage pulse. I) Lines of force at t = 0; II) at t = 5000 μsec. A: 1) 0.1; 2) 0.2; 3) 0.3; 4) 0.4.

NUMERICAL CALCULATION

Figure 1 shows one quadrant of the cross section of the iron-free magnet. The aperture dimension is adopted as the unit of length along the x and z axes. We are treating a relatively simple configuration of conductors and iron polepiece, characterized by the parameters H and R. The parameter R is chosen so that the induction in the polepiece is roughly one sixth that at the center of the aperture; hence the iron in the magnetic circuit is not saturated when the induction at the center is ~10 T. The aperture dimension is 2 cm and the conductor metal has a conductivity $5.9 \cdot 10^7 \Omega^{-1} \cdot m^{-1}$ (corresponding to copper). The calculated results can be extended to the cases of other conductivities and apertures through the use of a similarity transformation for the heat-conduction equation. The magnet length L = 1 m.

The iron of the magnetic circuit is assumed to have a relative permeability $\mu = 100$. Calculations show that the characteristics of the field in the aperture of this magnet are weak functions of μ (as well as of the shape of the magnetic-circuit pole) and are essentially the same in the case $\mu = 100$ as in the case $\mu = \infty$.

We assume that the length of the magnet along the y axis is much larger than its transverse dimension. We are to find the solution of the equation for a certain potential in the plane-parallel case:

$$\gamma \frac{\partial A}{\partial t} = \frac{\partial}{\partial x} \frac{1}{\mu} \frac{\partial A}{\partial x} + \frac{\partial}{\partial z} \frac{1}{\mu} \frac{\partial A}{\partial z} + \gamma E^{g}, \qquad (1)$$

where A and E^g are the y components of the vector potential and the electric field gradient. The coefficient γ has the constant value $a^2 \sigma \mu_0$ (where σ is the conductivity of the medium) within the conductor and vanishes elsewhere. The electric field gradient is constant over the cross section of the conductor (by virtue of the condition curl $E^g = 0$). The circulation integral of this vector along the contour of the turn formed by the conductors is equal to the potential difference between the leads of the conductors, i.e., is equal to the applied voltage, u(t). By virtue of the symmetry of the problem, the values of E^g in the two conductors are the same in magnitude but opposite in sign. We assume that the voltage u(t) is applied to the right-hand conductor with respect to the left-hand conductor; then in the right-hand conductor we have

$$E^{g}=\frac{u(t)}{2L}.$$

Equation (1) with this value of E^g is calculated by a difference method in the rectangular region shown in Fig. 1 with the initial condition

$$A|_{t=0}=0$$

and the boundary conditions

$$\left.\frac{\partial A}{\partial z}\right|_{\Gamma 1}=0,\quad A|_{\Gamma 2}=0. \tag{2}$$

The coordinate grid is constructed so that the intersections of the grid lines with the contour of the conductor are grid points, for improved accuracy. In the lower left-hand corner the grid is uniform in each direction. The grid is uniform along the x axis out to x = 0.75, with the specified spacing h; along the z axis it is uniform up to z = H, with approximately the same spacing. Thus, each unit of the grid is about 10% larger than the preceding unit, in both directions. The increase in the spacing is chosen so that the x = R line coincides with a grid line. To simplify the program the contour of the iron polepiece is chosen to be different from that specified (the dashed lines), but the difference is less than half a spacing. In Fig. 1, with a 19×22 grid (the first number is the number of spacings in the horizontal direction, and the second number is that in the vertical direction), we have h˙ = 0.5/4; the modified contour is shown by the dashed lines.

The difference equations, as in the case of the heat-conduction equation with variable coefficients, are obtained from the balance equation written for each grid cell.[10] In our case the balance equation is the equation giving the total current through the area bounded by the dashed lines in Fig. 2, S, averaged over the time from t_{l-1} to t_l. The vector potential in the l-th time layer A^l is given by the difference equation

$$-\bar{\gamma}\,\frac{A^{l}-A^{l-1}}{\tau_l}+\sigma_l\lambda A^{l}+(1-\sigma_l)\,\lambda A^{l-1}+\bar{\gamma}\,\frac{u^{l-1/2}}{2L}=0, \tag{3}$$

where τ_l is the time spacing and σ_l is the weight of the upper layer, $t = t_l$.

At point i, j we have

$$\bar{\gamma}_{i,j}=\frac{1}{\hbar_{x,i}\hbar_{z,j}}\int\limits_{S}\gamma(x,\ z)\,dx\,dz,$$

$$\hbar_{x,i}=\frac{h_{x,i}+h_{x,i+1}}{2};\quad \hbar_{z,j}=\frac{h_{z,j}+h_{z,j+1}}{2},$$

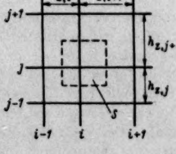

Fig. 2.

where

$$\lambda=\lambda_1+\lambda_2$$

is the difference operator corresponding to the differential on the right-hand side of Eq. (1). The operator λ_1 acts along the lines:

$$\lambda_1 A=a_i A_{i-1,j}-(a_i+b_i)\,A_{i,j}+b_i A_{i+1,j},$$
$$a_i=\frac{1}{\mu_{i-1/2}\hbar_{x,i}h_{x,i}}\quad b_i=\frac{1}{\mu_{i+1/2}\hbar_{x,i}h_{x,i+1}},$$

where $\mu_{i\pm 1/2}$ is the half-sum of the limiting values of μ to the left and right of the line i ± 1/2 at $z = z_j$. The operator λ_2, which acts along the columns, is analogous.

Equation (3) and boundary conditions (2) give a system of difference equations for determining A^l. To calculate the vector potential in the l-th time layer we must hold the values of the vector potential in the preceding layer, in the conductor region, in the computer memory. Elsewhere we have $\bar{\gamma} = 0$ and $\lambda A^{l-1} = 0$, and the values of the vector potential need not be stored.

An iteration method is used to solve the difference equations in each time layer. We have tried two such methods; one, for the Poisson equation, involves a time integration of the heat-conduction equation

$$\frac{\partial\varphi}{\partial t}=\Delta\varphi+\rho \tag{4}$$

until the solution reaches a steady state, with $\partial\varphi/\partial t = 0$ (ref. 10). Here we use the same approach; to determine A^l we write the longitudinal–transverse iteration scheme

$$\left.\begin{aligned}
&A^{l,s+1/2}+\mu\tau^{s}\left(\frac{\bar{\gamma}}{\sigma_l\tau_l}A^{l,s+1/2}-\lambda_1 A^{l,s+1/2}\right)=F^{s},\\
&A^{l,s+1}+\mu\tau^{s}\left(\frac{\bar{\gamma}}{\sigma_l\tau_l}A^{l,s+1}-\lambda_2 A^{l,s+1}\right)=F^{s+1/2},\\
&F^{s}=A^{l,s}+\mu\tau^{s}\left(\lambda_2 A^{l,s}+f^{l}\right),\\
&F^{s+1/2}=A^{l,s+1/2}+\mu\tau^{s}\left(\lambda_1 A^{l,s+1/2}+f^{l}\right),\\
&f^{l}=\begin{cases}\dfrac{\bar{\gamma}}{\sigma_l\tau_l}A^{l-1}+\dfrac{1-\sigma_l}{\sigma_l}\lambda A^{l-1}+\dfrac{\bar{\gamma}}{2L\sigma_l}u^{l-1/2}, & \text{if}\quad \bar{\gamma}\neq 0,\\ 0, & \text{if}\quad \bar{\gamma}=0.\end{cases}
\end{aligned}\right\} \tag{5}$$

Here s is the iteration number. To find $A^{l,s+1/2}$ we use the pivotal condensation method, working along the rows, while to find $A^{l,s}$ we work along the columns. The coefficient of the iteration parameter τ^s is the relative permeability at the given point of the grid, i.e., we are essentially solving an equation like (4) ($\rho = 0$) in the iron-filled region. Without this coefficient we would have the equation $\mu(\partial\varphi/\partial t) = \Delta\varphi$; we thus see that the introduction of the factor of μ in the iteration scheme makes the process of the signal propagation in the iron-filled region identical to that in the region outside the iron (where $\mu = 1$). This approach significantly reduces the number of iterations required. To accelerate the convergence we use a cyclic choice of parameters τ^s, determined in the same manner as for the Direchlet problem in a square of side b and with a quadratic grid of spacing h. The value of b in the equations for τ^s (ref. 11) is assumed to be equal to the transverse dimension of the magnetic circuit, DE (in units of the aperture b = 3). The iterations according to scheme (5) are stopped when

$$\frac{\Delta A}{A_m}\leqslant 10^{-6}, \tag{6}$$

where ΔA is the maximum magnitude of the correction to the vector potential during a cycle of the pivotal condensation method along rows or columns, and A_m is the maximum magnitude of the vector potential. The adequacy of condition (6) is checked in a large number of calculations; it is found that this iteration method converges reliably in practice and can be used to solve problem (3). We have also tested the upper-relaxation method.[8] This method is simpler to use, but it requires some two or three times as much computer time.

In the case of a linear problem, like that treated here (in which μ is not a function of the induction and the conductivity of the conductor is not a function of the temperature), it is sufficient to calculate the field for a δ-function or step-function dependence of the voltage on time. In this form the calculated results are universal, since they can be used in a simple manner to determine the field for any functional dependence of u on t. Below we consider the case of a δ-function voltage. Any linear combination of the vector potential and its derivatives, β, is given by the following expression for an arbitrary functional dependence of u on t:

$$\beta(t)=\int_0^t \beta_0(t-\tau)\,u(\tau)\,d\tau, \qquad (7)$$

where β_0 is the same linear combination for the case of a δ-function voltage.

The field is calculated in the electrostatic approximation (corresponding to an infinitesimally thin skin) for time zero ($l = 0$). For this calculation we use scheme (5), with $\sigma_0 = 0.5$, $\tau_0 = 10^{-8}$ sec, $f^0 = \bar{\gamma}/2L\sigma_0\tau_0$, and $A^{0,1} = 0$. The resulting calculated values of the vector potential A^0 correspond to the field which arises with the zero initial condition under the influence of a rectangular voltage pulse with base τ_0 and unit area. The parameter τ_0 is small enough for us to consider this pulse to be a δ function.

For $l \geq 1$ the calculated values of the vector potential describe the field relaxation; here the voltage is assumed to vanish in the equations; the first approximation, $A^{l,1}$, is assumed equal to A^{l-1}, and the parameters τ_l and σ_l are functions of l. Since the field changes most rapidly as a function of the time during the relaxation at small t, the time spacing is initially small, increasing with increasing l, to improve the accuracy. The quantities τ_l and σ_l are found as functions of l on the basis of the following considerations: The field relaxation in the aperture is described by

$$B(t)\approx B^0\frac{a}{a+2\delta(t)}\approx B^0\left(1-\frac{2\delta(t)}{a}\right),$$

where B^0 is the induction at the center of the aperture at zero time, and δ is the skin thickness. Since $\delta \sim \sqrt{t}$, the integration is not carried out over the coordinate t, but over the coordinate $\theta = \sqrt{t/T}$, where T is the time at which the integration is ended in the balance equation. The functional dependence of the field on θ at small θ is nearly linear, and better accuracy can be achieved through integration over this coordinate. In fact, the quantity $\sigma_l\lambda A^l + (1-\sigma_l)\lambda A^{l-1}$ in Eq. (3) is an approximation of the integral

$$\frac{1}{\tau_l}\int_{t_{l-1}}^{t_l}\lambda A\,dt=\frac{1}{\tau_l}\int_{\theta_{l-1}}^{\theta_l}\lambda A 2T\theta\,d\theta.$$

Since $\lambda A \approx \gamma(\partial A/\partial t)$ and since $\partial A/\partial t \sim t^{-1/2}$ in the skin, the integrand on the right is a weak function of θ. We approximate the integral by means of the trapezoid equation:

$$\frac{1}{\tau_l}\int_{\theta_{l-1}}^{\theta_l}\lambda A 2T\theta\,d\theta\simeq\frac{T(\theta_l-\theta_{l-1})}{\tau_l}(\Lambda A^l\theta_l+\Lambda A^{l-1}\theta_{l-1}).$$

Since $\theta_l - \theta_{l-1} = \tau_l/T(\theta_l + \theta_{l-1})$, this expression can be rewritten as

$$\sigma_l\lambda A^l+(1-\sigma_l)\lambda A^{l-1},$$

where $\sigma_l = \theta_l/(\theta_l+\theta_{l-1})$. In the calculations T is set equal to 5 msec, and the step in the coordinate θ is uniform ($l \geq 1$):

$$\theta_l=\frac{l}{N},\quad t_l=T\theta_l^2,$$

$$\tau_l=\frac{T(2l-1)}{N^2},\quad \sigma_l=\frac{l}{2l-1},$$

where N is the number of steps in the coordinate θ. For all $l \geq 1$ we have $\sigma > 1/2$, a necessary condition for the stability of the scheme.

In the course of the calculations we found, by increasing the number of grid points and by increasing N, that the difference problem described above is stable and converges.

ACCURACY OF THE CALCULATIONS; RESULTS

The errors in the calculation result from the conversion of the problem to discrete steps in the time and the space variables as well as from the approximate nature of the solution of the difference equations. Condition (6) provides a number of iterations sufficient for us to neglect errors of this latter type. The error due to the discrete nature of the time steps is a function of l. Table 1 shows the calculated values of the induction at the cen-

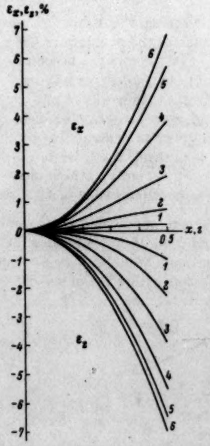

Fig. 3. Field inhomogeneity in the horizontal and vertical directions for the case of a δ-shaped pulse. θ: 1) 0; 2) 0.2; 3) 0.4; 4) 0.6; 5) 0.8; 6) 1.0.

ter of the aperture found for various values of N with a 31×36 grid with $h = 0.5/8$. Comparison of these results shows that with even l ($\theta = 0.5$ with $N = 4$, 8 and $\theta = 1$ with $N = 2$, 4, 8) the calculation error is much smaller than with odd l. The number of steps, N, is thus chosen even, and the necessary quantities are stored and printed for even l.

Table 2 shows some calculated values of the field parameters on a 42×47 grid with $h = 0.5/12$ in the case $N = 10$.

In Table 2, δ is the skin thickness, which is calculated, as in the case of an infinitely thick conductor, from

$$\delta=\frac{\Phi(t)}{B(t)},$$

where $\Phi(t) = \int_0^t E^g dt - A_g(t)$ is the magnetic flux in the conductor at time t, $A_g(t)$ and $B(t)$ are the vector potential and the induction at the surface of the conductor (at the point $x = 0.5$, $z = 0$), B_0 is the induction at the center of the aperture, I is the current in the conductors (twice the value of the integral of the field over the segment OB), F is the force per unit length exerted on the conductor (twice the value of the integral of $B^2/2\mu_0$ over the same segment) calculated for $B_0 = 10$ T, and

$$\varepsilon_x(x)=\frac{B_z(x,\,0)-B_0}{B_0}\,100\%, \qquad \varepsilon_z(z)=\frac{B_z(0,\,z)-B_0}{B_0}\,100\%.$$

are the field inhomogeneities in the horizontal and vertical directions (Fig. 3).

The calculation error for the data in Table 2 is due primarily to the discrete nature of the problem in the spatial variables. The size of this error can be determined by comparing the results in Table 2 with the results calculated for a 31×36 grid with $h = 0.5/8$ and a 19×22 grid with $h = 0.5/4$, i.e., with large values of h. It is found that the maximum error in determining the field B_0 and the current I is less than[1)] 0.4%, while the maximum error in the values of ε_x and ε_z, which characterize the field distribution, is of the order of 1%.

The error due to the discrete nature of the step in θ is lower by a factor of about 5 to 10 for the data in Table 2. In this case the minimum value of N is governed primarily by the error in the approximation of the calculated values of the vector potential for a δ-shaped voltage at other values of t. This procedure is required in order to determine the field from Eq. (7) for an arbitrary functional dependence of the voltage on the time. For better accuracy the approximation by polynomials should be carried out with respect to the coordinate θ rather than t. Calculation of the field during the discharge of a capacitor shows (see below) that the value $N = 10$ is sufficient to keep the error of the approximation below the calculation errors specified above.

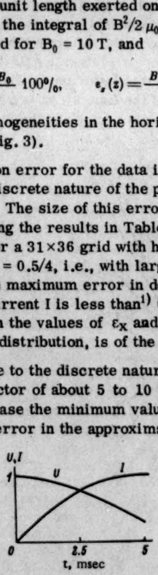

Fig. 4.

An important characteristic of an iron-free magnet is the energy required to produce a given field in the aperture for a specific rise time of the field. Pulsed magnets are usually supplied power from capacitor banks. We illustrate the calculation method for the discharge of a capacitor into a magnet 1 m long; this calculation is straightforward when the solution is known for the case of a δ-function voltage. The current in the circuit is given by

$$I(t)=\int_0^t u(\tau)\,I^{(0)}(t-\tau)\,d\tau, \tag{8}$$

where $I^{(0)}(t)$ is the current corresponding to a δ-function voltage, and $u(t)$ is the voltage on the capacitor. We also write

$$\frac{du(t)}{dt}=-\frac{1}{C}I(t), \tag{9}$$

where C is the capacitance of the capacitor.

We partition the integration range in (8) into equal segments of length τ and denote the value of the functions at time $t = m\tau$ by the subscript "m." We write the integral in (8) by means of the trapezoid equation, and we write Eq. (9) in difference form:

$$\left.\begin{aligned} I_m&=S_{m-1}+\frac{\tau I_0^{(0)}u_m}{2},\\ S_{m-1}&=\tau\left(\frac{I_m^{(0)}u_0}{2}+\sum_{i=1}^{m-1}u_iI_{m-i}^{(0)}\right),\\ \frac{u_m-u_{m-1}}{\tau}&=-\frac{1}{C}\,\frac{I_m+I_{m-1}}{2}.\end{aligned}\right\} \tag{10}$$

The sum in the expression for S_{m-1} with $m = 1$ should be set equal to zero. Eliminating I_m from these equations, we find

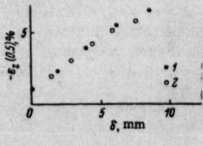

Fig. 5. The quantity ε_z as a function of the skin thickness for two functional dependences of the voltage on the time, u(t). 1) A δ-function pulse; 2) a capacitor discharge ($t = t_r$).

$$u_m = \frac{u_{m-1} - \frac{\tau}{2C}(I_{m-1} + S_{m-1})}{1 + \frac{\tau^2}{4C} I_0^{(0)}}. \tag{11}$$

Setting $I_0 = 0$ and $u_0 = u(0)$, we can use recursion relations (10) and (11) to find I_m and u_m; then we can determine any linear combination of the vector potential and its derivatives from Eq. (7).

Table 3 shows the calculated results; here t_r is the specified time required for the field to rise from zero to $B_{max} = 10$ T, and C, u_0, and W are the necessary capacitance, initial voltage, and energy $(Cu_0^2/2)$ of the capacitor. The other parameters have the same meaning as in Table 2. Their values correspond to a time $t = t_r$. Figure 4 shows the circuit voltage and current, normalized to their maximum values, which occur at $t_r = 5$ msec. The data in Table 2 are used in the calculations.

The force acting on a conductor cannot be found from Eq. (7); it is necessary to use the field distribution on segment OB for various values of θ in a δ-function pulse. We see from Table 2 that the change in the force as a function of the skin thickness, which is related to the change in the field geometry in the gap (Fig. 1), is small, and for Table 3 we can assume $F \simeq 2$ metric tons/cm. A more accurate value can be found if some skin thickness in Table 3 can be associated with the force in Table 2 for the same thickness. This procedure can also be used to determine other parameters. As long as the skin thickness is small in comparison with the aperture, the field parameters for various u(t) but for the same skin thickness differ very little (Fig. 5). The skin thickness, on the other hand, can be determined easily for a given u(t).

All these calculations have been carried out on the BÉSM-6 computer of the Computation Center, Siberian Branch, Academy of Sciences of the USSR. The program is written[12] in ALPHA. The time required to calculate the data in Table 2 is 6 min.

CONCLUSION

These calculations have shown that the solution of the equation for the vector potential by the net-point method in the quasisteady-state case reduces to a simple and efficient calculation scheme. In the case of iron-free magnets this method can be used for a numerical search for the optimum conductor geometry and the polepiece of the magnetic circuit. The method is easily generalized to systems with rotational symmetry.

Solution of the problem for a δ-function voltage yields a universal characteristic of the system of conductors and considerably reduces the expenditure of computer time. The calculation for an arbitrary u(t) is carried out in a simple manner. Furthermore, as is shown by a calculation of the field for the case of the discharge of a capacitor, this solution permits the system to be matched with various loads in a simple manner.

Calculation methods not involving iteration can be used in the case of the two-dimensional problem in a region in which the conductivity is nonvanishing everywhere or in the case of the one-dimensional problem. In the one-dimensional problem, the pivotal condensation method can be used, while in the two-dimensional problem the method of variable directions can be used. In these cases it is particularly efficient to use the difference method.

Above we have treated the case of conductors in a symmetric arrangement, with E^g known in each conductor. For symmetric conductors, as in the case of a multiturn system, the value of E^g in each conductor must be determined in the course of the calculation. The formulation of the problem for such cases will be treated in a separate paper.

Here we have assumed a relatively simple geometry for the conductors, and we have used a simple rectangular grid. Accurate results can be calculated by placing grid points on the contour of the conductor. In general, this procedure requires the construction of a special grid, e.g., as in certain programs used in calculations for fixed-field magnets.[9]

The authors thanks V. L. Auslender, Yu. B. Glagolev, A. A. Livshits, B. L. Faktorovich, and B. V. Chirikov for discussion.

---

[1] Doubling the integral of the field over the segment OB yields a current too low by about 0.3% because of the incomplete integration contour. The ac-

curacy stated in the test actually holds for this integral, rather than for the current.

Flux loss in the production of ultrastrong fields by rapid compression of conducting shells

V. I. Yurchenko

Institute of Nuclear Physics, Siberian Branch,
Academy of Sciences of the USSR, Novosibirsk

(Submitted May 10, 1973; resubmitted November 19, 1973)
Zh. Tekh. Fiz., 44, 1650-1655 (August 1974)

The flux-loss problem is written as a system of two equations under the assumption that the shell compressing the flux is solid and that certain parameters, which are functions of the shell geometry alone, are specified. These equations are solved for certain particular cases of compression. Despite the loss through the sliding contact, the field amplification is much higher in systems in which the shell contour decreases in length during the compression.

The explosion method of producing strong magnetic fields, proposed and investigated in 1951 (ref. 1), is currently used in various research projects. In devices operating on the basis of this method, there is always some flux loss because of the finite conductivity of the shell material: The flux through the area subtended by the shell is lower at the end of the compression than at the beginning. In practice, this effect reduces significantly the field amplification[2] and must be taken into account in the design of explosion generators.

The only exact flux calculation which has been reported is that for parallel plates with constant conductivity moving toward each other at a constant speed.[3-5] Various approximate methods are used for such calculations. Below, by assuming the shell material to be solid and by assuming that certain parameters which are functions of the shell geometry alone are specified, we write the flux-loss problem as a system of equations which can be solved numerically; for certain particular cases different from those treated in refs. 3-5, we are able to give exact solutions of these equations.

THE INITIAL EQUATIONS

A cross section of a shell compressing the flux in region G is shown schematically in Fig. 1. The contour F(t), a function of the time, is chosen so that the current-density vector is parallel to the contour at each point s. We assume that there is no flux loss through contact C due to surface inhomogeneities, that the flux compression begins at time t = t_b, and that the initial flux is produced in the interval 0 ≤ t ≤ t_b. To calculate the current in this system we use the flux-balance equation. Taking account of the penetration of some part of the flux into the conductor and the flux loss through the sliding contact,[2] we can write this equation as

$$\Phi(t)+\int\limits_{F(t)}\varphi(s,\ t)\,ds+\int\limits_{t_b}^{t}v(\tau)\left[\varphi_k^+(\tau)+\varphi_k^-(\tau)\right]d\tau =\Phi(t_b)+\int\limits_{F(t_b)}\varphi(s,\ t_b)\,ds, \tag{1}$$

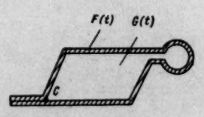

Fig. 1

where $\Phi(t)$ is the flux through the area subtended by contour F, $\varphi(s, t)$ is the shell per unit length of F at point s, v(t) > 0 is the velocity at which contact C moves along contour F(t), and $\varphi_k^+(t)$ and $\varphi_k^-(t)$ are the values of $\varphi(s, t)$ on the two sides of C.

When there are several contacts, a sum of integrals over all the contacts should stand on the left-hand side of (1). To calculate the current I(t) we must write $\Phi(t)$ and $\varphi(s, t)$ in terms of it.

We assume that the skin thickness is much smaller than the radius of curvature of the shell and we assume that the penetration of the field into the metal is described by the one-dimensional problem for the field in a conductor filling the half-space x > 0. The vector potential is measured from infinity:

$$A\, x,\ t)=-\int\limits_{x}^{\infty}B(x,\ t)\,dx,$$

where B(x, t) is the induction. Then in the electric-field equation

$$\mathbf{E}=-\frac{\partial\mathbf{A}}{\partial t}-\nabla\varphi$$

we are left with only the first term [in this case we have $\nabla\varphi$ = const by virtue of the condition curl$(\nabla\varphi)$ = 0]; assuming that **A**, **E** = 0 at x = ∞, we find from the electric-field equation that $\nabla\varphi = 0$. We can now write the following equation for the vector potential for x > 0:

$$\sigma_s\mu_0\frac{\partial A_s}{\partial t}=\frac{\partial^2 A_s}{\partial x^2}, \tag{2}$$

where $\sigma_s(x, t)$ is the conductivity of the shell material. The detailed equation for the case of nonlinear diffusion is treated in ref. 6. Here, the subscript "s" implies that we are considering the situation at point s; at this point we can write

$$\varphi(s,\ t)=-A_s(0,\ t). \tag{3}$$

The boundary condition for Eq. (2) can be written as

$$\frac{\partial}{\partial x}A_s\Big|_{x=0}=\mu_0\frac{I(t)}{b(s,\ t)}. \tag{4}$$

Here, b(s, t) is the average length of a line of force at the given point of the contour. We assume b (s, t) to be known. In cases of practical interest it is only a weak function of the skin thickness, being governed only by the instantaneous conductor configuration. The quantity b(s, t) can be set equal to the height of the plates forming the generator, provided that this height is greater than the plate separation. When the fringing fields are taken into account, b(s, t) is found to be larger by an amount roughly equal to this distance. The value of b(s, t) can be measured in a prototype apparatus.

We assume that L(t), the inductance of a turn enveloping the region G in the case of an infinitesimally thin skin, is also known. The value of L(t) is a function only of the instantaneous conductor configuration; it, too, can be measured in a prototype apparatus. Then we can write the flux through the area enveloped by contour F as

$$\Phi(t)=L(t)\,I(t). \tag{5}$$

To determine I(t) from Eqs. (1)-(5) we must specify the functional dependence on the time in the interval $0 \le t \le t_b$, during which the initial field is produced. Only Eq. (2) is solved for this interval.$^{1)}$

Then the functional dependence of the current on the time can be determined from the solution of Eqs. (1) and (2).

For fields of $\leqslant$ 0.5 MOe, for which we can neglect thermal effects[2] and assume $\sigma_g(x,\,t)=\sigma=\mathrm{const}$, the problem is simplified. From Eq. (2) and (4) for this case we find

$$\varphi(s,\,t)=\sqrt{\frac{\mu_0}{\sigma\pi}}\int_0^t\frac{I(\tau)\,d\tau}{b(s,\,\tau)\sqrt{t-\tau}}, \tag{6}$$

and the problem reduces to the solution of Eq. (1) alone.

ANALYSIS OF CERTAIN SIMPLE CASES

We turn to certain simple cases of flux compression with $\sigma_g(x,\,t)=\sigma=\mathrm{const}$. We assume that in each case the shell height is uniform [b(s, t) = const] and that the field within the shell is homogeneous, equal to H(t). We assume for simplicity that the initial field is produced instantaneously at time t = 0. From Eqs. (1) and (6) we find the following equation for H(t):

$$H(t)\,S(t)+\frac{1}{\sqrt{\sigma\mu_0\pi}}\int_0^t\left(\mathscr{L}(\tau)\frac{d}{d\tau}\int_0^\tau\frac{H(\eta)\,d\eta}{\sqrt{\tau-\eta}}\right)d\tau=H(0)\,S(0), \tag{7}$$

where S(t) is the area enveloped by contour F, and $\mathscr{L}(t)$ is the length of this contour. Taking the time derivative of (7), dividing the result by $\mathscr{L}(t)$, and integrating the resulting equation from 0 to t, we find

$$\frac{H(t)\,S(t)}{\mathscr{L}(t)}+\frac{1}{\sqrt{\sigma\mu_0\pi}}\int_0^t\frac{H(\eta)\,d\eta}{\sqrt{t-\eta}}=\frac{H(0)\,S(0)}{\mathscr{L}(0)}-\int_0^t\frac{H(t)\,S(t)}{\mathscr{L}^2(t)}\frac{d}{dt}\mathscr{L}(t)\,dt. \tag{8}$$

Written in this form, the initial equation is more convenient in the calculations for the cases considered below.

Let us compare three cases of the compression of a generator shell consisting of two parallel plates (Fig. 2), initially a distance a_0 apart. We introduce the notation

$$\tau=\frac{t}{t_0};\quad h(\tau)=\frac{H(\tau)}{H(0)};\quad \varepsilon=\frac{2}{a_0}\sqrt{\frac{t_0}{\sigma\mu_0}}.$$

We are also to determine the value of t_0 for each case.

a. For the case illustrated in Fig. 2a the contact C begins to move from point x = 0 along the x axis at a constant velocity v_x. Here we have $a=a_0=\mathrm{const}$, $t_0=l/v_x$, and the end of compression at time $\tau_k=l_k/(v_x t_0)$. We consider the case $l-l_k\gg a_0$; here $\mathscr{L}(t)\approx 2(l-v_x t)$ and $S(t)=a_0(l-v_x t)$. Equation (8) becomes

$$h(\tau)+\frac{\varepsilon}{\sqrt{\pi}}\int_0^\tau\frac{h(\eta)\,d\eta}{\sqrt{\tau-\eta}}=1+\int_0^\tau\frac{h(\eta)\,d\eta}{1-\eta}. \tag{9}$$

The solution of this equation is (see the Appendix)

$$h(\tau)=e^{\varepsilon^2\tau}\mathit{Erf}(\varepsilon\tau^{1/2})+g(\tau)+\varepsilon\pi^{-1/2}\int_0^\tau\frac{g(\xi)}{\sqrt{\tau-\xi}}\,d\xi, \tag{10}$$

where

$$g(\tau)=\frac{\tau}{1-\tau}\left[(1+2\varepsilon^4\tau^2)\,e^{\varepsilon^2\tau}\mathit{Erf}(\varepsilon\tau^{1/2})-2\pi^{-1/2}\varepsilon\tau^{1/2}\right]. \tag{11}$$

We introduce the quantity $K_0=1/(1-\tau_k)=S(0)/S_L$ (S_L is the area of the load turn), which is equal to the field amplification in the case of superconducting conductors. With $K_0\gg 1$ and rapid compression ($\varepsilon\ll 1$), we find from (10) and (11)

$$K=h(\tau_k)\approx K_0\left[1-\frac{4\varepsilon}{\sqrt{\pi}}\left(1-\frac{\pi K_0^{-1/2}}{4}\right)\right]. \tag{12}$$

As long as the approximation $l-v_x t\gg a$ is valid, with sufficiently rapid compression the functional dependence of the field on the time is described by $1/(1-\tau)$.

b. The case of Fig. 2b is analogous to that treated in refs. 3-5, differing only in the presence of a load turn. The generator plates approach each other at a constant speed v_y over the range $0\le x\le l$. In Eq. (8) we have

$$S(t)=la_0\left(1-\frac{t}{t_k}\right)+S_L,$$
$$\mathscr{L}=2l+\mathscr{L}_L=\mathrm{const},$$

where $t_k=a_0/v_y$; S_L is the area of the load turn, and $\mathscr{L}_L$ is its length. In this case we use

$$t_0=\left(a_0+\frac{S_L}{l}\right)\frac{1}{v_y},\quad \varepsilon=\frac{\mathscr{L}(0)}{S(0)}\sqrt{\frac{t_0}{\sigma\mu_0}}$$

[for cases of practical interest $\varepsilon\approx(2/a_0)\sqrt{t_0/\sigma\mu_0}$].

For $h(\tau)$ we find the equation

$$h(\tau)(1-\tau)+\frac{\varepsilon}{\sqrt{\pi}}\int_0^\tau\frac{h(\eta)}{\sqrt{\tau-\eta}}\,d\eta=1.$$

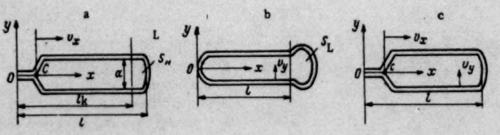

Fig. 2

This equation is solved in ref. 5; the solution for time $\tau_k = t_k/t_0$ can be written as

$$h(\tau_k)=\frac{1}{2}K_0^{3/2}e^{\varepsilon^2 K_0}\int\limits_{K_0}^{\infty}\left(1+\frac{2\varepsilon}{\sqrt{\pi}}\sqrt{\frac{\eta}{\eta-1}}\right)e^{-\varepsilon^2\eta}\eta^{-5/2}d\eta,$$

where $k_0 = 1/(1-\tau_k) = S(0)/S_L$.

For large values of K_0 the quantity within the parentheses in the integrand can be replaced by $1+2\varepsilon/\sqrt{\pi}$, so that the field amplification becomes

$$K\approx\left(1+\frac{2\varepsilon}{\sqrt{\pi}}\right)K_0\left[1-\sqrt{\pi}\,\varepsilon\sqrt{K_0}\,e^{\varepsilon^2 K_0}\,\mathrm{Erf}\left(\varepsilon\sqrt{K_0}\right)\right].$$

In the case of rapid compression, with $\varepsilon^2 K_0 \ll 1$, this expression yields

$$K\approx K_0\left(1-\sqrt{\pi}\,\varepsilon\sqrt{K_0}\right), \tag{13}$$

while with $\varepsilon^2 K_0 \gg 1$

$$K\approx K_{\lim}\left(1-\frac{3}{2\varepsilon^2 K_0}\right),$$

where

$$K_{\lim}=\frac{1}{2\varepsilon^2}+\frac{1}{\sqrt{\pi}\,\varepsilon}, \tag{14}$$

which is the limiting value of K in the absence of a load ($K_0 = \infty$) (refs. 3-5).

c. In this case (Fig. 2c) contact C moves at a constant speed v_x, and the plates come together at a relative velocity v_y. There is no load turn. The relation between v_x and v_y is such that when contact reaches the point $x = l$ the distance between the plates vanishes. In the case $l \gg a_0$, we have

$$\mathscr{L}\approx 2l(1-\tau),\ S=a_0 l(1-\tau)^2,\ t_0=\frac{l}{v_x}=\frac{a_0}{v_y}.$$

For $h(\tau)$ we find

$$h(\tau)(1-\tau)+\frac{\varepsilon}{\sqrt{\pi}}\int\limits_0^{\tau}\frac{h(\xi)\,d\xi}{\sqrt{\tau-\xi}}=1+\int\limits_0^{\tau}h(\xi)\,d\xi.$$

We use the notation $f(\tau)=\int\limits_0^{\tau}h(\eta)d\eta$. For the transform $F(p) \doteqdot f(\tau)$ we find

$$\frac{dF}{dp}+(1+\varepsilon p^{-1/2})F=p^{-2}.$$

The inverse of the transform which obeys this equation is calculated in ref. 3. We find

$$h(\tau)=\frac{\varepsilon}{\sqrt{\pi}}\int\limits_{1-\tau}^{1}\frac{\xi^{-2}(1-\xi^{1/2})}{(\xi-1+\tau)^{3/2}}\exp\left(-\frac{\varepsilon^2(1-\xi^{1/2})^2}{\xi-1+\tau}\right)d\xi.$$

Hence the field at the end of compression is

$$h(1)=\frac{3}{4}\varepsilon^{-4}+\frac{3}{\sqrt{\pi}}\varepsilon^{-3}+\frac{3}{2}\varepsilon^{-2}+\frac{1}{\sqrt{\pi}}\varepsilon^{-1}.$$

Comparison of these cases shows that despite the loss through the contact the best compression method is that in which the length of the contour F over which the loss occurs decreases during the compression. For a given value of ε the flux loss is strongly influenced by the compression method. It follows from (12) and (13) that, for a given value of K_0, the flux loss in case b is larger than that in case a by a factor of $\pi\sqrt{K_0/4}$. The limiting field in case c with $\varepsilon \ll 1$ is larger by a factor of $(3/2)\varepsilon^{-2}$ than that in case b [Eq. (14)]. The difference is important, since $K_0 \gg 1$ and $\varepsilon \ll 1$.

The area enveloped by contour F has different functional dependences on the time in cases b and c, but this difference does not affect our comments. If we adopt for case b the behavior of the area corresponding to case c, i.e., $S = la_0(1-\tau)^2$ ($S_L = 0$, $\mathscr{L}_L = 0$), we find that the plates begin to move toward each other at a speed $2v_y$ at the same t_0; decelerating uniformly, they reach zero velocity at the end of compression. In this case the limiting field is obviously even weaker than predicted by Eq. (14).

APPENDIX

In Eq. (9) we use the replacement

$$h(\tau)=(1-\tau)f(\tau). \tag{A.1}$$

We apply a Laplace transform to the equation for $f(\tau)$:

$$(1-\tau)f(\tau)+\frac{\varepsilon}{\sqrt{\pi}}\int\limits_0^{\tau}\frac{(1-\eta)f(\eta)}{\sqrt{\tau-\eta}}d\eta=1+\int\limits_0^{\tau}f(\eta)\,d\eta.$$

We find the transform $F(p) \doteqdot f(\tau)$ to satisfy

$$\frac{dF}{dp}+\left(1-\frac{1}{p+\varepsilon\sqrt{p}}\right)F=\frac{1}{p+\varepsilon\sqrt{p}}. \tag{A.2}$$

We introduce the auxiliary transform

$$G(p)=\frac{F(p)}{(\varepsilon+\sqrt{p})^2}.$$

We denote the corresponding inverse transform by $g(\tau)$; then it follows from Eqs. (A.1) and (A.2) that

$$(1-\tau)g(\tau)\doteqdot\frac{d}{dp}G(p)+G(p)=\frac{1}{\sqrt{p}\,(\varepsilon+\sqrt{p})^3},$$

$$h(\tau)\doteqdot\frac{1}{p+\varepsilon\sqrt{p}}+\left(1+\frac{\varepsilon}{\sqrt{p}}\right)G(p).$$

Then we find Eqs. (10) and (11) for $h(\tau)$ and $g(\tau)$.

---

1) If the initial field is produced by the discharge of a capacitor we can use the results for a turn of two parallel conductors,[7] assuming that the inductance of the gap between the conductors is L(0) and that the gap width is

$$d=\frac{2L(0)}{\mu_0}\left(\int\limits_F\frac{ds}{b(s,0)}\right)^{-1}.$$

Stability of the diode

V. A. Buts

(Submitted September 28, 1973; resubmitted January 14, 1974).
Zh. Tekh. Fiz. 44, 1656-1661 (August 1974)

The stability of an electron beam in a diode and the effect of an external electric field on the Pierce stability criterion are considered. It is shown that the instability arises when the beam is slowed down; an accelerated beam is stable. It is also shown that an external electric field changes the Pierce threshold and causes new instabilities. The mechanism by which the threshold is increased for an accelerated beam is explained.

Electron beams are used to generate and amplify electromagnetic waves, to heat plasmas and for many other purposes. In most cases the beams are formed in diodes. Hence it is desirable to know whether it is possible to excite a required oscillation spectrum directly as the beam is being formed or what is necessary in order to produce a beam with a given modulation.

In this note we consider the stability of a uniform electron beam which is infinite in the transverse direction and which moves with a variable velocity $v_0 = f(z)$ from the cathode ($z = 0$) to the anode ($z = L$). The solution of this problem will provide an answer to some of the questions listed above.

1. GENERAL DISPERSION EQUATION

To describe the development of a perturbation in the system we use the following set of equations:

$$\frac{d\mathbf{P}}{dt} = e\mathbf{E};\quad \frac{\partial\rho}{\partial t} + \operatorname{div}\mathbf{j} = 0;\ \operatorname{div}\mathbf{E} = 4\pi\rho. \tag{1}$$

We linearize this system and take the time dependence in the form $e^{-i\omega t}$. Eliminating $\tilde{p}$ and $\tilde{v}$ from the linearized equations we obtain the following equation for $\tilde{E}$:

$$\mathcal{E}'' + Q^2\mathcal{E} = F, \tag{2}$$

where

$$\mathcal{E} \equiv \tilde{E}\exp\left[\frac{1}{2}\int_0^z X(z_1)\,dz_1\right],\quad \mathcal{E}' \equiv \frac{d\mathcal{E}}{dz},$$

$$X \equiv -\frac{2i\omega\gamma_0}{c\sqrt{\gamma_0^2-1}} + 3\frac{\gamma_0'}{\gamma_0}\left[1-\frac{1}{\gamma_0^2-1}\right],\quad \gamma_0 \equiv (1-\beta_0^2)^{-1/2},$$

$$\beta_0 \equiv \frac{v_0}{c},\quad Q^2 \equiv \left[\frac{\omega_b^2}{c^2}\frac{\beta_0}{(\gamma_0^2-1)^{3/2}} + \frac{5(\gamma_0')^2}{(\gamma_0^2-1)^2} + \frac{9}{4}\left(\frac{\gamma_0'}{\gamma_0}\right)^2\right]$$
$$-\frac{3}{2}\frac{\gamma_0''\gamma_0}{(\gamma_0^2-1)} - \left(\frac{\gamma_0'}{\gamma_0}\right)^2\left[3+\frac{5}{\gamma_0^2-1}+\frac{17}{4}\frac{1}{(\gamma_0^2-1)^2}\right],$$

$\omega_b^2 \equiv 4\pi e\rho_0/m$; m is the rest mass,

$$F \equiv -A\frac{\gamma_0}{c\sqrt{\gamma_0^2-1}}\left[\frac{i\omega\gamma_0}{c\sqrt{\gamma_0^2-1}} - \frac{2\gamma_0'}{\gamma_0(\gamma_0^2-1)} - \frac{3\gamma_0'}{\gamma_0}\right]\exp\left[\frac{1}{2}\int_0^z X\,dz_1\right],$$

and A is an arbitrary constant, which appears when the equation of continuity and Poisson's equations $\operatorname{div}(-i\omega\tilde{E} + 4\pi\tilde{j}) = 0$ are solved simultaneously. The expressions for Q^2, X, and F are simplified considerably in the nonrelativistic case ($\beta_0^2 \ll 1$), and for high beam velocities ($\gamma_0^2 \gg 1$). In ref. 1 the stability of a nonrelativistic beam whose velocity varies with coordinate is considered. Since the beam is infinite, $A = 0$. In the case of a bounded beam (in the longitudinal direction) it is necessary to take this constant into account. In the nonrelativistic case Eq. (2) without the right side is the same as the equation obtained in ref. 1.

We use the following boundary conditions to obtain the dispersion equation for the perturbed quantities:[2]

$$\tilde{\rho}(0) = \tilde{v}(0) = \tilde{\varphi}(0) = \tilde{\varphi}(L) = 0, \tag{3}$$

where

$$\tilde{E} = -\nabla\tilde{\varphi}.$$

Solving Eq. (2) and substituting the solution into the boundary conditions (3), we obtain the following dispersion equation for the frequency ω:

$$\int_0^L dz\exp\left[-\frac{1}{2}\int_0^z X\,dz_1\right]\left\{\frac{i\omega}{4\pi A}\left[\mathcal{E}_{01}\int_0^z \mathcal{E}_{02}F\,dz_1 - \mathcal{E}_{02}\int_0^z \mathcal{E}_{01}F\,dz_1\right]\right.$$
$$\left. + [\mathcal{E}_{01}\mathcal{E}_{02}'(0) - \mathcal{E}_{02}\mathcal{E}_{01}'(0)] - \frac{1}{2}X[\mathcal{E}_{01} - \mathcal{E}_{02}(0)\mathcal{E}_{02}\mathcal{E}_{01}(0)]\right\} = 0, \tag{4}$$

where $\mathcal{E}_{0s}$ is the particular solution of the homogeneous equation (2).

Equation (4) is valid for both a neutralized beam and a nonneutral beam, and for any dependence of the unperturbed velocity $v_0(z)$ on the z coordinate. We consider the case of a diode in which the unperturbed beam velocity $v_0(z)$ is determined both by the electrode potentials and by the space charge of the beam itself (2), and the case in which the space charge of the beam is neutralized and the dependence of the velocity $v_0(z)$ on z is determined solely by the external fields (3).

2. STABILITY OF THE BEAM
IN THE DIODE

Solving the unperturbed set of equations (1) in the nonrelativistic case with the boundary conditions $\varphi_0(0) = U_k$, $\varphi_0(L) = U_A$ [where U_k (U_A) is the constant potential applied to the cathode (anode)], we find the unperturbed velocity in the diode:

$$v_0 = (\psi \pm \eta z)^{2/3}, \tag{5}$$

where

$$\psi \equiv \left(U_k\frac{2e}{m}\right)^{3/4};\ \eta \equiv \sqrt{18\pi j_0\frac{e}{m}};\ j_0 = \rho_0 v_0 = \text{const}.$$

The minus sign describes the case in which the beam is retarded in the diode.

Substituting Eq. (5) into Eq. (2) and making the substitution $x = \psi + \eta z$, we obtain

$$\frac{d^2\mathscr{E}}{dx^2} + \frac{2}{9x^2}\mathscr{E} = F_1, \tag{6}$$

where $F_1 \equiv F/\eta^2$.

The following functions are solutions of the homogeneous equation (6):

$$\mathscr{E}_{01} = x^{2/3}, \quad \mathscr{E}_{02} = x^{1/3}. \tag{7}$$

Substituting these functions in Eq. (4) and introducing the quantity $\xi \equiv (\omega/\eta)\sqrt[3]{x}$, for $\xi \gg 1$ we obtain the following dispersion equation:

$$e^{-3i(\xi_L - \xi_0)} = -\frac{\xi_0}{3}\frac{1}{(\xi_L^3 - \xi_0^3)}\left(\frac{\xi_L}{\xi_0}\right)^{5/4} \times \left\{\left[10 - 14\left(\frac{\xi_0}{\xi_L}\right)^{1/3}\right] + i\left[3 - 7\left(\frac{\xi_0}{\xi_L}\right)^{1/3}\right]\right\}. \tag{8}$$

It is evident from Eq. (8) that instability is possible only when $\xi_0 > \xi_L$, i.e., only when the beam is slowed down. Taking $U_k \gg U_A$ and using Eq. (8) we get the following simple expressions for the frequency and growth rate:

$$\left.\begin{aligned} \operatorname{Re}\omega &= \frac{2\pi n}{3}\sqrt{\frac{2e}{m}U_k} = \frac{2\pi n}{3}\frac{v_k}{L}, \\ \operatorname{Im}\omega &= \frac{2}{3}\frac{v_k}{L}\ln\left(\frac{2\pi n}{3}\right), \end{aligned}\right\} \tag{9}$$

where n is an integer ($n \gg 1$), and v_k is the velocity of the beam at the cathode.

Since the growth rate of the oscillation increases (slowly) as n increases, a question arises regarding the maximum value of n. In order to determine this quantity, and correspondingly, the maximum frequency generated by the beam in the diode, it is necessary to take the thermal motion into account. To do this we must add the following term to the right side of the linearized first equation (the equation of motion) of system (1) (see, for example, ref. 1):

$$m\left[\frac{\rho}{\rho_0}\frac{\partial\rho_0}{\partial t} - \frac{\partial\rho}{\partial z}\right]\frac{v_T^2}{\rho_0}. \tag{10}$$

Taking this term into account leads to the following inequality:

$$2\pi n < \sqrt{\frac{v_k v_A}{v_T^2}}, \tag{11}$$

where v_A is the velocity of the beam at the anode, and v_T is the thermal velocity.

This limitation leads to the following value of the maximum frequency generated by the beam:

$$\operatorname{Re}\omega_{\max} = \frac{v_k}{L}\frac{\sqrt{v_k v_A}}{3v_T}, \quad \operatorname{Im}\omega_{\max} = \frac{2}{3}\frac{v_k}{L}\ln\left(\frac{\sqrt{v_k v_A}}{3v_T}\right). \tag{12}$$

As an example we substitute the following values of the velocities in Eq. (12): $v_k = 3 \cdot 10^9$, $v_A = 3 \cdot 10^8$, and $v_T = 3 \cdot 10^7$. Then for L = 1 cm the beam in the diode will generate a frequency $\omega_{\max} = 5.5 \cdot 10^{10}$ with a growth rate $\operatorname{Im}\omega_m = 4.9 \cdot 10^9$.

A device in which the beam is slowed down at the anode is a triode with an accelerating grid and a retarding anode. The instability in such a system has been observed experimentally in refs. 3 and 4 (see also ref. 5). In this case it is assumed that the generation of oscillations in such a triode is due to oscillations of electrons about the positive grid and that the frequency is determined either by external circuits,[4] or by the frequency of oscillation of the electrons around the grid.[3] The analysis above shows that another instability mechanism is possible in a triode with a positive grid. In this case it is clear that the maximum oscillation efficiency will obtain when the frequency of the external circuit (with respect to the electron beam) coincides with one of the frequencies generated by the beam.

3. EFFECT OF AN EXTERNAL ELECTRIC FIELD ON THE PIERCE CRITERION

We consider the effect of an external electric field on the stability of an electron beam traveling with constant velocity v_0 through a system with two electrodes. As is well known,[2,6] such a beam is unstable with respect to the excitation of aperiodic oscillations $\operatorname{Re}\omega \ll \operatorname{Im}\omega$ (Pierce instability). The ion background neutralizes the electron-beam charge ($n_i = n_{0e}$). Equation (2) describes the behavior of a perturbation in such a system.

We assume that the external electric field and the time during which it acts are fairly small so that we can neglect the motion of the ions and use the WKB approximation in solving Eq. (2), i.e., we assume that the distance L over which the beam velocity changes appreciably (by a factor of 2) is much greater than the characteristic wavelength $\lambda \sim 1/Q$ ($L \gg \lambda$). Solving the homogeneous equation (2) in this approximation we obtain

$$\mathscr{E}_{01} = \frac{1}{\sqrt{Q}}\exp\left[i\int_0^z Q\,dz_1\right], \quad \mathscr{E}_{02} = \frac{1}{\sqrt{Q}}\exp\left[-i\int_0^z Q\,dz_1\right]. \tag{13}$$

To solve the dispersion equation (4) with the solutions (13) we consider the relativistic and nonrelativistic cases separately.

The nonrelativistic case ($\beta_0^2 \ll 1$). The dependence of the velocity on the coordinate can be chosen in the following form:

$$v_0 = V(1 + \zeta z), \tag{14}$$

where $\zeta = eE_0/mV^2$, $\zeta L \ll 1$, and E_0 is the external field. The WKB approximation holds when $\zeta \ll 2/3\,(\omega_b/V)$. The dispersion equation (4) becomes

$$\Delta = \zeta L \Phi, \tag{15}$$

where

$$\Delta \equiv 2\alpha\xi[1 - e^{i\xi_1}\cos\alpha_1] + ie^{i\xi_1}(\xi^2 + \alpha^2)\sin\alpha_1 + i\frac{\xi^2}{\alpha}(\xi^2 - \alpha^2),$$

$$\alpha \equiv \frac{\omega_b}{V}L, \quad \xi \equiv \frac{\omega}{V}L, \quad \alpha_1 \equiv \alpha\left(1 - \frac{3}{4}\zeta L\right), \quad \xi_1 \equiv \xi(1 - \zeta L),$$

Φ is an unwieldy expression, so that we will write it in explicit form for the special cases considered below.

Assuming $\xi \ll 1$ we substitute $\alpha = \pi n + \delta$ in Eq. (15), where $n = 1, 3, 5, \ldots$, and $\zeta L < \delta \ll 1$; we find $\Phi \to 0\,(\xi, \delta)$ and

$$\xi = i\frac{\pi n}{4}\left[\delta - \frac{3}{4}\pi n\zeta L\right]. \tag{16}$$

For $\zeta = 0$, Eq. (16) gives the growth rate for the Pierce instability.[6]

It can be seen from Eq. (16) that an external electric field which accelerates the electron beam leads to a threshold for the Pierce instability, while a retarding electric field increases the growth rate.

We will now show that an external electric field not only can quench the Pierce instability but also can cause new instabilities. To show this we put $\xi = \alpha + \mu$, where $\zeta L \ll \mu \ll 1$. From Eq. (15) we have

$$\Phi = \frac{1}{\mu}\alpha^3;\ \mu^3 = \frac{\zeta L\alpha^3}{2i\alpha + 2\alpha^2 + ie^{i\alpha}\sin\alpha}. \tag{17}$$

Hence, when $\alpha \gg 1$

$$\left.\begin{aligned} \operatorname{Re}\omega &= \omega_b - \frac{V}{L}\frac{1}{(2)^{1/3}}(\zeta L\alpha)^{1/3}, \\ \operatorname{Im}\omega &= \frac{V}{L}\frac{\sqrt{3}}{(2)^{1/3}}(\zeta L\alpha)^{1/3} \end{aligned}\right\} \tag{18}$$

and when $\alpha \ll 1$

$$\operatorname{Re}\omega = \omega_b,\ \operatorname{Im}\omega = \frac{V}{L}\left[\frac{1}{3}\zeta L\alpha^2\right]^{1/3}. \tag{19}$$

The relativistic case ($\gamma_0^2 \gg 1$). We assume that γ_0 varies as

$$\gamma_0 = \gamma(1 + \zeta z). \tag{20}$$

To satisfy the WKB approximation we require

$$\zeta \ll \frac{2}{3}\frac{\omega_{b1}}{c},\ \text{where}\ \omega_{b1}^2 \equiv \frac{4\pi e^2 n}{m\gamma^3}.$$

Substituting into the expressions for Q^2, X and F, from Eq. (4) we obtain the dispersion equation

$$\Delta_1 = \zeta L\Phi_1, \tag{21}$$

where

$$\Delta_1 \equiv 2\alpha\xi[1 - e^{i\xi}\cos\alpha_1] + ie^{i\xi}(\xi^2 + \alpha^2)\sin\alpha_1 + i\frac{\xi^2}{\alpha}(\xi^2 - \alpha^2),\ \xi \equiv \frac{\omega}{c}L,\ \alpha \equiv \frac{\omega_{b1}}{c}L,\ \alpha_1 \equiv \alpha\left(1 - \frac{3}{4}\zeta L\right).$$

The expressions for Φ_1, as in the nonrelativistic case, will be written for some special cases.

For $\xi \ll 1$ we substitute $\alpha = \pi n + \delta$ in Eq. (21), where $\delta \ll 1$. Then $\Phi_1 \to 0\,(\xi, \delta)$, and we obtain (16) for ξ, i.e., as in the nonrelativistic case, an external electric field which accelerates the beam increases the Pierce instability threshold.

Putting $\xi = \alpha + \mu$, we obtain the following values of the frequency and growth rate

$$\left.\begin{aligned} \operatorname{Re}\omega &= \omega_{b1} - \frac{1}{2}\frac{V}{L}\left(\frac{3}{4}\zeta L\alpha\right)^{1/3} \\ \operatorname{Im}\omega &= \frac{\sqrt{3}}{2}\frac{V}{L}\left(\frac{3}{4}\zeta L\alpha\right)^{1/3} \end{aligned}\right\} \tag{22}$$

for $\alpha \gg 1$, and

$$\operatorname{Re}\omega = \omega_{b1};\ \operatorname{Im}\omega = \frac{V}{L}\left(\frac{1}{2}\zeta L\alpha^2\right)^{1/3} \tag{23}$$

for $\alpha \ll 1$.

Hence, both in the relativistic and in the nonrelativistic cases an accelerating external electric field increases the Pierce instability threshold, and generates new instabilities.

4. THE MECHANISM BY WHICH THE OSCILLATION THRESHOLD IS INCREASED

It is of interest to understand why the Pierce instability threshold is increased when the beam is accelerated to understand why the instability develops when the beam is slowed down in a diode, and why it is quenched when the beam is accelerated.

As is well known,[7-9] for a collective instability to develop it is necessary that each particle of the beam should radiate (i.e., an elementary radiation mechanism is necessary) so that the radiating particles form coherent bunches, and that there should be coherence between the bunches. The instability develops in the following way. The perturbation groups the particles into bunches: They begin to radiate coherently, increasing the amplitude of the perturbation, etc. It follows from this, that for the instability to be quenched it is necessary to reduce the radiating capacity of the particles, or the number coherently radiating particles, in order to compensate the increase in the perturbation. Since the perturbations usually grow from the thermal noise level, one might expect that this interference requirement will not be very severe.

The increase in the Pierce instability threshold occurs due to a reduction in the number of coherently radiating particles in a bunch. A change in the number of coherently radiating bunches plays no part in this case. It can be shown that for any instabilities for which $\operatorname{Re}\omega \gg \operatorname{Im}\omega$, a change in the number of particles in the bunches will play the main part. This can be seen from the fact that in determining $\operatorname{Im}\omega$ we use the unperturbed value of $\operatorname{Re}\omega$, i.e., we neglect the change in the wavelength in determining the growth rate to a first approximation. In the general case, for the instability to be quenched, it is necessary to accelerate the beam; in this case the number of coherent bunches and the number of particles in a bunches are both reduced. This can be clearly seen in the above example of the instability of a beam in a diode.

To summarize, we have obtained the following results.

1. A retarded electron beam in a diode is unstable with respect to the excitation of longitudinal oscillations at frequency $\omega = (v_k/L)2\pi n/3$ with growth rate $\operatorname{Im}\omega =$

$(^2/_3)v_k/L\ln(2\pi n/3)$. An accelerated beam in a diode is stable.

2. Thermal motion sets an upper limit to the frequency of the oscillations generated by the beam in the diode

$$\omega_{\max}=\frac{v_k}{L}\frac{\sqrt{v_k v_A}}{3v_T}; \quad \operatorname{Im}\omega_{\max}=\frac{3}{2}\frac{v_k}{L}\ln\left(\frac{\sqrt{v_k v_A}}{3v_T}\right).$$

3. An accelerating external electric field leads to an increase in the Pierce instability threshold, while a retarding field increases the growth rate of this instability.

4. An external electric field leads to new instabilities.

5. The mechanism by which the oscillation threshold increases when the electron beam is accelerated has been determined.

In conclusion I wish to thank V. I. Kurilko for drawing my attention to the problem.

Low-frequency oscillations in counter-streaming high-current electron beams

A. F. Timoshenko, D. V. Iremashvili, and Yu. K. Udovichenko

(Submitted March 26, 1973; resubmitted February 4, 1974)
Zh. Tekh. Fiz., 44, 1662-1668 (August 1974)

Low-frequency (lf) oscillations are investigated experimentally in counterstreaming beams in a background plasma in a homogeneous magnetic field. The current is 3 A, the electron beam energy is 25 keV, and the magnetic field varies from 250 to 1000 Oe. The counterstreaming beams are produced by reflection of the electron beam from a negative electrode. The oscillation frequency is close to the ion plasma frequency; the oscillations are radial oscillations of the density. These oscillations cause periodic excitation of high-frequency (hf) oscillations at half the electron cyclotron frequency and its harmonics $n\omega_H/2$ ($n = 1, 2, 3, \ldots$). The lf oscillations can result from the interaction of drift instabilities in the counterstreaming beams. The current cutoff due to the lf oscillations limits the amplitude of the hf oscillations.

As reported earlier,[1] the interaction between counterstreaming electron beams in a system in which the magnetic field increases at the imput leads to hf oscillations at half the electron cyclotron frequency, and its harmonics $n\omega/2$, which are strongly modulated at low frequencies under certain conditions.

In the present paper we study lf oscillations and the effect on the hf oscillations excited in counterstreaming electron beams.

The investigation is carried out on the apparatus described in ref. 1. The beam parameters are as follows: current I 3 A, electron energy eV 25 keV, and pulse length 10-40 μsec. The glass test chamber, 4 cm in diameter and L = 40 cm long, with a movable electrode (collector), is located with the electron gun in a constant homogenous magnetic field H = 250-1000 Oe. Counterstreaming beams are produced by reflection of the beam injected into the test chamber; the beam originates from an electrode at a negative potential equal to the cathode potential. The beam is 1 cm in diameter at the entrance to the system. The lf and hf oscillations are detected by coaxial probes. A system of probes that can move along the length and radius enables us to measure the intensity and to observe the phase shift of the lf oscillations in space. The lf oscillations can also be detected from the envelope of the oscillations at frequencies $n\omega_H/2$. The diameters of the injected and oscillating beams are measured in cross section by using a current-detecting spherical probe which is rotated about its own axis, which is asymmetric to the axis of the system. The probe can be moved along the chamber. This probe is used to measure the amplitude of the lf oscillations of the density. The current in the cathode and electrode (collector) circuits is recorded by a Rogowski loop. A probe is used to determine the density n_p and electron temperature T_e. The longitudinal electron distribution function of the injected beam is measured by a multigrid analyzer located behind the collector. The particles enter the analyzer through an aperture 0.03 cm in diameter. Similar apertures placed along the diameter are used to obtain radial and azimuthal measurements of the phase and amplitude of electron density oscillations in the injected beam with the aid of a system of microcollectors. Segmented collectors (two segments, a disk and a diaphragm) are also used to investigate the phase of density oscillations.

The pressure in the gun region is $\sim 10^{-6}$ mm Hg. The pressure in the test chamber can be varied from $5 \cdot 10^{-6}$–1.10^{-3} mm Hg. Nitrogen is usually the working gas; hydrogen, helium, argon, and krypton are used in certain experiments.

The investigation indicates that (as for high-current counterstreaming electron beams in an inhomogeneous magnetic field) in a system with a homogeneous magnetic field intense oscillations are excited at frequency $n\omega_H/2$. The dependence of the intensity and frequency of lf oscillations on different parameters is similar to that studied in ref. 1. A general characteristic of these systems is the strong modulation of the hf oscillations by lf oscillations.

The lf oscillations under study appear in the system after the electrons in the oscillating beam are neutralized. The oscillations develop faster if the current and pressure are increased; they disappear when conditions for the development of a beam–plasma discharge occur in the system. The density n_p is measured by two electric probes in the pressure range $p = (2\text{-}4) \cdot 10^{-4}$ mm Hg preceding the beam–plasma discharge, when the lf oscillations have almost disappeared, and the density is 10^8–10^9 cm^{-3}, $T_e \simeq 20$–40 eV for I = 0.2–1.5 A, eV = 5–15 keV. The measurements show lf oscillations for plasma densities from $n_p \ll n_b$ to $n_p \sim n_b$ (n_b is the density of beam electrons); in the calculations we assume $n_i \simeq n_b$.

In Fig. 1, the frequency (curve 1) and amplitude (curve 2) of the lf oscillations and the beam diameter $2a$ (curve 3) are given as functions of the current. The beam radius a is estimated at 1/3 the height of the time-averaged radial distribution of the current density.

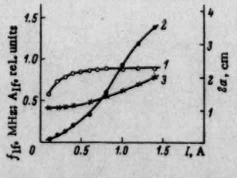

Fig. 1. Frequency (1) and amplitude (2) of the lf oscillations, and diameter of the beam (3) as functions of current. eU = 15 keV, H = 750 Oe, L = 30 cm, p = $1 \cdot 10^{-4}$ mm Hg.

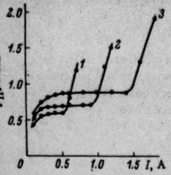

Fig. 2. Frequency of the lf oscillations as a function of beam current for different energies. 1) 5; 2) 7.5; 3) 15 keV. The other parameters are the same as in Fig. 1.

It is evident from the figure that the frequency at I = 0.1-0.4 A increases for a small change in the beam diameter. With a further increase in the current the frequency becomes saturated and the beam diameter increases noticeably. With an increase in current the amplitude of the lf oscillations increases considerably. Figure 1 shows the maximum amplitude of the oscillations over the beam cross section.

In Fig. 2, the frequency of the lf oscillations in counterstreaming beams is shown as a function of current for different energies of the injected beam. The frequency increases as the injected energy increases. As the measurements indicate, the radius of the beam changes. For example, with I = 0.5 A in curves 1, 2, and 3 the beam radius is 7.5, 6.5, and 5 mm, respectively. As the current changes, the beam radius in curves 1, 2, and 3 changes in a fashion similar to curve 3 in Fig. 1. At a certain current I', the frequency of lf oscillations increases significantly. This result is discussed below. When I < I' the oscillations are regular.

The diameter of the beam also depends on the length of the test chamber. If the length of the system is increased the beam diameter increases and the frequency of the lf oscillations decreases. The oscillation frequency is roughly inversely proportional to the square root of the gas mass M, is independent of the pressure ($p = 2 \cdot 10^{-5} - 2 \cdot 10^{-4}$ mm Hg), and varies slowly with the magnetic field.

With H = 800-1000 Oe, eV = 10-25 keV, and a negligible change in a, the intensity of the lf oscillations decreases as the injection energy increases for a constant current and does not vary for a constant beam density n_b for an increasing electron energy. In other words, the intensity of the lf oscillations is determined by the density n_b of the beam and not by the energy eU.

In view of the dependence of frequency and amplitude on the system parameters (eU, I, p, M) and the conditions for onset ($n_p < n_b$) we conclude that the lf oscillations are determined by the density of the ions n_i which neutralize the beam.

Measurements and estimates that include the beam diameter indicate that the frequency of the lf oscillations coincides with ion plasma frequency ($\omega \simeq \omega_i$). Investigations employing probes that move along the radius of the chamber and located 180° apart indicate that the phase of the lf oscillations changes along the radius but not in azimuth. The oscillations are concentrated in the beam region. The intensity distribution of the lf oscillations along the beam is such that the maximum amplitude occurs at the center of the chamber, i.e., a standing half-wave is formed.

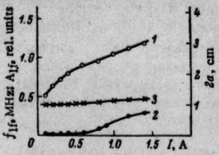

Fig. 3. Frequency (1) and amplitude (2) of the lf oscillations, and diameter of the injected beam (3) as functions of the current. $p = 6 \cdot 10^{-5}$ mm Hg. The other parameters are the same as in Fig. 1.

The experimental results indicate that the lf oscillations are radial oscillations of the density of the beam.

It is well known from the experiments in ref. 2 that an electron beam injected into a chamber in the presence of a background plasma, can exhibit a drift instability at the frequency described by (1), with wave vector $k = (k_z^2 + k_\varphi^2 + k_r^2)^{1/2}$ ($k_z \sim 1/L$ and $k_r \simeq k_\varphi \sim 1/r$ are the longitudinal, radial, and azimuthal components of the wave vector). If we assume that the same instability develops in a reflected beam, then the azimuthal component can be cancelled in a system of counterstreaming beams. Since $k_z \ll k_r$ the lf oscillations are radial. Since the experimental conditions of the present paper differ from those of ref. 2, additional experiments on lf oscillations have been performed with a straight-through beam (the collector at ground potential). Figure 3 gives the frequency (curve 1), the amplitude (curve 2), and the beam diameter (curve 3) as functions of the current. The oscillation frequency increases with the current. The beam diameter varies comparatively slowly (curve 3, Fig. 3). The oscillation amplitude increases slowly as the current increases. A marked increase in the amplitude occurs at I = 0.6 A. Figures 1 and 3 give values of the amplitude in the same relative units. Evidently the amplitude for straight through conditions (for the same injection current) is appreciably smaller than for a reflected beam. This situation can be caused by the strong feedback associated with the reflected electron beam.

In the present paper all the experimental results are given for the case of a negligible space charge in the cathode region of the gun. In the presence of a large space charge near the cathode, obtained by increasing the cathode–anode spacing for the same electrical parameters of the gun, frequency saturation of the lf oscillations with a corresponding change in the beam diameter) is also observed under straight-through conditions with I ≃ 0.2 A (eU = 15 keV and H = 700 Oe). An appreciable increase in the oscillation amplitude is also observed at I ≃ 0.2 A; this may be due to the amplification coming from the feedback as a result of the large space charge in the cathode region of the gun, similar to that discussed in detail in ref. 3.

These and several other investigations of the dependence of the frequency of the lf oscillations on the parameters eU, L, p, H, and M, with the change in beam diameter included, have shown that under straight-through conditions oscillations can develop in the system with a frequency close to the ion plasma frequency ($\omega \simeq \omega_i$).

Investigations of space phase correlations employing probes and microcollectors indicate that the phase of lf oscillations varies in both azimuth and radius. A half-wave fits into the length of the system. The currents to the 0.5 cm diameter disk (admitting the central portion of the beam) and the diaphragm (admitting the peripheral portion of the beam) are modulated by the lf oscillations. The current oscillations are in opposite phase. The same pattern is observed when two segments are used which divided the injected beam into two equal parts. The total current to the collector (two segments, a disk and a diaphragm) shows no lf modulation.

The experimental results and estimates indicate that under straight-through conditions the drift instability that is thoroughly studied in refs. 2 and 4 develops in the system. We consider the well-known dispersion relation

$$\omega^2 = \frac{\omega_i^2}{1 + \frac{1}{k^2 d^2}}, \tag{1}$$

where d is the electron Debye radius.

With the instability $n_p \ll n_b$ and $T_e \simeq 20\text{-}40$ eV and thus the current is neutralized by the ions. For example, with the parameters of Fig. 3 at a current $I \simeq 1A$, a density $n_b \simeq 1 \cdot 10^9$ cm^{-3}, setting $T_e = 40$ eV and $n_p \simeq 1 \cdot 10^8$ cm^{-3}, we have $1/k^2d^2 \simeq 0.2$. According to (1), when $1/k^2d^2 \ll 1$ the oscillation frequency is $f = f_i = 1.18$ MHz, which is close to the experimental value. When $1/k^2d^2 \gg 1$, the drift instability should change to an ion-acoustic instability for a density $n_p \simeq 3 \cdot 10^9$ cm^{-3} and with these parameters, the lf oscillations are quenched.

It follows from the experimental results that an appreciable increase in the intensity of lf oscillations is always accompanied by a broadening of the beam diameter under both beam conditions.

Under straight-through conditions, broadening of the beam due to an appreciable increase in the amplitude of lf oscillations is observed at I = 0.2–0.6 A. These currents are of the same order as the calculated value of the critical current $I_{cr} \simeq 0.6$ A. The value of I_{cr} is determined from[2]

$$I_{cr} = \frac{ma^2}{4e} \frac{k^2 v^3}{\left[1 + 2k_\varphi \frac{v}{a\omega_H k_z}\right]}, \tag{2}$$

where v is the beam velocity.

Analysis of the results obtained leads to the conclusion that radial lf oscillations in counterstreaming beams are generated by the interaction with drift instabilities developed in the injected and reflected beams. The azimuthal component of the electric field of the lf oscillations is cancelled. Evidently, this is due to the qualitative difference in the radial distribution of the amplitude of lf oscillations under straight-through (curve 1) and reflected-beam (curve 2) conditions (Fig. 4).

The amplitude of the lf oscillations under reflected-beam conditions varies slowly at chamber pressures of $p = 2.10^{-5}\text{-}2.10^{-4}$ mm Hg; under straight-through conditions this occurs for $p = 1.5 \cdot 10^{-5}\text{-}1.10^{-4}$ mm Hg (eU = 15 keV, $I \simeq 1$ A, H = 500 Oe). A further increase in pressure leads to a decrease in the amplitude. Under straight-through conditions the amplitude decreases sharply at $p = (1\text{-}2) \cdot 10^{-4}$ mm Hg; under reflected-beam conditions at $p = (2\text{-}4) \cdot 10^{-4}$ mm Hg. The decrease in the amplitude of the oscillations for an increasing pressure up to the time they disappear under both conditions is ascribed, as in ref. 2, to the destruction of the conditions for excitation of drift instability as the plasma density increases.[4]

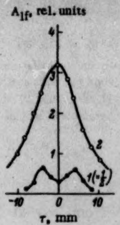

Fig. 4. Radial distribution of the amplitude of lf oscillations of beam density under direct-beam (1) and reflected-beam (2) conditions. I = 0.6 A, eU = 15 keV, H = 500 Oe, L = 35 cm, $p = 8 \cdot 10^{-5}$ mm Hg.

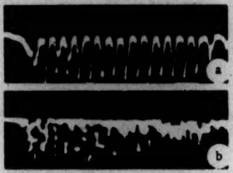

Fig. 5. Oscilloscope traces of hf oscillations. eU = 15 keV, H = 600 Oe, $p = 1 \cdot 10^{-4}$ mm Hg, L = 40 cm; I in A: a) 0.5; b) 1.4. 18 μsec scans.

The difference in the pressures at which lf oscillations disappear from the system under both conditions is explained on the basis that under straight-through conditions a substantial contribution to the generation of the plasma is made by secondary low-energy electrons. Under reflected-beam conditions the plasma density can drop sharply due to the loss of ions from the system resulting from more intense lf oscillations than in the reflected-beam mode, and the extraction of ions by the electrode.

Similar dependences of lf oscillations on I, eU, L, and M under reflected-beam conditions are obtained using a magnetically shielded gun placed at the exit to the test chamber with an increasing magnetic field.[1] The experimental results are in qualitative agreement with those given above. Quantitative estimates are complicated due to the presence of a large transverse velocity component $v_\perp$ of the beam electrons.

It can also be seen in Fig. 2 that there is a sharp increase in the oscillation frequency as well as saturation at large beam currents. The oscillations exhibit an irregular random nature which appears simultaneously in the random excitation of half-cyclotron oscillations (Fig. 5b). In Fig. 5a, hf oscillations modulated by regular lf oscillations are shown.

When intense lf oscillations develop at high currents under straight-through conditions, a cutoff (a sharp drop in the current to the collector) is observed similar to that in ref. 4. In this case the value of the current at which the cutoff occurs should be considered the limiting current I_{l_1}. A similar characteristic is observed under reflected-beam conditions. The cutoff could be estimated from the sharp decrease in current to the spherical probe 0.03 cm in diameter which is placed in the os-

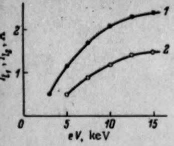

Fig. 6. Cutoff current under direct-beam I_{l_1} (1) and reflected beam I_{l_2} (2) conditions as a function of electron beam energy. H = 500 Oe, L = 35 cm, p = $2\cdot 10^{-5}$ mm Hg.

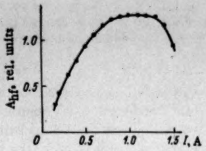

Fig. 7. Amplitude of integral hf signal as a function of beam current. eU = 15 keV, p = $1\cdot 10^{-4}$ mm Hg, L = 30 cm.

cillating beam at the axis of the test chamber. With counterstreaming beams there is no current in the circuit of the reflecting electrode; therefore, the value corresponding to the cutoff current should be considered spurious. The current is recorded under counterstreaming conditions by a Rogowski loop from the total current in the cathode circuit with the current transmission coefficient taken into account. Current cutoff under both beam conditions is accompanied by an increase in the frequency of the lf oscillations. Figure 6 gives the cutoff current as a function of electron beam energy for straight-through I_{l_1} (curve 1) and reflected-beam I_{l_2} (curve 2) conditions.

The measurements indicate that the value of I_l increases with an increasing magnetic field H. The increase in I_{l_1} with increasing H and eU under straight-through conditions agrees with the results of ref. 4. Under reflected-beam conditions the increase in I_{l_2} with increasing H and eU indicates a similar mechanism for current cutoff resulting from the development of drift instabilities in counterstreaming beams. As expected, under reflected-beam conditions $I_{l_2} \simeq I_{l_1}/2$.

The values of I_{l_2} under reflected-beam conditions coincide with the currents at which a sharp increase in the frequency of the lf oscillations is observed in the system (Fig. 2). This phenomenon allows us to understand the observed decrease in the amplitude of the integral hf oscillations at frequencies $n\omega_H/2$ for a beam current $I \simeq 1.3$–1.5 A (Fig. 7). At first, the amplitude of hf oscillations increases with the increase in the current (in the density n_b, and thus in the growth rate[6] $\gamma \sim \omega_b$, where ω_b is the electron plasma frequency). With a further increase in current, saturation occurs which can be ascribed to nonlinearities broadening the oscillation spectrum. For $I \simeq 1.3$–1.4 A the amplitude of hf oscillations drops considerably. This decrease is related to the current cutoff. The phenomenon of current cutoff is a significant obstacle to the possible increase in oscillation intensities at $n\omega_H/2$ when a system of counterstreaming beams is used to generate hf oscillations.

The presence of strong radial modulation of beam density over time is due to the periodic nature of the excitation of oscillations at $n\omega_H/2$ (Figs. 5a and 5b in Ref. 1). Actually, with a given magnetic field H and a thermal velocity spread v_T (a measured value $v_T \sim 1\% v$), hf oscillations will develop at a density n_{b_1} determined by[7]

$$n_{b_1} \simeq \frac{1}{2mc^2}\left(\frac{v_T}{v} H\right)^2. \tag{3}$$

On the other hand, hf oscillations will develop for a density n_{b_2} at which the growth rate of hf oscillations ($\gamma \sim \omega_{b_2}$) is larger than the inverse time of flight of beam electrons in the test chamber ($\gamma > v/L$). Thus, for a mononenergetic beam $v_T \sim 1\% v$, with $v = 7.10^9$ cm/sec, H = 700 Oe, and L = 35 cm, $n_{b_1} \ll n_{b_2}$; when $v_T \sim 5\% v$, $n_{b_1} \gg n_{b_2}$. The threshold beam density at which hf oscillations are generated is determined by the largest values of n_{b_1} and n_{b_2}. And since the beam density is strongly modulated (up to 80–90%) by lf oscillations, the conditions for development of oscillations at frequencies $n\omega_H/2$ occur periodically and their intensity agrees with the variation in n_b.

Zh. Tekh. Fiz., 44, 1669-1674 (August 1974)

Electron beams with various cross sections from high-voltage discharges find wide use in engineering, particularly for welding purposes (refs. 1-3). Therefore, the physical processes occurring in systems used to produce such beams are of special interest. This paper presents results of an investigation of the discharge process and the formation of a fine pencil beam of circular cross section with a very simple electrode system called a cell. A discussion is given of methods for the design of electrode systems to form beams of arbitrary shape using the cell.

INTRODUCTION

In the cathode fall of a glow discharge one typically finds directed motion of the charges, as opposed to random motion in the positive column. In a high-voltage discharge, which corresponds to the left branch of the Paschen curve, near the ignition potential the cathode fall fills the entire interelectrode space. The high field gradients, especially at the cathode, and the low gas pressure enhance the directed motion. This feature holds in both homogeneous and inhomogeneous electric fields.

One consequence of this directed motion of the charges is the development of a high-voltage discharge in homogeneous fields along specific trajectories, as has been pointed out by Gusev.[4] In this case most of the electrons ejected from the cathode and of the ions formed in the discharge gap move along definite trajectories, as they do in vacuum.

Because of the directed motion of the charges each cathode point is related to a specific trajectory for the electrons leaving the point. For a trajectory along which Q_i ions are formed on the average and arrive at the cathode at the point of liberation of the electron, one finds that the discharge ignites along the trajectory when the charge conservation relation is satisfied:

$$Q_i\gamma = 1 \tag{1}$$

(where γ is the average number of electrons liberated by one ion from the cathode). The motion of the electrons and the ions along the trajectory is a necessary condition for the ignition of a high-voltage discharge along the trajectory.

All field lines of force near the cathode are straight in a certain region L_m. In some cases this section is of negligible extent; in other cases it is large, and can even occupy the entire space up to the anode. If the field gradient near the cathode is large enough each electron emerging from the cathode moves along the rectilinear section of the appropriate line of force. It is only after the line of force has begun to deviate from a rectilinear path that the electron trajectory can begin to curve. All the ions formed in this rectilinear cathode section will move along the same line of force, and will reach the cathode, because of their mass, at the point where the electron emerges i.e., the above-mentioned necessary discharge ignition condition will be satisfied along these lines of force.

The number of ions formed in a rectilinear cathode section of length L_m depends on the length, the gas pressure p, and the field distribution in the section. The number of ions increases as the pressure increases. However, not all the ions formed in the rectilinear section will move towards the cathode along the line of force. Only ions formed at places with sufficient field gradient to direct them towards the cathode will move to the cathode. Let L0 be the length of the rectilinear section within which all ions are directed by the field towards the cathode ($L_0 \leq L_m$).

A proportional increase in the electrode potentials does not alter the electric field configuration (in the absence of space charge), and therefore does not change the value of L_m. The field gradients will change, and L_0 along with them, and there will therefore be a change in the number of ions directed towards the cathode, for the same gas pressure. Thus, Eq. (1) can be satisfied by a choice of the values of the potentials and the pressure. Then the discharge will ignite along the rectilinear section.

CELL

Our analysis of existing gas-discharge electron beams and our experimental experience have led to the evolution of a so-called beam element, the cell (ref. 3), which generates a pencil beam of electrons (a small-diameter, cylindrical beam of circular cross section). This cell can be used to generate beams of arbitrary shape.

The electrode system comprising the cell element is shown in Fig. 1a. The cell consists of a planar cathode K, a planar anode A, and a planar diaphragm D with a circular aperture of diameter d_D; V_a and V_D are the potentials of the anode and the diaphragm relative to the cathode ($V_a = V_D$). The distance h between K and D is such that no discharge ignites outside the aperture in the diaphragm at the working gas pressures $p = 10^{-2}$ to 10^{-1} torr and voltages $V_a \leq 50$ kV. The quantity H is the distance between the cathode and the anode. The cell field is axisymmetric about axis OZ. Figure 1b shows the field distribution in an axial section for h = 10 mm, d_D = 10 mm, and H = 100 mm. Figure 1c shows the variation of the potential along the cell axis.

The rectilinear line of force of maximum length L_m = H is located along the cell axis. The value of L_m drops as one moves away from the axis.

For specific values of V_a and p the discharge ignites along the cell axis in the form of a thin pencil beam of

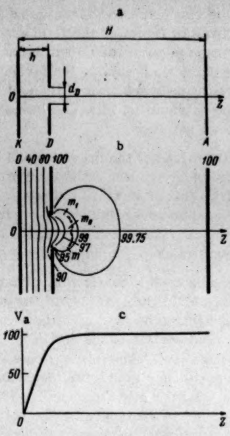

Fig. 1. a) Diagram of the cell; b) field distribution in an axial section of the cell; c) variation of the potential along the cell axis.

circular cross section. The beam diameter is much smaller than that of the diaphragm aperture (see Fig. 7). Figure 2 shows the dependence of the ignition potential on the pressure, $V_i = f(p)$, for H = 100 mm, h = 10 mm, d_D = 20 mm, He gas filling, and cathodes of Ti, Cu, and duralumin D-16. The current in the cell does not exceed 1 μA at ignition.

To check the proposition that only a small axial zone of the cathode surface where the rectilinear lines of force begin takes part in forming the discharge, we carry out the following experiment. The surfaces of cathodes of Ti and D-16 are covered by a thin layer of electrically deposited copper. For these cathodes the ignition curves first obtained coincide with the analogous curve for Cu (Fig. 2). After the cell has been operated for a certain time the ignition curves change and coincide with the corresponding curves for Ti and D-16. Inspection shows that the copper layer has been removed from the cathode in the axial region as a result of ion bombardment. The diameter of the affected spot is less than 0.8 mm. The rest of the cathode remains covered with copper. The fact that the appropriate ignition curves coincide, when the entire cathode surface is of Ti or D-16, when it is completely covered with copper, and when only the central part has exposed the Ti or D-16, is evidence that only the central part of the cathode takes part in sustaining the discharge. The nonaxial parts of the cathode only take part in generating the electric field. Figure 3 shows discharge ignition curves in the cell with a cathode of dural D-16, and Al anode, with cell parameters h = 5, 10, and 15 mm, d_D = 14 and 20 mm, H = 100 mm, and with air filling. Here the ignition potentials fall in the range 0.5 to 5 kV, while the ignition potentials outside the diaphragm aperture exceed 25 kV for values of h ≤ 15 mm and pressures $p = 5 \cdot 10^{-2}$ torr. At lower h the ignition potentials along the cell axis decrease (Fig. 3), while the ignition potentials outside the aperture increase. Even for h = 5 mm the latter exceed 10^5 in refs. 5 and 6. These facts enable us to increase the voltage V_a at the anode appreciably, in comparison with the ignition potential, without disturbing the conditions favoring the formation of a thin pencil beam. The value of V_a reaches 50 kV in these experiments.

As V_a increases the ionization processes in the discharge gap become more intense, leading to the formation of a plasma toward the anode and a dark space at the cathode. The dark space penetrates through the aperture in the diaphragm in the region between D and A. The broken line mm_0m_1 in Fig. 1b shows the interface between the dark space and the plasma.

The electron beam intersects the dark-space boundary at the point m_0. A flux of ions is directed from the vicinity of m_0 towards the cathode, thus increasing the flux of electrons in the beam. Experiment shows that an increase or decrease in the plasma density in the vicinity of m_0 leads to a corresponding increase or decrease in the beam. As the gas pressure is increased the mm_0m_1 boundary approaches the cathode and increases the charge density in the vicinity of m_0, thus increasing the current in the beam.

The field structure at the cathode is determined both by the geometry of the cell electrode system and by the space charge in the discharge. Therefore the length of the axial section where the necessary condition for sustaining the discharge is met (section L_0) may be smaller than H. The section $0 \le Z \le L_0$ is the beam generation zone. The section $L_0 \le Z \le H$ is the beam drift region. Departure from the rectilinear condition is not allowable in the formation region, since it perturbs the necessary discharge ignition condition. Beam bending in the drift region does not perturb the ignition condition, on the other hand. In order to check that the above-mentioned zones are present, we pass the beam formed in the cell through a magnetic or electrostatic deflection system. When the deflection system is positioned in the drift region one observes the normal deflection for such cases. But with the deflection system positioned in the formation zone, where

one must not perturb the rectilinearity of the beam, attempts to deflect the beam quench the beam.

The characteristics of the pencil electron beam (the total current and the current density distribution in the beam) are determined by the cell parameters: h and d_D, the gas density, and the voltage V_a. The current density distribution in the beam is approximately Gaussian. For $d_D = 10$, h = 10, $p = 7\cdot10^{-2}$ torr, and V_a = 25 kV, the total beam current is 48 mA. The maximum current is then $j(r = 0) = 41$ mA/mm² with half-width $d_{0.5} = 0.9$ mm.

PRODUCTION OF ELECTRON BEAMS OF ARBITRARY SHAPE

The cell can be used with electrode systems to form electric fields which will produce cylindrical and conical beams with an arbitrary directrix. For example, to form a cylindrical beam with directrix $y = \varphi(x)$ and given direction of generators, one needs to form an electric field with a set of rectilinear lines of force near the cathode coincident with the generators of the cylinder. The field distributions along these lines of force must be identical, to ensure that L_0 is equal to the length of the formation zone along each generator. In addition, the main part of the field must be concentrated within the rectilinear sections of these lines of force. If the field gradients are small outside these sections there will be no forces to perturb the electron beam outside the formation zone. All the other rectilinear sections of lines of force at the cathode must be so small that the self-sustaining condition (ref. 1) is not satisfied.

For specific values of the pressure and the supply voltage, our discharge ignites in the field produced, and forms an electron flux or beam of cylindrical shape on the anode side, and an equal flux of ions on the cathode side. Outside the formation zone we have a beam of electrons of the required shape, moving through the gas.

The cell can be used to produce electrode systems to form the above fields. The surfaces of the desired electrodes can be generated by motion of the straight lines, which form an axial section of the cell (Fig. 1a). If the plane of the section is displaced in such a way that the cell axis, considered as a generator, describes a cylinder with directrix $y = \varphi(x)$ while the plane itself always remains perpendicular to the tangent at the point of its intersection with the directrix, then a cylindrical beam with directrix $y = \varphi(x)$ will be formed in the electrode system. The system thus formed consists of a planar cathode, a planar anode, and a diaphragm with an aperture in the

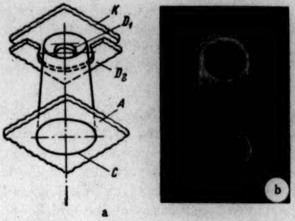

Fig. 5. Cylindrical electron beam, V_a = 25 kV, beam current 400 mA. The rear view shows the hot glowing ring formed by the beam.

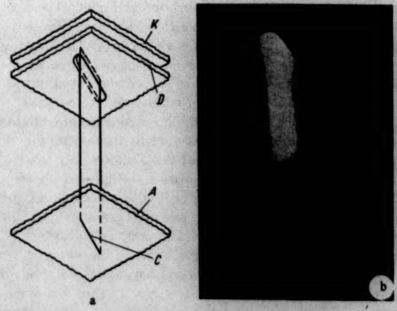

Fig. 6. Line-shaped or ribbon-type electron beam, V_a = 17 kV, beam current 600 mA. On the back side the glowing trace of the beam is visible.

Fig. 7. A multipencil electron beam. V_a = 25 kV, beam current 3× 45 mA. On the rear side of the anode one can see glowing spots generated by the electron beams.

form of a slot, whose average length is given by the equation $y = \varphi(x)$. Similarly one can form electrode systems to obtain conical beams. Here one must assign the directrix of the cone vertex and displace the axial section of the cell in an analogous way.

Figure 4 shows a method of forming an electrode system to generate a conical annular beam. The lines of the cathode K, the diaphragm D, and the OZ axis determine the plane of the section of the cell element. When this plane is rotated about the axis 0'0", the straight lines m_1–m_2, n_1–n_2, and n_3–n_4 draw out the surface of the required electrode system which will form the electron beam along the set of OZ axes. Depending on the angle β, the electron beam will either converge, $0 \leq \beta \leq \pi/2$, have a concentration of power at the anode A and a deconcentration of power liberated at the cathode, or will diverge, $\pi/2 \leq \beta \leq \pi$ and have a concentration of ion beam power at the cathode.

Figures 5 and 6 are photographs of ring-shaped and line-shaped or ribbon-type electron beams. In the upper parts of the pictures one can see the annular and rectangular slots, respectively, in the diaphragm. At the cathode (in Fig. 5) one can clearly see a bright ring where there is ion bombardment of the cathode surface. The lower parts of the pictures show the anodes A, which are stainless steel plates of thickness 1.5 mm. As a result of bombardment by a beam of 25 keV electrons the anode shows, respectively, a glowing ring and a glowing rectangle, visible on the back side of the anode.

When there are several circular apertures in the diaphragm a multipencil beam is formed, as shown in the photograph of Fig. 7. In actual fact this case has three cell elements combined into a single diaphragm. Again, on the back side of the anode one can see three glowing spots formed by the three beams.

Scattering of an electron beam in a straight dc turbulent plasma

Yu. P. Golovanov, L. P. Zakatov, A. S. Kingsep, and A. G. Plakhov

(Submitted July 7, 1973)
Zh. Tekh. Fiz., 44, 1675-1681 (August 1974)

A sharp reduction is observed in the current density of an external electron beam that moves through a turbulent straight dc discharge. It is established that the reduction in beam current density is correlated with radiation at twice the plasma frequency and with x-ray radiation bursts. The sharp reduction in current density is due to scattering of beam electrons by turbulent plasma fluctuations in localized regions. On the basis of theoretical estimates and controlled experiments the electron scattering is related to fluctuations associated with electron plasma oscillations.

A great deal of experimental work has been done on the transmission of electron beams through plasmas. Usually, plasma heating and beam retardation due to fluctuations excited by the beam itself are investigated. However, there is great interest, both for the physics of turbulent plasmas and for diagnostic purposes, in investigating the passage of a beam through a plasma with a high level of turbulence produced by some additional source of noise.

In the present paper we investigate the interaction between an external electron beam[6] and the plasma in a straight discharge, in which, as is well known,[1,2] the turbulence W/nT can reach 10^{-2}.

DESCRIPTION OF THE APPARATUS

A schematic diagram of the apparatus is given in Fig. 1. A fixed mirror field is produced by a system of coils 1 with a maximum field of 1 kOe at the center and 5 kOe at the mirrors. The mirror separation is 85 cm. A metal vacuum chamber 2 is evacuated to a residual pressure 10^{-6} torr. A plasma injector 3, set up at the axis of the apparatus near one of the mirrors, fills the trap with a plasma with a density up to $(1\text{-}2)\cdot 10^{12}$ cm^{-3}.

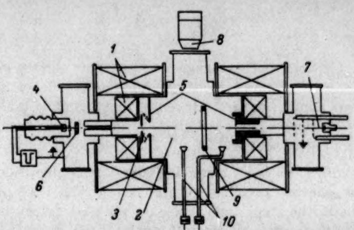

Fig. 1. Experimental arrangement. 1) Magnet coils; 2) vacuum chamber; 3) plasma injector; 4) electron gun; 5) discharge gap electrodes; 6) Rogowski loop; 7) multigrid analyzer; 8) x-ray detector; 9) diamagnetic probe; 10) microwave detector.

The plasma injector has an aperture on the axis for admitting the external electron beam produced by the electron gun 4. The beam parameters are as follows: current up to 10 A, energy 20-40 keV, and pulse length 130 μsec. The direct current is generated by a 0.5 μF capacitor bank, charged to 5-7 kV, and applied to a column of previously prepared plasma. The electrodes 5 are 55 cm apart, and the electrode diameter is 4.5 cm. Under typical conditions the discharge current is 500-800 A with a pulse length of 4-5 μsec. The electron beam and the plasma injector operate simultaneously, and the start of the dc discharge is delayed for 50-70 μsec. The electron beam current at the entrance to the trap is measured by a Rogowski loop 6 placed between the gun anode and the drift channel.

A high-voltage electrode 5 has a 1-mm diameter aperture, through which the central portion of the electron beam falls on a multigrid probe 7 set up behind the mirror. The x-ray bremsstrahlung from targets located a certain distance from the beam is recorded by scintillation counters 8. The counters are enclosed in lead containers, and the radiation from the tungsten-needle targets is incident on the crystals only through narrow, long channels in the lead collimators. The intensity of radiation from the plasma volume is several orders of magnitude smaller, and therefore is not recorded. If a needle is removed from the field of view of a collimator the signal from the corresponding counter disappears completely. The plasma energy is measured by a diamagnetic probe 9. High-frequency electromagnetic oscillations excited in the plasma are picked up by two horns, one set up at the center of the chamber and the other to the side, 20 cm from the center. The dc current is recorded by the Rogowski loop, and the voltage across the discharge is measured by a low-inductance resistance divider.

EXPERIMENTAL RESULTS

Both transmission of current and passage of an external electron beam through a cold plasma heat the plasma. The heating is observed by noting the increase in plasma diamagnetism due to the separate and combined effect of the electron beam and the discharge current. An oscilloscope trace of the diamagnetic signal is given in Fig. 2a for the case of plasma heating by a direct current. The magnitude of this signal when the current is terminated, when there is no paramagnetic effect, indicates that the plasma pressure is ~ 10^{15} eV/cm^3. An oscilloscope trace of the signal from the diamagnetic probe is given in Fig.

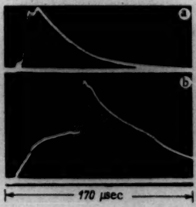

Fig. 2. Oscilloscope traces of diamagnetic signals. a) Direct discharge alone; b) electron beam and direct discharge.

2b for the case of combined heating by an electron beam and dc current. The cold plasma and the electron beam are injected simultaneously. The plasma is heated by the beam to a certain steady-state level; then the dc discharge is switched on, and the thermal energy of the plasma increases rapidly due to transmission of the current. The increase in the diamagnetic signal is roughly on the same scale as for one electron beam. The results given below refer to these operating conditions, when plasma turbulence increases greatly due to transmission of the dc current through the plasma. The increase in turbulence above the level produced by the beam itself sharply modifies the transmission of the electron beam through the plasma. Numerous experiments on the passage of monochromatic electron beams through a cold plasma in a magnetic field indicate that the longitudinal velocities of the beams are greatly spread out and the beams lose a significant portion (up to 70%) of their energy in generation of oscillations and heating the plasma. Also, longitudinal beam energy is effectively connected to transverse energy. However, the radius of the beam at exit from the plasma increases by very little (by a Larmor radius), and the beam current density at the entrance of the analyzer undergoes essentially no change.[3,4]

An electron beam injected into a turbulent plasma does not penetrate the plasma during certain stages of the discharge. Experimentally, this is observed from the sharp decrease in beam current density at the entrance to the multigrid analyzer as compared with the density at times corresponding to beam transmission. The nature of the phenomenon is illustrated in Fig. 3, which gives oscilloscope traces of a direct-discharge and beam current. The number of dips in the beam current (current cutoffs) depends, to a considerable degree, on the nature of the discharge current, but the dips themselves are observed under any discharge conditions and are independent of polarity at the electrodes. It is quite clear that under strongly oscillatory (inductive) conditions (Fig. 3) the current cutoffs are correlated with points at which the discharge-current goes through zero (voltage peaks across the electrodes) and thus, with electric fields in the plasma. The observed beam cutoffs are due either to scattering of beam particles by fluctuations in the turbulent plasma or deflection of the beam as a whole in the azimuthal electric fields associated with the current-convective instability.

Different stages of the electron beam in the turbulent discharge can be investigated using x-ray analysis. For this purpose a tungsten needle is placed in the center of the apparatus along the radius of the vacuum chamber; the distance of the point of the needle from the boundary of the beam is roughly equal to the beam radius. Control experiments indicate that bremsstrahlung from the needle is absent if only the electron beam or only the discharge current is transmitted through the plasma. With combined beam and discharge-current transmission, intense surges of x-ray radiation are observed from the needle with the same instrumental sensitivity. The radiation bursts occur at times that are correlated with current cutoffs (Fig. 4). The x-ray bursts are due to electrons scattered from the beam by turbulent fields excited in the plasma by the direct current. Proof that scattering of beam electrons occurs rather than deflection of the beam as a whole is provided by experiments which simultaneously record x-ray radiation from two needle targets set up around the beam at a distance from each other that is more than twice the beam diameter. Figure 5 illustrates the good correlation between the x-ray radiation from both targets. It is clear from the traces in Fig. 4 that every cutoff of the beam current is not accompanied by an x-ray burst. The discrepancy between the number of current cutoffs and the number of bursts can be explained if it is assumed that the beam is scattered in local regions with a potential jump whose length is less than the length of the apparatus. The electron beam penetrates through the entire length of the apparatus and unavoidably passes through all the regions where scattering occurs; therefore, the number of current cutoffs is always determined by the stages of the transmission of the discharge current. The number of x-ray bursts recorded only from the center of the apparatus is two times smaller on the average since the bursts from the localized

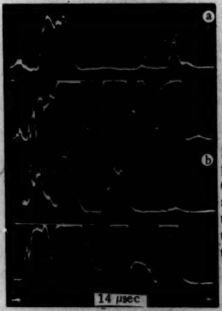

Fig. 4. Traces of x-ray radiation (upper curves and trace of beam current (lower curves) for two typical experiments, (a) and (b). The disparity between the number of x-ray bursts and the number of current cutoffs indicates the presence of local regions.

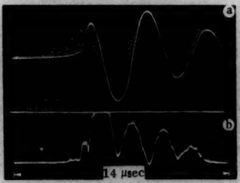

Fig. 3. a) Trace of a direct-discharge current; b) electron beam current. Cutoffs of the beam current correspond to certain stages of current transmission.

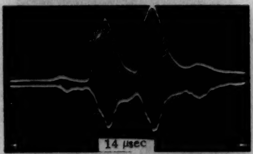

Fig. 5. Traces of x-ray radiation from two targets set up around the beam at different azimuths. The distance between the targets is greater than twice the beam diameter.

noise regions to the right of the center along the beam path will not be recorded since back-scattering of electrons has a low probability, and obviously does not occur.

Microwave radiation at twice the plasma frequency ($2\omega_{pe}$) is recorded to enable us to understand the nature of the fluctuations which scatter the beam electrons. It turns out that radiation at frequency $2\omega_{pe}$ occurs only at times of beam current cutoff, and its intensity is more than an order of magnitude higher than the radiation due to the electron beam itself. Radiation at twice the plasma frequency indicates electron plasma oscillations are excited during certain stages of the direct current flow. The traces in Fig. 6 are taken from two different experiments and indicate that the peaks of microwave radiation actually are correlated with dips in the beam current. As in the x-ray experiments, the number of peaks observed in the microwave radiation picked up by the horn at the center of the apparatus is always smaller than the number of beam current cutoffs. This is an indication that the beam is not scattered along the entire length of the apparatus, but in fairly narrow regions, where the noise is localized. To check the existence of such localized regions the microwave radiation is measured by two horns placed 20 cm apart along the length of the apparatus. In Fig. 7, the traces of microwave radiation are obtained by simultaneous pickups of the two antennas in two different experiments. In Fig. 7 a, the upper trace shows the radiation peaks obtained from the center antenna, and the lower trace is from the side antenna. The peaks in both traces are correlated well and correspond to radiation from regions in the field of view of both antennas. In the upper trace in Fig. 7b, the radiation peaks are farther apart in time, and in the lower trace only one peak is observed. This is possible only when the localized noise regions occur at random points along the length of the apparatus; these points are not always in the field of view of one horn or the other and are even less likely to be in the field of view of both horns simultaneously.

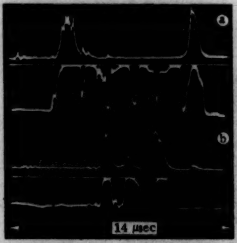

Fig. 6. Radiation from the plasma at twice the plasma frequency (upper traces) and beam current (lower traces) for two typical experiments (a) and (b).

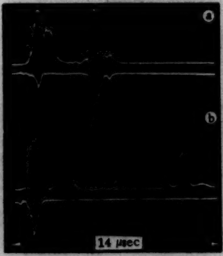

Fig. 7. Radiation signals at twice the plasma frequency from different places in the apparatus for two typical experiments (a) and (b), demonstrating the local nature of the scattering effect.

Intense beams of runaway electrons are not observed in these experiments. However, electron beams with negligible density (below 0.5 A/cm^2) escape from the turbulent plasma with the appropriate electrode when the external electron beam passes through the plasma without scattering. When the external beam is effectively scattered the current of runaway electrons vanishes.

DISCUSSION OF RESULTS

The scattering of beam electrons observed in this dc-discharge can be ascribed to interactions either with ion-acoustic fluctuations or with electron plasma oscillations, which are generated during certain stages of the development of current instability.[5] In both cases the particle velocity of the probe beam is much larger than the characteristic phase velocity of the fluctuations. For ion acoustic waves this is obvious; in regard to electron plasma oscillations the energy of the exciting particles in the discharge cannot exceed the voltage applied to the discharge gap, so that we obtain

$$\left(\frac{\omega}{kv_b}\right)^2 \leqslant \frac{eU}{\varepsilon} \ll 1, \tag{1}$$

where v_b is the velocity, ε is the beam energy, and U is the voltage across the electrodes.

Under condition (1), relaxation of the beam only leads to a spread with respect to the transverse velocities,[6] which are governed by

$$\left.\begin{aligned} &\langle v_\perp^2\rangle \sim D(v_b)t,\\ &D(v_b) = 4\pi^2\frac{e^2}{m^2v_b}\int W_k\delta(\omega - kv)v\,dk \simeq \omega_{pe}\frac{W}{nT_e}\frac{v_b^2}{\langle k\rangle r_D}\left(\frac{v_{Te}}{v_b}\right)^3, \end{aligned}\right\} \tag{2}$$

where W is the integrated fluctuation density, $\langle k\rangle$ is the characteristic wave number, and r_D is the Debye radius. Accordingly, the Langmuir radius of the beam particles is changed at the exit from the discharge gap:

$$\rho_b^2 \sim \rho_0^2\frac{W}{nT_e\langle k\rangle r_D}\left(\frac{v_{Te}}{v_b}\right)^3\frac{L}{v_b}\omega_{pe}, \tag{3}$$

where L is the length of the region in which the noise is localized (in particular, this can be the length of the apparatus), and $\rho_0 = v_b/\omega_{He}$ is of the order of 1 cm under our conditions. Since the beam diameter is of the same order of magnitude, it can be seen that the current density of the beam (and, thus, the current to the analyzer) decreases by one order of magnitude if the transverse energy of the beam particles is the same order of magnitude as the longitudinal energy.

It is reasonable to assume that the scattering of the beam particles is the result of electron plasma noise, which, as we have shown, is localized in regions with dimensions smaller than the length of the apparatus. Earlier,[4] we have established that the relaxation of the beam becomes essentially non-one-dimensional (an angular spread appears) along the length of the apparatus even for an increase in the beam current from 10 to 20 A, i.e., roughly at double the noise energy.

In experiments on turbulent heating of a plasma, the level of electron plasma oscillations is an order of magnitude higher than the level generated by a beam with our parameters (under our conditions this is controlled by the power radiated at frequency $2\omega_{pe}$). This noise level is adequate for beam retardation in a length much smaller than the length of the apparatus.

It can be seen from (3), however, that with sufficient intensity, the ion-acoustic waves effectively retard the beam (it is true that in this case $\langle kr_D \rangle \sim 1$, thus increasing the scattering length). As a result, we estimate that under such conditions $\langle v_\perp^2 \rangle \sim v_b^2$. This can be done if we take into account that the effective scattering frequency of thermal plasma electrons by ion-acoustic noise is

$$\nu_{\text{eff}} \sim \omega_{pe} \frac{W_s}{nT_e} \frac{1}{\langle k \rangle r_D}. \tag{4}$$

On the other hand, we have

$$eE = m\nu_{\text{eff}} \frac{j}{ne}; \quad \nu_{\text{eff}} \leqslant \frac{eE}{mc_s} \sim \frac{eU}{mc_s L}. \tag{5}$$

It is evident from Eqs. (3)-(5) that

$$\frac{\langle v_\perp^2 \rangle}{v_b^2} \sim \frac{T_e}{\varepsilon} \frac{eU}{\varepsilon} \sqrt{\frac{M}{m}}. \tag{6}$$

In order to exclude scattering by ion-acoustic waves a control experiment has been carried out with 40-keV beam energies and a 2 kV direct discharge. We estimate the upper limit of the electron temperature in the direct discharge is eU. Then the retardation length for ion-acoustic waves is 10 times larger than the dimensions of the potential drop region of the direct discharge [on the right side of (6), this is of the order of 1/10]. Nevertheless, oscilloscope traces of the beam current in this case do not differ significantly from those of Fig. 3. This result indicates that the beam retardation in the turbulent plasma is due to electron plasma oscillations.

Thus, our experiments have established that an energetic beam of electrons is effectively scattered in a turbulent direct-discharge plasma. Retardation of the beam is the result of the interaction with electron plasma oscillations in localized regions.

The authors thank L. I. Rudakov for valuable discussions.

Effect of loss on electron avalanches in optical breakdown

V. I. Fisher

I. I. Mechnikov Odessa State University

(Submitted May 15, 1973; resubmitted January 17, 1974)
Zh. Tekh. Fiz., 44, 1682-1686 (August 1974)

The experimental functional dependence of the threshold for optical breakdown of inert gases on the pressure and characteristic dimensions of the focal region can be explained by an avalanche-ionization mechanism that takes elastic loss and diffusion loss into account.

The threshold for optical breakdown is a function of the parameters of the laser beam (the divergence and frequency of the radiation, the pulse length, and the diameter of the focal spot) and of the gas pressure and impurity concentration. The mass and excitation energy of the gas atoms are of great importance. Excitation of electronic levels can retard or accelerate the breakdown, depending on the level structure of the particular gas and on the radiation intensity. Optical breakdown has been studied in many previous experiments, but the results are compatible only to an order of magnitude because of the differences among the radiation parameters and because of the inadequate methods used to determine the dimensions of the breakdown region.

In this note we describe the processes which occur in the focal region as the degree of ionization increases from the initiating level to the breakdown level; the latter, according to the results of ref. 1, is 10^{-3} for helium and argon.

The electron temperature in the avalanche is described by

$$\frac{3}{2}n(\mathbf{r},t)\frac{\partial T(\mathbf{r},t)}{\partial t}=\frac{4\pi e^2}{mc}n(\mathbf{r},t)\frac{\nu}{\omega^2+\nu^2}q(\mathbf{r},t)-\frac{3m}{M}\nu n(\mathbf{r},t)T(\mathbf{r},t)-I\left(\frac{\partial n(\mathbf{r},t)}{\partial t}\right)_i. \tag{1}$$

Here, e and m are the charge and mass of the electron, n and N are the densities of electrons and atoms, c is the speed of light, ω and $q(r, t)$ are the frequency and intensity of the radiation, I and M are the first excitation energy and mass of the atom, $\nu = \langle\sigma^y v\rangle N$ is the frequency of elastic electron–atom collisions, v is the electron velocity, and σ^y is the cross section for elastic collisions. In the calculation of $\langle\sigma^y v\rangle$ we use the experimental cross sections $\sigma^y(v)$ of ref. 2. The light-absorption coefficient is corrected for stimulated emission.[3] Elastic energy loss, which becomes important at high pressures, is taken into account. The ionization rate $(\partial n/\partial t)_i$ is assumed to be equal to the rate at which the lower-lying atomic levels are excited by electron impact. Instantaneous photoionization of the excited levels is assumed for helium on the basis of the results of ref. 4. This ionization mechanism is also adopted for the argon calculations. In this case we can write the ionization rate as

$$\left(\frac{\partial n}{\partial t}\right)_i=\langle\sigma^*(v)v\rangle Nn.$$

In averaging we use the excitation cross sections for the lower-lying levels, $\sigma^*(v)$, given in ref. 3.

When the electron avalanche in the radiation field is initiated the temperature rise is terminated, since the absorbed radiation energy is expended completely in ionization and in the replenishment of elastic loss. This situation obtains until Coulomb collisons increase ν considerably, i.e., up to a burst. We can then determine the electron temperature during the avalanche by setting the right-side of Eq. (1) equal to zero. The temperature turns out to be a weak function of the radiation intensity. Over the range of threshold intensities which have been observed experimentally we can assume the electron temperature to be 4 eV in helium and 3 eV in argon.

Electron diffusion from the focal region reduces the growth rate of the electron density:

$$\frac{\partial n}{\partial t}=\left(\frac{\partial n}{\partial t}\right)_i+D\Delta n. \tag{2}$$

Here, D is the free-diffusion coefficient of the electrons. By "focal region" we mean the volume of a cylinder whose diameter is $d = f\alpha$ and whose height is $l = (\sqrt{2}-1)f^2\alpha/A$, where f is the focal length of the lens, α is the divergence of the radiation, and A is the diameter of the laser beam. In this case the characteristic diffusion length Λ satisfies

$$\frac{1}{\Lambda^2}=\left(\frac{4.8}{d}\right)^2+\left(\frac{\pi}{l}\right)^2.$$

Recombination is neglected since the breakdown sets in at a small degree of ionization, in which case

$$\left(\frac{\partial n}{\partial t}\right)_i\gg\left(\frac{\partial n}{\partial t}\right)_{\text{recomb}}\sim n^2.$$

The radiation of a single-mode laser has a Gaussian intensity distribution in the focal plane:

$$q(r,t)=q(0,t)\exp\left(-\frac{r^2}{r_0^2}\right).$$

Here, r_0 is the characteristic Gaussian radius, which governs the diameter of the focal region. We neglect the intensity distribution along the beam axis, a simplification which is valid when the loss due to diffusion along the axis is much smaller than that in the transverse direction:

$$\left(\frac{4.8l}{\pi d}\right)^2=\left[\frac{4.8(\sqrt{2}-1)f}{\pi A}\right]^2\gg1,$$

i.e., for $f \gg 3$. Using (1) and the constancy of the temperature in the avalanche, we can write the electron-

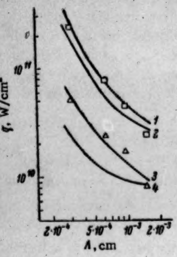

Fig. 1. Threshold intensity for breakdown in argon as a function of the diffusion length. Pressure p, atm: 1, 2) 3.7; 3,4) 11.7. A single-mode ruby laser is used. 1,3) Equation (3); 2,4) Eq. (4b).

diffusion equation for the case of a Gaussian intensity distribution as

$$\frac{\partial n(r,\ t)}{\partial t}=D\Delta n(r,\ t)+\frac{4\pi e^2}{mcI}\frac{\nu n(r,\ t)}{\omega^2+\nu^2}q(0,\ t)\exp\left(-\frac{r^2}{r_0^2}\right)-\frac{3mT\nu}{MI}n(r,\ t). \tag{3}$$

We seek a solution in the form

$$n(r,\ t)=e^{t/\tau}\varphi(r).$$

Substitution into (3) yields an equation for $\varphi(r)$:

$$D\Delta\varphi(r)+\left(\frac{4\pi e^2}{mcI}\frac{\nu}{\omega^2+\nu^2}q(0,\ t)\exp\left(-\frac{r^2}{r_0^2}\right)-\frac{3mT}{MI}\nu-\tau^{-1}\right)\varphi(r)=0,$$

which is solved numerically by a variational method with the test function

$$\varphi(r)=2e^{-\gamma r}-e^{-2\gamma r},$$

which displays the correct behavior at large r and has a vanishing derivative at r = 0.

Figure 1 compares the results of the numerical calculation with experimental results.[5] The threshold intensity is seen to be a function of the diffusion length in argon. In the corresponding experiments a single-mode ruby laser with a pulse half-width of 10^{-8} sec is used.

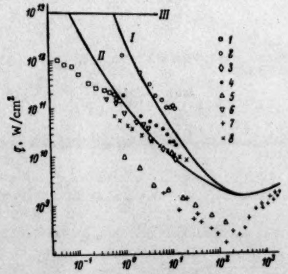

Fig. 2. Threshold intensity for breakdown in argon as a function of the pressure. I,II) Equation (4b) $\tau = 10^{-9}$ Λ, cm: I) $2.5\cdot10^{-4}$; II) $2\cdot10^{-3}$; III) threshold for multiphoton breakdown.[10] Singlemode lasers: 1) ref. 1; 2,3) ref. 5. Multimode lasers: 4) ref. 5; 5) ref. 6; 6) ref. 7; 7) ref. 8; 8) ref. 9. Λ, cm: 1) $\sim 2\cdot10^{-3}$; 2) $2.5\cdot10^{-4}$; 3) $1.5\cdot10^{-3}$; 4) $1.58\cdot10^{-3}$; 5) $2.4\cdot10^{-3}$; 6) $\sim 10^{-3}$; 8) $\approx 2\cdot10^{-3}$; 7) d $\sim 10^{-2}$.

If the electron density in the focal region, $\alpha_e = n/N$ increases from the seed value $\alpha_e^0 \le 10^{-7}$ to the breakdown value $\alpha^* \sim 10^{-3}$ in the pulse length τ, the characteristic time for avalanche development, τ_l, can be determined from the breakdown condition

$$\tau^{-1}=\tau_l^{-1}\ln\frac{n^*}{n^0}.$$

For a rectangular pulse, τ_l is the pulse length; for a triangular pulse, it is the half-width. In the latter case the radiation intensity near the maximum must be a slowly varying function of the time:

$$\sqrt{\frac{\partial^2 q(0,\ t_{\max})}{\partial t^2}\Big/q(0,\ t_{\max})}\leqslant\tau^{-1}.$$

Here, $q(0, t_{\max}) = q_{\max}$ is the maximum value of q(r, t).

The radiation intensity has a complicated spatial profile and is characterized by the quantity $\bar{q}$ averaged over the area. We assume the intensity to be equal to $\bar{q}$ within the focal region and negligibly small elsewhere.

Since the results of the various experiments[1,5-9] agree only in order of magnitude, for simplicity we replace Δn by $-n/\Lambda^2$ in Eq. (3) [the satisfactory agreement between the results found in this manner with the experimental results and with the results of the numerical solution of Eq. (3) (Fig. 1) is evidence in favor of this simplification]:

$$\frac{n(r,\ t)}{\tau}=-\frac{D}{\Lambda^2}n(r,\ t)+\frac{4\pi e^2}{mcI}\frac{\nu n(r,\ t)}{\omega^2+\nu^2}\bar{q}-\frac{3m}{MI}\nu Tn(r,\ t).$$

In the analysis it is more convenient to rewrite this equation as

$$\bar{q}=\frac{mc\omega^2I}{4\pi e^2\nu}\left(1+\frac{\nu^2}{\omega^2}\right)\left(\tau^{-1}+\frac{3m}{M}\frac{T}{I}\nu+\frac{D}{\Lambda^2}\right). \tag{4}$$

Substitution of the numerical values into Eq. (4) yields

$$\bar{q}=\frac{112}{p}(1+5.4\cdot10^{-7}p^2)\left(\tau^{-1}+1.64\cdot10^8p+\frac{3\cdot10^3}{p\Lambda^2}\right)\text{W/cm}^2 \tag{4a}$$

for helium and

$$\bar{q}=\frac{74.4}{p}(1+4.06\cdot10^{-7}p^2)\left(\tau^{-1}+1.85\cdot10^7p+\frac{2.6\cdot10^3}{p\Lambda^2}\right)\text{W/cm}^2 \tag{4b}$$

for argon. The pressure is measured in atmospheres and the diffusion length in centimeters.

Figures 2 and 3 compare the functional dependence of the threshold intensity on pressure with the experimental results of refs. 1,5-9. A single-mode ruby laser was used in certain experiments,[1,5] and a multimode laser in others.[6-9] The pulse shapes and half-widths, the impurity concentrations, the focal volumes, and the methods used to determine them differ in these experiments. In ref.

8 the diameter of the focal volume is determined by burning holes in a thin foil, but the length is not measured. These holes result from evaporation, which is a linear effect in q(r), while optical breakdown, a nonlinear effect, is more sensitive to the decrease in q(r) with distance from the center, so that the diameter of the breakdown region is lower. If we assume the error to be a factor of 2, we conclude that the intensity is lower by a factor of 4 and that its corrected values would agree with the theoretical values for argon, since the curves are identical over the entire pressure range. Surprisingly, the results of ref. 6, which, in the case of helium, agree with the results of refs. 1,5, 7, and 9 and with the theoretical results, are severalfold different from the results for argon in the work cited. The results of ref. 8 for helium are also too low.

At high pressures the threshold is governed by elastic energy loss alone and is independent of the diffusion length. The corresponding pressure range for helium is $p \geqslant 100$ atm, and that for argon, whose atoms are 10 times as heavy, is $p \geqslant 1000$ atm. As the pressure is reduced the curves corresponding to different values of Λ diverge more markedly, implying an increased role for diffusion loss. At comparatively large values of $p \leqslant 1$ for argon in the range 1-10 atm the threshold is governed primarily by the ionization rate, but for the more typical values of Λ and in the center of the pressure range all loss channels must be taken into account.

Multiphoton ionization by a picosecond pulse occurs at a radiation intensity of 10^{13} W/cm^2 in argon and $6 \cdot 10^{13}$ W/cm^2 in helium,[10] so an avalanche cannot occur for small values of Λ at low pressures. For example, with $\Lambda = 2.5 \cdot 10^{-4}$ cm and at a pressure of 0.7 atm, an intensity of 10^{13} W/cm^2 is required for avalanche breakdown in argon, but this intensity causes multiphoton ionization, rather than avalanche ionization. Accordingly, large focal volumes, i.e., long-focal length lenses, are required to study electron avalanches at low pressures. Otherwise, the breakdown threshold can be a multiphoton threshold.

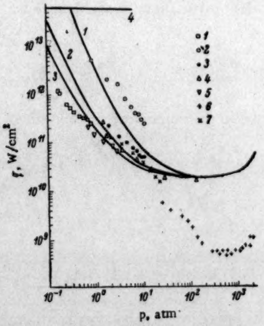

Fig. 3. Threshold intensity for breakdown in helium as a function of the pressure. I-III) Equation (4a). $\tau = 10^{-9}$, Λ, cm: I) $2.5 \cdot 10^{-4}$; II) 10^{-3}; III) $2 \cdot 10^{-3}$; IV) threshold for multiphoton breakdown.[10] Single-mode lasers: 1) ref. 1; 2) ref. 5. Multimode lasers: 3) ref. 5; 4) ref. 6; 5) ref. 7; 6) ref. 8; 7) ref. 9. Λ, cm: 1) $\sim 2 \cdot 10^{-3}$; 2) $2.5 \cdot 10^{-4}$; 3) $1.58 \cdot 10^{-3}$; 4) $2.4 \cdot 10^{-3}$; 5) $\sim 10^{-3}$; 7) $\approx 2 \cdot 10^{-3}$; 6) d $\sim 10^{-2}$.

Figure 1 shows the breakdown threshold as a function of the diffusion length according to Eq. (4b). The agreement with experiment is satisfactory, but poorer than that found when the pulse shape is taken into account [Eq. (3)].

The functional dependence for the breakdown threshold on the diffusion length at a pressure of 8.15 atm observed in ref. 6 cannot be attributed to free electron diffusion from the over-all focal volume. A multimode neodymium-glass laser is used in these experiments and the spatial structure of the radiation has not been studied. It is reasonable to assume that there are local radiation inhomogeneities a few microns in size with an intensity greater than the average intensity by a factor of 10 or more in the focal plane; such inhomogeneities have been observed in ruby.[11] If the avalanche develops experimentally in a cylindrical volume with a diameter equal to 0.6–0.8 of the diameter of the focal spot, and if the intensity exceeds the average intensity by a factor of 5-10, Eq. (4) can explain the functional dependence of the breakdown threshold on the diffusion length observed in ref. 6 for helium and argon. It should be noted that the actual shape of the local inhomogeneity is not cylindrical, and we can only state that the assumption of a local nature for the breakdown caused by the radiation of a multimode laser yields plausible estimates of the threshold. In the case of the single-mode laser[5] taking account of free electron diffusion from the focal volume leads to good agreement with the experimental results.

The author thanks S. I. Anisimov for useful discussion; D. I. Polishchuk for assistance, and É. I. Vitkin for the numerical calculations.

Power spectrum of potential fluctuations in a moving magnetoactive plasma

V. M. Kostin

Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation,
Academy of Sciences of the USSR, Moscow

(Submitted July 2, 1973; resubmitted February 11, 1974)
Zh. Tekh. Fiz., 44, 1687-1692 (August 1974)

The thermal fluctuations of the potential between two moving points in a plasma are studied. The singularities of the power spectrum at the lower and upper hybrid frequencies are analyzed in detail.

There is interest at the present time in measuring such parameters of the near-earth plasma as the ion and electron temperatures and densities by means of a correlation analysis of the signals from two probes located at two different points in space.[1] To this end Grabowski[1,2] has calculated the spectral density of the square of the potential difference between two spatially-separated points in a plasma in the absence of an external magnetic field. A calculation of this kind has been carried out by the present author[3] for the case of a magnetoactive plasma. However, in the analysis of experiments performed in near-earth plasma, allowance sometimes has to be made for the relative motion of the plasma.[4] In the present paper the potential correlation function in a uniformly moving magnetoactive plasma is calculated for the case $V \ll v_e$, which is usually satisfied in near-earth plasma.[4] The plasma is considered in the collisionless approximation, and the particles are assumed to have a Maxwellian distribution.

The fluctuation field of the charges in the plasma creates between two points a potential difference given by

$$U(t)=\int_0^l E_\parallel dx,$$

where $E_\parallel$ is the longitudinal component of the electric field. Since the integral is independent of the path, the integration in this expression can be taken along the straight line l joining these points. The mean value of U(t) is zero, and the spectral density over positive frequencies of the potential-difference correlation function is calculated from the expression

$$\langle U^2\rangle_\omega=2\int_0^l dx_1\int_0^l dx_2\int d\mathbf{k}\,\langle E_\parallel^{(1)}E_\parallel^{*(2)}\rangle_{\omega,\mathbf{k}}\exp i\mathbf{k}(\mathbf{x}_1-\mathbf{x}_2). \quad (1)$$

Here, the angle brackets ⟨⟩ signify statistical averaging and the indices ω and k denote, respectively, time and space Fourier components. Below the angle brackets will be omitted from $\langle U^2\rangle_\omega$. We note that expressions similar to (1) arise in the calculation of the spectral density of the noise emf of an antenna immersed in a plasma.[5-7] The spectral density of the correlation function $\langle E_\parallel E_\parallel^*\rangle_{\omega,\mathbf{k}}$ is given by

$$\langle E_\parallel E_\parallel^*\rangle_{\omega,\mathbf{k}}=\frac{1}{2\pi^3}\frac{k_z^2}{k^2}\frac{T}{\omega-\mathbf{kV}}\operatorname{Im}\frac{1}{\varepsilon^*(\omega-\mathbf{kV},\ \mathbf{k})}. \quad (2)$$

Expression (2) represents the correlation function for potential fields in a plasma with a Doppler frequency shift.[8] As is well known, the dielectric constant has the following form in the general case:

$$\varepsilon(\omega-\mathbf{kV},\ \mathbf{k})=1+\sum_{j,n}\frac{\exp\left(-\frac{k_\perp^2\rho_j^2}{2}\right)I_n\left(\frac{k_\perp^2\rho_j^2}{2}\right)}{k^2D^2}\times\left(1+i\sqrt{\pi}\frac{\omega-\mathbf{kV}}{k_zv_j}W\left(\frac{\omega-\mathbf{kV}-n\omega_{Bj}}{k_zv_j}\right)\right), \quad (3)$$

where W(x) is the Cramp function, V is the relative velocity of the plasma, $D=\sqrt{T/4\pi e^2N}$ is the Debye radius, N is the particle density, $\rho_j=v_j/\omega_{Bj}$ is the Larmor radius, $v_j=\sqrt{2T/m_j}$ is the thermal velocity, ω_{Bj} is the cyclotron frequency, $\omega_{0j}=\sqrt{4\pi Ne^2/m_j}$ is the plasma frequency, and $k_{\perp,z}$ denote the components of the wave vector transverse and parallel to the external magnetic field B. In (3) the summation extends over the species of particles j and over the index n.

It is readily shown, following ref. 3, that for points uniformly moving relative to the plasma the mean square of the potential difference, i.e., the integral of expression (1), does not vary over frequency. In a similar manner as for stationary points,[3] we obtain

$$U^2=\frac{2\sqrt{2}T}{D}\left\{1-\frac{D}{\sqrt{2}l}\left[1-\exp\left(-\frac{\sqrt{2}l}{D}\right)\right]\right\}.$$

This means that the motion has the effect of redistributing the spectral density U_ω^2 over the frequency spectrum. Clearly, in the evaluation of (1) the Doppler frequency shift in (2) must lead to a smoothing of the singularities of U_ω^2 occurring in the case of stationary points[3] which are caused by fluctuations at the characteristic frequencies of oscillation of the plasma. The imaginary part of the dielectric constant is negligibly small, and the following relationship[8] can be used in the integration of (1):

$$\operatorname{Im}\frac{1}{\varepsilon(\omega,\ \mathbf{k})}=\pi\delta(\varepsilon(\omega,\ \mathbf{k})).$$

Performing the double integration in (1) with respect to x_1 and x_2 utilizing this expression, we obtain the contribution to the spectral density U_ω^2 from the fluctuating fields of the potential oscillations in an unperturbed plasma:

$$U_\omega^2=\frac{2T}{\pi^2}\int\frac{1-\cos(k_zl\cos\theta+k_\perp l\sin\theta\cos\psi)}{\omega-\mathbf{kV}}\delta(k^2\varepsilon(\omega-\mathbf{kV},\ \mathbf{k}))\,d\mathbf{k}, \quad (4)$$

where θ is the angle between the vector l and the magnetic field B, and ψ is the angle between the projections of k and l on a plane perpendicular to B. Let us now examine how the motion affects the spectrum U_ω^2.

Slow extraordinary wave. The power spectrum of the potential[3] has a sharp maximum at the upper hybrid frequency $\omega_u = \sqrt{\omega_{0e}^2 + \omega_{Be}^2}$. The dielectric constant (3) can be taken in the cold-plasma approximation. The condition $V \ll v_e$ usually holds[4] in the near-earth plasma. Accordingly, the validity of the expansion of (3) in $\omega/k_z v_e < 1$ and $k_\perp \rho_{e,i} < 1$, in which the approximation used below for $\varepsilon(\omega, k)$ is obtained, is not violated by the motion of the body. Near ω_u we have

$$\varepsilon(\omega - \mathbf{kV}, \mathbf{k}) = \frac{k_z^2}{k^2}\frac{\omega_{Be}^2}{\omega_u^2} - \frac{k_\perp^2}{k^2}\frac{2\omega_u(\mathbf{kV} - \Delta\omega)}{\omega_{0e}^2}, \tag{5}$$

where $\Delta\omega = \omega - \omega_u$. With this value of $\varepsilon(\omega, k)$ expression (4) is readily integrated with respect to k_z, and

$$U_\omega^2 = \frac{2T}{\pi^2}\frac{\omega_u}{\omega_{Be}^2}\int \frac{1 - \cos(k_\perp^2 a l V_z \cos\theta + k_\perp l \sin\theta\cos\psi)\ \cos\left(l\cos\theta\sqrt{(k_\perp^2 a V_z)^2 + 2k_\perp^2 a(k_\perp V_\perp\cos\varphi - \Delta\omega)}\right)}{\sqrt{(k_\perp^2 a V_z)^2 + 2k_\perp^2 a(k_\perp V_\perp \cos\varphi - \Delta\omega)}}\, k_\perp dk_\perp d\varphi. \tag{6}$$

Here, φ is the angle between the projections of k and V on a plane perpendicular to B. For convenience we use the notation $a = \omega_u^3/\omega_{0e}^2\omega_{Be}^2$.

The oscillating term in the numerator of (6) is important under certain conditions. The case $l \gg \rho_e$ is of most interest for the ionospheric plasma.[4] The characteristic range of integration in (6) with respect to $k_\perp$ will be ρ_e^{-1}. In this case the second term in the numerator of (6) must be taken into account only if $\theta < \rho_e/l$ and at frequencies $\Delta\omega_{\text{eff}}/\omega_u < \rho_e^2/l^2$. The sharp reduction of U_ω^2 in this case is due to the fact that the oscillations at frequency ω_u are transverse to the magnetic field while the vector distance between the points l is along B. The field associated with these oscillations is therefore not important. The effective Doppler frequency shift cannot be large either since oscillations with frequencies $\omega < \omega_u$ are not transverse to l and B.

Let us consider the evaluation of the main term in (6). We integrate with respect to $k_\perp$ from 0 to ρ_e^{-1} in the region in which oscillations exist, i.e., where the expression under the radical in the denominator of (6) is positive:

$$k_\perp \leqslant k_{\perp 1} = \frac{1}{aV_z^2}\left(V_\perp\cos\varphi - \sqrt{V_\perp^2\cos^2\varphi + 2a\Delta\omega V_z^2}\right);$$

$$k_\perp \geqslant k_{\perp 2} = \frac{1}{aV_z^2}\left(V_\perp\cos\varphi + \sqrt{V_\perp^2\cos^2\varphi + 2a\Delta\omega V_z^2}\right).$$

The limitations on the range of integration are connected with the transverse wave vectors: Near the hybrid frequency ω_u, the waves are almost perpendicular to B. Performing the integration with respect to $k_\perp$ we obtain

$$U_\omega^2 = \frac{4T}{\pi^2}\frac{\omega_u}{aV_z\omega_{Be}^2}$$

$$\times \int_0^{\arccos\max\left\{-1,\ \frac{\Delta\omega\rho_e}{V_\perp} - \frac{aV_z^2}{2\rho_e V_\perp}\right\}} d\varphi \ln\frac{aV_z^2 + \rho_e V_\perp\cos\varphi + V_z\sqrt{(aV_z)^2 + 2a\rho_e V_\perp\cos\varphi - 2a\rho_e^2\Delta\omega}}{\sqrt{V_\perp^2\cos^2\varphi + 2a\Delta\omega V_z^2}}. \tag{7}$$

The integrand in (7) is weakly dependent on the parameter of integration; accordingly it is useful to consider the two cases $V_z \gg V_\perp$ and $V_z \ll V_\perp$ for which the integral can be evaluated. More precisely, the criterion

$$\frac{aV_z^2}{\rho_e V_\perp} > 1 \tag{8}$$

signifies that the mean Doppler frequency shift in (5) due to the longitudinal motion is greater than the corresponding shift due to the transverse motion.

We expand the radical in the numerator of the logarithm in (7) in the parameter (8) and retain two terms. The integral with respect to φ is then readily evaluated by integration in the complex plane.

For frequencies satisfying the condition

$$\Delta\omega = \omega - \omega_u \leqslant -\frac{V_\perp^2}{2aV_z^2}, \tag{9}$$

the power spectrum of the potential between two points is given by

$$U_\omega^2 = \frac{4T\omega_u}{\pi a V_z \omega_{Be}^2}\ln\frac{2aV_z^2\left(1 + \sqrt{1 - \frac{2\rho_e^2\Delta\omega}{aV_z^2}}\right)}{\rho_e V_\perp\left(\frac{V_z}{V_\perp}\sqrt{-2a\Delta\omega} + \sqrt{-\frac{2a\Delta\omega V_z^2}{V_\perp^2} - 1}\right)}. \tag{10}$$

At the point where the equality sign in (9) is satisfied the function U_ω^2 has a discontinuous change of slope (break) and, for large $\Delta\omega$, is given by (10) without the bracketed expression in the denominator of the logarithm, which has a singularity.

This behavior is explained by the fact that for frequencies that do not satisfy criterion (9) wave vector k in (5) becomes discontinuous at $\varphi = \pi$.

For $\Delta\omega \geq 0$ there remains of this region only the part corresponding to short wavelengths. As a result U_ω^2 has a kink at the point $\Delta\omega = 0$, where $\omega = \omega_u$, and its behavior is given by the following expression:

$$U_\omega^2 = \frac{4T\omega_u}{\pi\omega_{Be}^2 a V_z}\ln\frac{2aV_z^2\left(1 + \sqrt{1 - \frac{2a\omega\rho e_z^2}{aV_z^2}}\right)}{\rho_e V_\perp\sqrt{1 + \frac{4V_z^2 a\Delta\omega}{V_\perp^2} + \sqrt{\left(1 + \frac{4aV_z^2\Delta\omega}{V_\perp^2}\right)^2 - 1}}}, \tag{11}$$

which is valid up to

$$\Delta\omega = \frac{aV_z^2}{2\rho_e^2} - \frac{V_\perp}{\rho_e}. \tag{12}$$

Starting at this value of $\Delta\omega$ there is a break in the wave vector space of the upper limit of integration and U_ω^2 begins to fall sharply. It can be shown by direct differentiation of (7) that at this point U_ω^2 exhibits a discontinuity in the first derivative.

Unlike the two breaks in U_ω^2 described above, which have a clear physical significance, the present one is connected with the approximate character of extrapolation (5) at the upper limit of integration in (7) and with terminating the integration over $k_\perp$ at the value ρ_e^{-1}.

The spectrum U_ω^2 is cut off at frequencies satisfying the equality

$$\Delta\omega = \frac{aV_z^2}{2\rho_e} + \frac{V_\perp}{\rho_e}. \qquad (13)$$

The contribution to the spectral density U_ω^2 from the natural longitudinal oscillations of the slow extraordinary wave is zero. It can be shown, in the same manner as in ref. 3, that $U_\omega^2 \approx T/v_e$ is determined by the fluctuating motion of individual electrons in the vicinity of a Debye radius about the point under consideration.

We shall show that similar results obtain in the limiting case opposite to condition (8). Expression (7) reduces to the following form in the limit $V_z \to 0$:

$$U_2^\omega = \frac{4\sqrt{2}\,T\omega_u}{\pi^2\omega_{Be}^2\sqrt{a\rho_e V_\perp}} \int\limits_0^{\operatorname{ars\,cos\,max}\left\{-1,\ \frac{\Delta\omega\rho_e}{V_\perp}\right\}} d\varphi\, \frac{\sqrt{\cos\varphi - \frac{\Delta\omega\rho_e}{V_\perp}}}{\cos\varphi}.$$

This integral can be expressed through the complete elliptic integrals of the first and third kinds. If $\Delta\omega\rho_e/V_\perp < -1$ we find that

$$U_\omega^2 = \frac{8T\omega_u\sqrt{\varkappa_1}}{\pi^2\omega_{Be}^2\sqrt{a\rho_e V_\perp}}\left[2K(\varkappa_1) - \Pi_1\left(\frac{\varkappa_1 V_\perp}{2\Delta\omega\rho_e},\ \varkappa_1\right)\right], \qquad (14a)$$

where $\varkappa_1 = V_\perp/[-\rho_e\Delta\omega + \sqrt{(\rho_e\Delta\omega)^2 - V_\perp^2}]$. If $\Delta\omega\rho_e/V_\perp > -1$ we obtain the following expression:

$$U_\omega^2 = \frac{8T\omega_u}{\pi^2\omega_{Be}^2\sqrt{a\rho_e V_\perp}}\left[K(\varkappa_2) - \frac{\Delta\omega\rho_e}{V_\perp}\Pi_1(-2\varkappa_2^2,\ \varkappa_2)\right], \qquad (14b)$$

where $\varkappa_2 = \sqrt{(V_\perp - \rho_e\Delta\omega)/2V_\perp}$.

Plots of the power spectrum U_ω^2 in the vicinity of the upper hybrid frequency are shown in Fig. 1 for three values of the parameter $\alpha = aV_z^2/\rho_e V_\perp = 10,\ 1,\ 0$. The first is constructed through Eqs. (10) and (11); the second is obtained by numerical calculation of (7); the third is obtained through Eq. (14). In the latter case the values of the elliptic integrals are taken from ref. 9, and the complete elliptic integrals of the third kind $\Pi_1(\nu, \varkappa)$ for the interval $\nu < -1$ are expressed in terms of the incomplete elliptic integrals of the first and second kinds through the equation[10]

Fig. 1. Contribution to function U_ω^2 from fluctuating fields due to characteristic plasma oscillations near the upper hybrid resonance frequency.

$$\operatorname{ctg}\beta\Delta(\beta,\ \varkappa)\,\Pi_1\left(-\frac{1}{\sin^2\beta},\ \varkappa\right) = E(\varkappa)F(\beta,\ \varkappa) - K(\varkappa)E(\beta,\ \varkappa).$$

A comparison of the curves shows that when the parameter $aV_z^2/\rho_e V_\perp \le 10$ the quantity max U_ω^2 shows little variation, being equal to

$$U_0^2 = \frac{16G\omega_u}{\pi^2\omega_{Be}^2\sqrt{aV_\perp\rho_e}}, \qquad (15)$$

where G = 0.916 is the Katalan constant. For $aV_z^2/\rho_e V_\perp > 1$ the maximum proper is shifted to the point $\Delta\omega = -V_\perp^2/2aV_z^2$, but up to values $\omega = \omega_u$ the spectral density U_ω^2 falls so slowly that the plateau approximation can be used. The following asymptotic expression can be used in place of (14) for frequencies for which $U_\omega^2 \ll U_0^2$:

$$U_\omega^2 = \frac{4T}{\pi}\,\frac{\omega_u}{aV_z\omega_{Be}^2}\ln\left(1 + \frac{V_z}{\rho_e}\sqrt{-\frac{a}{2\Delta\omega}}\right). \qquad (16)$$

It is readily seen that in the limit $V_z \to 0$ this expression coincides with Eq. (13) of ref. 3.

We note that max U_ω^2 begins to fall slowly with increasing value of the parameter (8). Thus, for $aV_z^2/\rho_e V_\perp = 100$, max U_ω^2 is smaller than (15) by a factor of 2, as is readily seen from Eq. (10) or (11).

Fast magnetoacoustic wave. At the lower hybrid frequency $\omega_L = [\omega_{Bi}\omega_{Be}(\omega_{0i}^2 + \omega_{Bi}^2)/(\omega_{Bi}\omega_{Be} + \omega_{0i}^2)]^{1/2}$ these oscillations are electrostatic, and the noise intensity U(t) also has a sharp maximum.[3] The situation here is similar to that at the upper hybrid frequency.

The dielectric constant in the cold-plasma approximation also applies here:

$$\varepsilon(\omega - \mathbf{kV},\ \mathbf{k}) = 1 - \frac{\omega_{0i}^2}{(\omega - \mathbf{kV})^2} + \frac{k_\perp^2}{k^2}\,\frac{\omega_{0e}^2}{\omega_{Be}^2 - (\omega - \mathbf{kV})^2} - \frac{k_z^2}{k^2}\,\frac{\omega_{0e}^2}{(\omega - \mathbf{kV})^2}.$$

Expansion (17) at the frequency ω_L has the form

$$\varepsilon(\omega - \mathbf{kV},\ \mathbf{k}) = \frac{2k_\perp^2}{k^2}\,\frac{(\omega_{Be}^2 + \omega_{0e}^2)(\omega - \omega_L - \mathbf{kV})}{\omega_L\omega_{Be}^2} - \frac{k_z^2}{k^2}\,\frac{\omega_{0e}^2}{\omega_L^2},$$

which is completely analogous to (5). As a result, all the equations for U_ω^2 in the vicinity of the lower hybrid frequency can be obtained from expressions (6)-(16) by making the simple substitutions ω_L/ω_{0e}^2 for ω_u/ω_{Be}^2, ρ_i for ρ_e, $\omega_L - \omega$ for $\Delta\omega$, and by setting $a = \omega_L(\omega_{Be}^2 + \omega_{0e}^2)/\omega_{0e}^2\omega_{Be}^2$.

For the ionosphere plasma[4], in which frequently $\omega_{0e} > \omega_{Be}$, max $U_{\omega_u}^2$/max $U_{\omega L}^2 = (\omega_{0i}/\omega_{Bi})^3$, where max U_ω^2 is given by expression (15). The less sharply expressed maximum at the lower hybrid frequency is due to the fact that the collective oscillations of the plasma occupy a smaller phase volume in k space than near ω_u.

At frequencies where there are no potential oscillations of the plasma it can be shown, as in ref. 3, that $U_\omega^2 \approx T/v_1$ and the main contribution comes from the fluctuating motions of individual ions in the neighborhood of a Debye radius about the points under consideration.

The conclusions of the present work can be summarized as follows.

1. The mean square of the potential difference between two points does not vary as a result of relative motion of the plasma. A redistribution of the spectral density occurs.

2. The effect of the relative motion of the plasma is to smooth the maxima of the power spectra U_ω^2 at the hybrid frequencies. If criterion (8) is obeyed, then max U_ω^2 is shifted towards lower frequencies in the region of the upper hybrid frequency, and towards higher frequencies in the region of the lower hybrid frequency. Starting at a frequency defined by expression (9), the spectral density U_ω^2 is approximately constant up to the hybrid frequency.

3. At the frequencies $\omega_{u,L}$ and at the frequency defined by (9), breaks occur in the curve of U_ω^2.

I should like to thank Ya. L. Al'perta for discussion and A. A. Andronov and Yu. V. Chugunov for a number of useful remarks.

Radiation emitted by charged particles trapped by plane electromagnetic waves

V. Ya. Davydovskii and A. S. Ukolov

Taganrog Radio Engineering Institute

(Submitted September 11, 1973; resubmitted January 11, 1974)
Zh. Tekh. Fiz., 44, 1693-1698 (August 1974)

Radiation emitted by a charged particle trapped by a plane monochromatic circularly polarized wave with slowly varying propagation and amplitude is considered. With radiative reactions neglected expressions are obtained for the energy emitted in a period of the phase oscillations, the average radiated power, and the time in which the phase oscillation energy varies significantly. The spectral composition of the radiation is investigated and it is shown that the trapped particles radiate primarily at the phase oscillation frequency, which can be very different from the wave frequency.

The motion of a charged particle trapped by a plane electromagnetic wave consists of two motions: a uniform motion together with the wave (plane motion), and oscillatory motion about some phase of the wave (phase oscillations). The latter motion should be accompanied by radiation that damps the oscillations. Investigation of this radiation is of interest for the following reasons. First, damping of the phase oscillations enhanches the confinement of the particle by the wave which, in turn, can increase the particle energy if the propagation velocity increases.[1-4] Second, the trapped particles radiate at the phase oscillation frequency, which is different from the wave frequency; this may be one of the mechanisms responsible for generation of astrophysical radio emission.

The energy emitted during a period T of a phase oscillation for particles moving in an electromagnetic field **E** and **B** can be written[5]

$$\Delta\varepsilon = \frac{2e^4}{3m^2c^3}\int_0^T \frac{\left(\mathbf{E}+\frac{1}{c}[\mathbf{vB}]\right)^2 - \frac{1}{c^2}(\mathbf{Ev})^2}{1-\frac{v^2}{c^2}}\,dt. \tag{1}$$

In Eq. (1) it is assumed that the variation in the parameters due to radiation can be neglected for the period of particle motion. Introducing the dimensionless velocity **u** and energy β of the particle, normalized, respectively, to the speed of light c in vacuum and the rest energy mc^2, and also the momentum **p** divided by mc, and remembering that

$$\frac{d\mathbf{p}}{dt} = \frac{e}{mc}(\mathbf{E}+[\mathbf{uB}]),\quad \frac{d\beta}{dt} = \frac{e}{mc}\mathbf{Eu}, \tag{2}$$

we rewrite (1) as

$$\Delta\varepsilon = \frac{2e^2}{3c}\int_0^T \left\{\left(\frac{dp}{dt}\right)^2 - \left(\frac{d\beta}{dt}\right)^2\right\}\beta^2 dt. \tag{3}$$

It is also convenient to introduce the phase θ on which the field depends:

$$\theta = t - \int_0^z n(z)\,dz. \tag{4}$$

Above, n(z) is the refractive index, which is assumed to remain essentially fixed during the period T. Replacing the time t by θ in Eq. (3), we obtain

$$\Delta\varepsilon = \frac{2e^2}{3c}\oint \left\{\left(\frac{dp}{d\theta}\right)^2 - \left(\frac{d\beta}{d\theta}\right)^2\right\}\beta(\beta - np_z)\,d\theta, \tag{5}$$

where it is assumed that $d\theta/dt = 1 - nu_z = 1 - np_z/\beta$. The integration in (5) is carried out over one period of θ.

We assume further that the electromagnetic field is a plane circularly polarized wave with potential A determined by

$$A_x = \frac{c}{\omega}\mathscr{E}(z)\cos\omega\theta,\quad A_y = -\frac{c}{\omega}\mathscr{E}(z)\sin\omega\theta,\quad A_z = 0, \tag{6}$$

where the amplitude $\mathscr{E}$ (z) is assumed to be a slowly varying function and ω = const. The motion of a particle trapped by a wave (6) has been thoroughly studied.[1,6] In particular, the expressions for the energy and momentum, assuming that the wave parameters do not vary, are

$$\left.\begin{aligned} \beta &= \frac{Yn}{n^2-1} + 2\sigma\sqrt{\frac{\lambda C}{n^2-1}\left(\tau - \sin^2\omega\frac{\theta-\theta_0}{2}\right)},\\ p_z &= \frac{Y}{n^2-1} + 2\sigma n\sqrt{\frac{\lambda C}{n^2-1}\left(\tau - \sin^2\omega\frac{\theta-\theta_0}{2}\right)}, \end{aligned}\right\} \tag{7}$$

$$\left.\begin{aligned} &\mathbf{p}_\perp = \mathbf{C} - \frac{e}{mc^2}\mathbf{A},\quad \lambda = \frac{e\mathscr{E}}{mc\omega},\quad \sigma = \frac{u_z n - 1}{|u_z n - 1|},\\ &Y = n\beta - p_z,\quad \tau = \frac{Y^2 - [(C-\lambda)^2+1](n^2-1)}{4C\lambda(n^2-1)},\quad \mathrm{tg}\,\omega\theta_0 = -\frac{C_y}{C_x}. \end{aligned}\right\} \tag{7a}$$

Here, $\mathbf{C} = \mathbf{i}C_x + \mathbf{j}C_y$ is the generalized transverse momentum, which remains constant since the field is independent of the x and y coordinates, Y for constant n is an integral of motion equivalent to the particle energy conserved in the wave coordinate system, and index $\perp$ denotes projection of the vectors onto the xy plane. We assume further that while the particle moves the refractive index n and the parameter λ (which is proportional to the amplitude of the wave), and thus Y and τ, vary negligibly.

Substituting (7) into (5) and integrating, we obtain the energy emitted by a trapped particle in one period normalized to mc^2

$$\Delta\beta = \frac{32e^2\lambda^{3/2}C^{1/2}\omega n}{9mc^3}\sqrt{1+4C\lambda\tau+(C-\lambda)^2}\left\{\left[\frac{C}{2} - 3\lambda(1-\tau)\right]K(\tau) + \left[3\lambda + C\left(\tau - \frac{1}{2}\right)\right]E(\tau)\right\}. \tag{8}$$

Here, K and E are complete elliptical integrals of the first and second kind, respectively.

The parameter τ characterizes the phase oscillation amplitude[1]; more precisely the range of variation of the phase θ for the particle motion is determined by

$$\theta_0-\frac{2}{\omega}\arcsin\sqrt{\tau}\leqslant\theta\leqslant\theta_0+\frac{2}{\omega}\arcsin\sqrt{\tau}. \tag{9}$$

The expression for $\Delta\beta$ in the limit $\tau \to 0$ is

$$\Delta\beta=\frac{4\pi e^2\lambda^{3/2}C^{1/2}\omega n}{9mc^3}\sqrt{1+(C-\lambda)^2}\,(5C+6\lambda)\,\tau. \tag{10}$$

In the opposite case of large phase oscillation amplitudes $\tau \to 0$ that are extremely large for captured particles, using the asymptotic behavior of the complete elliptical integrals we obtain,

$$\Delta\beta=\frac{16e^2\lambda^{3/2}C^{1/2}\omega n}{9mc^3}\sqrt{1+(C+\lambda)^2}\ln\frac{4}{\sqrt{1-\tau}}. \tag{11}$$

We note that Eq. (8) does not contain the factor n^2-1; consequently, the energy emitted during a period tends to a finite value for $n \to 1$. This cannot be said of the radiated power. Actually, the period of phase oscillation of the particle[1] is

$$T=\frac{8nK(\tau)}{\omega(n^2-1)}\left[\tau+\frac{1+(C-\lambda)^2}{4C\lambda}\right]^{1/2}, \tag{12}$$

and the average power radiated by the particle is

$$I=\frac{\Delta\beta}{T}=\frac{8e^4\mathcal{E}^2C(n^2-1)}{9m^3c^5}\left\{\frac{C}{2}-3\lambda(1-\tau)+\left[3\lambda+C\left(\tau-\frac{1}{2}\right)\right]\frac{E(\tau)}{K(\tau)}\right\}. \tag{13}$$

We note that the average radiated power has only a very weak (through the parameter λ) dependence on the frequency, but is proportional to the square of the wave amplitude and falls sharply in the limit $n \to 1$. For small τ this quantity becomes

$$I=\frac{2e^4\mathcal{E}^2C(n^2-1)}{9m^3c^5}(6\lambda+5C)\,\tau, \tag{14}$$

and for $\tau \to 1$

$$I=\frac{4e^4\mathcal{E}^2C^2(n^2-1)}{9m^3c^5}. \tag{15}$$

We obtain the expression for the emission time, i.e., the time in which there is substantial variation of the phase oscillation amplitude. The oscillation amplitude of the energy is obtained from (7) if we set $\sin\omega(\theta-\theta_0)/2 = 0$,

$$\delta\beta=2\sqrt{\frac{\lambda C\tau}{n^2-1}}. \tag{16}$$

Differentiating this expression with respect to time and equating the result to the average radiated power (13), we obtain

$$\frac{d\tau}{dt}=\frac{8}{9}\sqrt{\frac{e^7\mathcal{E}^3C(n^2-1)^3\omega\tau}{m^5c^9}}$$

$$\times\left\{\frac{C}{2}-3\lambda(1-\tau)+\left[3\lambda+C\left(\tau-\frac{1}{2}\right)\frac{E(\tau)}{K(\tau)}\right\}. \tag{17}$$

The solution of (17) is not expressed in terms of known functions. Therefore, we are limited to the case of small τ

$$\tau=\frac{\tau_0}{(At\sqrt{\tau_0}+1)^2}, \tag{18}$$

where τ_0 is the value of τ at $t = 0$, and

$$A=\frac{1}{9}\sqrt{\frac{e^7\mathcal{E}^3C(n^2-1)^3\omega}{m^5c^9}}(6\lambda+5C). \tag{19}$$

The time of the decrease in τ is twice

$$t_0=\frac{\sqrt{2}-1}{A\sqrt{\tau_0}}. \tag{20}$$

It is easy to see that this time is very large for realistic values $\lambda_0 = 2\pi c/\omega \sim 1$ m, $\mathcal{E} \sim 1$ V/cm, and $C \sim 1$. Emission cannot occur in processes that take place inside the solar system; it may occur in such interstellar phenomena as the flare-up of new stars and supernovae.

We now consider the frequency composition of the radiation. We do not find the radiation field of the trapped particle since this field depends on the properties of the medium (the effect of the medium is essential: In vacuum the wave velocity is equal to c and there is no trapped particle of finite rest mass); we are interested in the relative magnitudes of the harmonic amplitudes. Under the above assumptions with respect to n and λ the instantaneous radiated power is a quasiperiodic function of time whose parameters are constant during time intervals comparable to the phase oscillation period of the particle. Therefore, to find the frequency composition of the radiation we expand the instantaneous radiated power in a Fourier series with fundamental frequency Ω equal to the phase oscillation frequency. In the coordinate system in which the wave is at rest the corresponding expressions are

$$I'=\frac{8e^2\lambda^2\omega^2(n^2-1)C}{3mc^2}\left\{\lambda\left(\tau-\sin^2\frac{k}{2}(z'-z_0')\right)+\frac{C}{4}\sin^2k(z'-z_0')\right\}, \tag{21}$$

$$\Omega'=\frac{2\pi\omega\sqrt{C\lambda(n^2-1)}}{4\beta'K(\tau)},\quad C_x=C\cos kz_0',\quad C_y=-C\sin kz_0', \tag{22}$$

and $k = \omega\sqrt{n^2-1}$; the primes denote values in the wave coordinate system.

If the average radiated power is to be an additive function of the harmonic number, one must expand the quantity $R = \sqrt{I'}$ in a Fourier series; this quantity is proportional to the field that the particle would radiate in vacuum

$$R=\sum_{j=0}^{\infty}(a_j\cos j\Omega't'+b_j\sin j\Omega't'), \tag{23}$$

Since t' and z' are related by

$$\frac{dz'}{dt'}=u_z'=\frac{p_z'}{\beta'}=\frac{\sqrt{\beta'^2-p_\perp'^2-1}}{\beta'}=\frac{2a}{\beta'}\sqrt{C\lambda\left(\tau-\sin^2k\frac{z'-z_0'}{2}\right)}, \tag{24}$$

for the wave in (6) we have

$$a_{2j}=(-1)^j\frac{4\beta'}{T'\sqrt{C\lambda}}\int_{z_0'}^{z_1'}R\cos\left[j\pi\frac{F(\tau,\varphi)}{K(\tau)}\right]\frac{dz'}{\sqrt{\tau-\sin^2k\frac{z'-z_0'}{2}}},\qquad(25)$$

$$b_{2j+1}=(-1)^j\frac{4\beta'}{T'\sqrt{C\lambda}}\int_{z_0'}^{z_1'}R\cos\left[\frac{2j+1}{2}\pi\frac{F(\tau,\varphi)}{K(\tau)}\right]\frac{dz'}{\sqrt{\tau-\sin^2k\frac{z'-z_0'}{2}}},\qquad(26)$$

where $F(\tau, \varphi)$ is an incomplete elliptical integral of the first kind, and

$$\left.\begin{aligned}\varphi&=\arcsin\left(\frac{1}{\sqrt{\tau}}\sin k\frac{z'-z_0'}{2}\right),\\ z_1'&=z_0'+\frac{2}{k}\arcsin\sqrt{\tau}.\end{aligned}\right\}\qquad(27)$$

All odd a_j and even b_j vanish indentically. Combining (25) and (26) and eliminating terms that do not occur in the calculation of the strengths, we obtain

$$a_j=\frac{4\beta'}{T'\sqrt{C\lambda}}\int_{z_0'}^{z_1'}R\cos\left[\frac{j}{2}\pi\frac{F(\tau,\varphi)}{K(\tau)}\right]\frac{dz'}{\sqrt{\tau-\sin^2k\frac{z'-z_0'}{2}}}.\qquad(28)$$

Changing to integration over φ and taking account of

$$\beta'=\frac{Y}{\sqrt{n^2-1}},$$

and substituting T' and i' from (21) and (22), we rewrite (28)

$$a_j=\frac{4e\lambda k}{K(\tau)}\sqrt{\frac{2C\tau}{3mc^3}}\int_0^{\pi/2}\sqrt{\frac{\lambda\cos^2\varphi}{1-\tau\sin^2\varphi}+\frac{C}{2}\sin^2\varphi}\,\cos\left[j\frac{\pi}{2}\frac{F(\tau,\varphi)}{K(\tau)}\right]d\varphi.\qquad(29)$$

The integral in (29) is not expressed in terms of known functions. However, in the limiting case of small oscillations and a weak wave

$$\tau\ll 1,\quad \lambda\ll C\qquad(30)$$

one can assume that $F(\tau, \varphi) \approx \varphi$ and $K(\tau) \approx \pi/2$. Then,

$$a_j=\frac{2e\lambda kC}{K(\tau)}\sqrt{\frac{\tau}{3mc^3}}\left[\frac{1-\cos(j+1)\frac{\pi}{2}}{j+1}-\frac{1-\cos(j-1)\frac{\pi}{2}}{j-1}\right]\qquad(31)$$

for $j \neq 1$, and

$$a_1=\frac{e\lambda kC}{K(\tau)}\sqrt{\frac{\tau}{3mc^3}}.$$

Thus, in this limiting case the coefficients a_j decrease as j increases, and the odd a_j are proportional to $1/(j^2 - 1)$ and the even a_j are proportional to the factor

$$\frac{j(-1)^{\frac{j+1}{2}}+1}{j^2-1}.$$

When the inequality (30) does not hold, the coefficients are calculated for different values of λ, C, and τ. The results of the calculations are shown in Table 1, which gives the values for $a_j/a_0 = a_j$.

Examination of Table 1 indicates that the radiation intensity, which is proportional to a_j^2, declines rapidly with increasing j, i.e., a significant portion of the energy is emitted by the particle at the fundamental and the first few harmonics.

In regard to the dependence of a_j on τ we note that the radiation intensity increases in the region $0.5 \leqslant \tau \leqslant 0.75$. It is understandable physically that there is a maximum of radiation intensity for the charged particles. When $\tau \to 0$, the phase oscillation amplitude, as well as the radiation intensity, tend to zero. When $\tau \to 1$ the period of the phase oscillation (12) increases infinitely, and the average power emitted by the particle also tends to zero. Consequently, in the region of variation of τ, $0 \leq \tau \leq 1$ the radiation intensity reaches a maximum.

This effect can lead to reradiation of the wave energy by particles trapped by this wave at frequencies different than the wave frequency. It can be seen from (12) that for a phase period that is the same as the period of the fundamental emitted harmonic, the latter can differ considerably from the period of the wave $2\pi/\omega$. Reradiation occurs largely at low frequencies, and the frequency decreases with increasing phase oscillation amplitude when τ increases. For small oscillations the period does not depend on τ.

$$T=\frac{2\pi}{\omega}\frac{n}{n^2-1}\sqrt{\frac{1+(C-\lambda)^2}{C\lambda}}.$$

In this case, however, since $n \gg 1$, and λ and C are small, $T > 2\pi/\omega$. The latter expression, like (12), is val-

id for slowly varying wave parameters, when n and λ are functions of z whose variation during a period of phase oscillations of the particle can be neglected. Therefore, the radiation frequency of the trapped particles can vary due to the gradient of the refractive index n, and also due to the variation in the wave amplitude, for example as a result of damping.

Investigation of a plasma focus with a time-resolved laser interferometer

I. M. Zolototrubov, I. P. Skoblik,

A. G. Tolstolutskii, and V. I. Privezentsev

(Submitted September 4, 1972; resubmitted January 7, 1974)
Zh. Tekh. Fiz., 44, 1699-1702 (August 1974)

A modified Mach–Zender interferometer with a He–Ne laser as light source and an SFR rotating mirror camera for time resolution is described. By sweeping the sharply focused laser beam a time resolution of to $3 \cdot 10^{-8}$ sec is achieved. The interferometer is used to observe plasma density fluctuations and to determine the geometrical size of a plasma focus.

A Mach–Zender interferometer with a laser light source and a rotating-mirror camera has been used to investigate the electron density in a plasma focus.

The optical system is chosen to give the best spatial and temporal resolution for the interferometer. Therefore a system is used which focuses the light beam in a region of the plasma. The light source is a He–Ne laser which gives the least spreading of the beam[1] when operating in the TEM_{00q} mode.

Figure 1 shows the arrangement. A light beam is formed by means of a telescopic lens system. The short focal length cylindrical lens 2 expands the beam to ~ 8 cm in the yz plane. Lens 3 forms a parallel beam in the yz plane and simultaneously focuses in the xy plane down to a size $2\delta = 5 \cdot 10^{-2}$ cm. The focal length of lens 3 is 70 cm, so that the minimum beam width δ coincides with the plasma focus region with the lens outside the vacuum chamber 6.

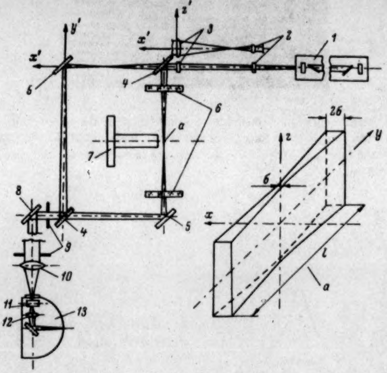

Fig. 1. The optical arrangement of the interferometer. 1) LG-36A He–Ne laser; 2) cylindrical lens; 3) lens forming the laser light beam; 4) beam-splitter mirror; 5) mirror blanks; 6) glass windows of the vacuum chamber; 7) coaxial plasma accelerator; 8) rotating mirror; 9) masking stops; 10) I-38 objective; 11) shutter; 12) RO2-2M objective; 13) SFR-2M camera. a) shape of the light beam in the probed region; l = 8 cm is the distance at which the minimum laser beam width is doubled.

The time sweep is accomplished by means of the SFR-2M camera (13), operating in the scan mode. An image of the test object and the interference bands is formed on the film by means of the objectives I-37 (10) and RO2-2M (12). In the focal plane of the objective 10 there is a shutter 11, adapted from the measuring device of a magnetoelectric system (ref. 2), with an opening time of ~ 1 μsec, which is equal to the time for one revolution of the SRF mirror when its speed is $n = 6 \cdot 10^4$ rev/min. Objective 12 focuses the laser beam sharply on the sensitive layer of the film in the form of a narrow light strip of width as large as $\delta' \approx 10^{-2}$ cm. Hence the time resolution of the interferometer, defined as

$$\Delta t = \frac{\delta'}{v_p},$$

is $3 \cdot 10^{-8}$ sec. Here v_p is the linear speed of the sweep, $3 \cdot 10^5$ cm/sec.

The spatial resolution of the interferometer in the direction perpendicular to the probe beam is determined by the width of the interference fringe related to the plasma probe region, and is about 2 mm.

Because of the small angular spreading of the laser beam it is easy to eliminate the plasma light by means of the stops 9 mounted in the path of the beam and by withdrawing the SFR camera to a distance of 3.5 m from the plasma source.

The coaxial gun used for the experiment is described in ref. 3. The capacitor bank is charged to 25 kV. The discharge period is ~ 12 μsec. About 1.2 cm³ of hydrogen is injected into the interelectrode gap of the coaxial accelerator. The delay time τ_d between the gas injection pulse and the voltage pulse to the electrodes is varied from 100 to 250 μsec. The plasma is probed at distances of 1.5, 4.5, and 6.5 cm from the end of the accelerator.

Figure 2 shows typical interferograms. Figure 2a illustrates the case in which the spatial resolution of the interferometer is inadequate: the spherical lens 3 in the experimental arrangement (Fig. 1) is replaced by a cylindrical lens, which increases the size of the probe beam in the plasma region to 0.5 cm. The temporal resolution of the interferometer remains unchanged. A possible reason for blurring of the interference fringes is substantial spatial variations of the plasma refractive index perpendicular to the direction of propagation of the probe beam. To observe the time variations of the refractive index by themselves (ref. 4), the beam width in the probe region must be smaller than the size of the inhomogeneity in the plasma.

Figures 2b and 2c are obtained with the probe beam focused in the plasma region with width $5 \cdot 10^{-2}$ cm. The interferograms give a good picture of the time variation

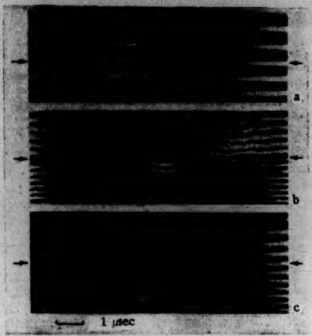

Fig. 2. Interferograms obtained 4.5 cm from the end of the accelerator. a) τ_d = 130 μsec, with no focusing of the probe beam, when δ = 0.5 cm; b) τ_d = 130 μsec, and c) τ_d = 250 μsec, with the probe beam focused, when 2δ = 0.05 cm.

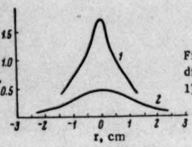

Fig. 3. Variation of $\bar{n}_e$ along the radius of the plasma filament. τ_d, μsec: 1) 130; 2) 250.

of the plasma refractive index, averaged over the plasma in the direction of propagation of the probe beam.

Figure 3 shows the average electron density $\bar{n}_e$ at various distances from the accelerator axis, as obtained by processing the interferograms of Figs. 2b and 2c, and with the values referred to the time of maximum fringe shift. The diameter of the plasma cylinder is determined separately for each accelerator operating condition from the position of the undisturbed edge fringes. It follows from Fig. 2 that with a 130 μsec delay a dense plasma is concentrated on the accelerator axis; the maximum average electron density reaches $1.6 \cdot 10^{17}$ cm^{-3}. When the delay time is increased to 250 μsec the plasma increases to the dimension of the central electrode of the coaxial accelerator (≈ 3 cm), while the average density diminishes by a large factor (curve 2).

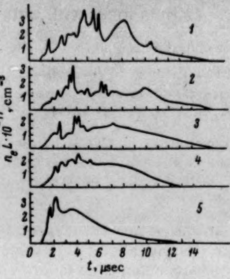

Fig. 4. The variation of n_eL with time near the accelerator axis. τ_d, μsec: 1) 100; 2) 130; 3) 150; 4) 200; 5) 250.

Figure 4 shows the variation of plasma density with time for various delay times. The curves are obtained from the deflections of the interference fringes, whose position in space corresponds to that of the accelerator axis. Density fluctuations with maximum frequency up to 5 MHz can be seen. These fluctuations are observed on more than one fringe. In Fig. 2b one can clearly see synchronous fluctuations of several fringes, which is evidence of the displacement of the plasma as a whole in the plane of the figure.

When the plasma probe plane is displaced along the axis of the accelerator the nature of the density variations remains much the same. However, at a distance of about 6.5 cm from the face of the accelerator one sees a displacement of the peripheral fringes in the opposite direction, indicating the appearance of a neutral "sleeve" of considerable density around the plasma cluster.

Thus, the interferometer measurements show that a dense plasma is concentrated at the exit, near the accelerator axis, with a maximum average density of $1.6 \cdot 10^{17}$ cm^{-3}, and that density fluctuations with frequencies up to 5 MHz are generated.

Plasma equilibrium and confinement in a poloidal heliotron configuration. I

V. G. Zykov, V. I. Karpukhin, Yu. F. Lonin, N. N. Podteregera, N. I. Rudnev, and V. T. Tolok

(Submitted July 4, 1973; resubmitted January 7, 1974)
Zh. Tekh. Fiz., 44, 1703-1712 (August 1974)

The equilibrium and confinement of an injected plasma [$n \sim 10^{12}$ cm^{-3}, $T_e \sim 10$ eV, $T_i \sim 5$-50 eV] have been studied in a toroidal trap with a poloidal heliotron field. The plasma reaches a stable equilibrium in the heliotron field with decay governed by the charged-particle loss at the supports of the opposed-field coils which produce the heliotron configuration.

INTRODUCTION

Toroidal drift of plasma particles can be suppressed in systems other than those having a rotational transform[1-3] e.g., bumpy torus.[3] Although this latter system provides single-frequency confinement, it does not satisfy the condition for MHD stability of the plasma. Theory[4] and experiment[5-7] have drawn attention to the heliotron configuration, which is essentially a modification of the bumpy-torus systems. These configurations are produced by a series of coils carrying a current whose magnitude and direction differ from those of the current in the coils of the main confining field. The bumpiness and the superposition of the main and opposed fields produce a min-B configuration, which suppresses the MHD flute instabilities locally, near the opposed-field coils.[4] Wiley[8] has predicted that, in addition to the local MHD stability, the average min B produced by the heliotron cells can exert a stabilizing influence on the flute and ballooning instabilities, which arise in regions with unfavorable curvature. In stellarators with low shear and rotational transform, one or more heliotron cells can increase the critical gas-kinetic pressure for the excitation of the ballooning instability. Experiments[9] with a potassium plasma in a straight Q machine with a heliotron configuration have demonstrated that the amplitude of the drift instabilities can be significantly limited through the imposition of an average min B or "connection length." Because of their stabilizing properties with respect to the most dangerous plasma instabilities and because of their simplicity, heliotron configurations are of interest for possible use in confining plasmas in closed toroidal traps. Below we report an experimental study of the plasma equilibrium and the stability of heliotron configurations displaying min-B properties in a toroidal field.

EXPERIMENTAL

The Pluton toroidal trap with a heliotron configuration is shown schematically in Fig. 1.

The basic parameters of the configuration are as follows: The toroidal field H_{tor} = 0-5 kOe; the radius of curvature R = 41 cm; the diameter of the toroidal vacuum chamber d = 14.7 cm; the axial circumference of the system L = 370 cm; the distance along the perimeter between the opposed-field coils, which produce the poloidal heliotron

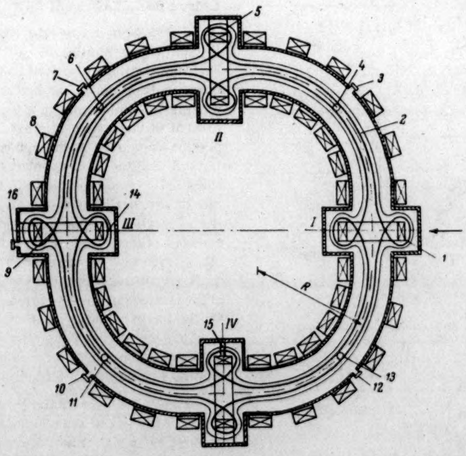

Fig. 1. The experimental apparatus. 1) Opposed-field coils; 2) $\psi = 0$ surface; 5) current conductors for the opposed field; 8) coils of the toroidal field; 9) regions of null magnetic field; 14) "plasma-bridge" regions; 15) supports for the opposed field coils; 3, 4, 6, 7, 10-13, 16) diagnostic ports. The arrow shows the injection direction.

configuration, is $L_{co} = L/4 = 92.5$ cm; the field at the magnetic axis in the cross sections corresponding to the positions of the opposed coils is $H_0 = H_{tor}/8$; the poloidal field in the magnetic flux linking the opposed-field coils (region 14 in Fig. 1) is $H_{pol} = 0.56\ H_{tor}$; the diameter of the field null near the opposed-field coils (region 9 in Fig. 1) is $d_0 = 9$ cm; and the magnetic surface intersecting the null-field regions, which is the separatrix for the lines of force closed within the confinement volume from those which link the opposed-field coils (the $\psi = 0$ surface in Fig. 1), has a diameter of $d_{\psi=0} = 4$ cm.

The opposed-field coils, which produce the poloidal heliotron configuration, are in the evacuated volume, mounted on the current conductors and held by supports (Fig. 1). The coils have an inside diameter of 21 cm, an outside diameter of 27 cm, and a width of 5 cm. The magnet system is driven by current from the discharge of a capacitor, which is common to the coils for the opposed and toroidal fields; this magnet system can produce a poloidal-heliotron configuration near the opposed-field coils.[6,7] An important parameter from the particle-confinement standpoint is the distance between the $\psi = 0$ surface and the housing of the opposed-field coils, Δr. The minimum value of Δr [(the distance between the $\psi = 0$ surface and the coil edge (Fig. 1)] is 0.41 cm, and the average value is $(\Delta r)_{av} = 1$ cm, so that the distance between the $\psi = 0$ surface and the coil housing corresponds, on the average, to 1 to 6 or 7 Larmor radii of 5-eV ions at a field of $H_{tor} = (0.6-4)$ kOe. In principle, the value of Δr can be raised by increasing the current through the opposed-field coils, but the power supply for the opposed-field coils used in these experiments (these coils are in series with the coils of the toroidal field) does not permit an adjustment of the opposed field, and the $\psi = 0$ surface occurs at only one position.

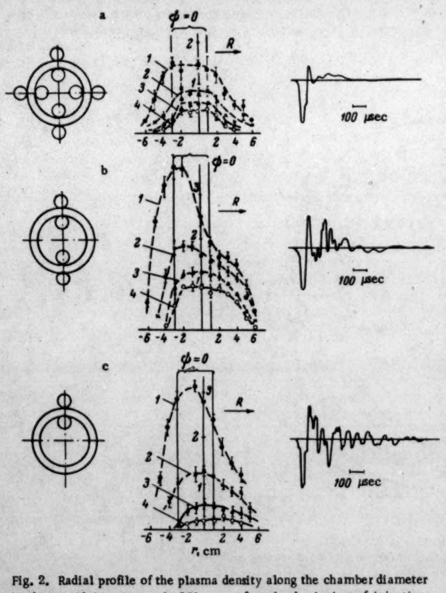

Fig. 2. Radial profile of the plasma density along the chamber diameter in the toroidal regions. 1) 250 μsec after the beginning of injection; 2) after 500 μsec; 3) after 750 μsec; 4) after 1000 μsec.

The plasma is injected across the magnetic flux linking one of the opposed-field coils from a coaxial plasma accelerator with pulsed gas injection. The plasma source is located 150 cm from the chamber since locating it in the immediate vicinity of the confinement volume causes rapid filling of the trap with neutral gas and undesirable particle loss due to recombination and charge exchange. The residual gas pressure in the chamber is $p_0 = 10^{-6}$ torr, so that these processes are not important. The neutral gas from the accelerator arrives at the trap chamber after a delay of about 1.5 msec, and this delay is usually longer than the plasma-confinement time.

Electrostatic (Langmuir) probes are used to measure the velocity and density of the injected plasma and the electron temperature and lifetime. In the measurements of the absolute densities and temperatures the probes are placed at a field null, under the opposed-field coils, in order to avoid the effect of the magnetic field on the probe readings. In certain cases the probes are calibrated against an 8-mm microwave diagnostic signal.

The average energy of the plasma ion component is determined from the transit time of the plasmoid between two probes. Typical parameters of the trapped plasma are an initial density of $n = 3-5 \cdot 10^{12}$ cm^{-3}, an electron temperature of $T_e \sim 5-10$ eV, and an average ion energy of 5 to 50 eV, depending on the operating conditions of the coaxial injector. In most of the experiments, this energy is $W_i \sim 5-7$ eV.

EXPERIMENTAL RESULTS

It has been shown previously[10,11] that a plasma equilibrium can be maintained in a toroidal magnetic field by "plasma limiters" formed in the min-B regions under the opposed-field coils. In analyzing the confinement of a plasma in equilibrium in a toroidal field with plasma limiters it is necessary to start from two conditions: The plasma-loss area at the opposed-field coils must be minimized, and the plasma must be stabilized. These conditions are mutually exclusive, since an improvement of the min-B properties of the configuration through an increase in the number of opposed-field coils would result in increased plasma loss at the coils and their supports. Another important parameter in connection with the flute and drift instabilities is the distance along the magnetic lines of force between min-B regions, i.e., the connection length.[8,9] On the basis of these considerations, we feel it worthwhile to study the effect of the number of plasma limiters and the connection length on the equilibrium and stability of a plasma in a toroidal field with a heliotron configuration.

Figure 2 shows radial profiles of the plasma density, obtained from a probe which is inserted through diagnostic port 10 in Fig. 1 and moved along the radius of curvature of the toroidal field. The radial profiles shown in the three parts of Fig. 2 are obtained with different numbers of poloidal heliotron configurations in operation: four, two, and one (through which the plasma is injected). The configuration is shown at the left in each part of the figure, and typical oscillograms of the fluctuations in the ion probe current are shown at the right. In these measurements the probe is placed at the maximum of the radial density profile. The observed density fluctuations are attributed to the flute instability on the basis of the frequencies and other characteristic features.

We see from the radial profiles that the plasma is detached from the walls and is located near the $\psi = 0$ surface. Because of the toroidal nature of the system, this surface is displaced inward from the geometric axis of the chamber. However, on the basis of a) the plasma-density fluctuations (which do not decay as a function of the time) observed when one or two of the opposed-field coils are turned on, b) the displacement of the radial-profile maximum from the region bounded by the $\psi = 0$ surface along the radius of curvature, and c) the decrease in the magnitude of grad n as a function of the time, we conclude that the equilibrium established by one or two plasma limiters is not stable. The constancy of the density profile over time and the damping of the density fluctuations within the confinement volume (within the $\psi = 0$ surface) show that the plasma is in equilibrium and stable when four plasma limiters are in operation (or with a connection length equal to one-fourth the circumference of the system).

Figure 3a shows the radial profiles of the relative plasma-fluctuation levels $\tilde{n}/n$ for one, two, and four (curves 1-3, respectively) plasma limiters; Fig. 3b shows the decay constant of the plasma density as a function of the connection length (this length is inversely proportional to the number of opposed-field coils which are activated; it is defined as $L_{co} = L/n$, where L is the circumference of the system, and n = 1, 2, 4 is the number of coils in operation). From these curves and Fig. 2, which show the radial density profiles as a function of the time, we can determine the relationship between the plasma lifetime and the observed instabilities. We see from Fig. 3a that with $L_{co} = L$ (one opposed-field coil activated) the plasma is stable essentially only in the region in which the curvature is favorable, and where grad n and grad H are antiparallel; in the case $L_{co} = L/2$ the boundary of the stability region is displaced outward, along the radius of curvature, and with $L_{co} = L/4$ the density fluctuations exist only in the density-gradient region beyond the $\psi = 0$ surface near the outer wall of the toroidal chamber. On the other hand, in Figs. 2b and 2c we observe a displacement of the plasma along the radius of curvature in the cases $L_{co} = L$, L/2, and in Fig. 3b we see a decrease in the density-decay time at the position of the initial density maximum for $L_{co} = L$, L/2. If the density decay were due solely to the charge-particle loss to the opposed-field coils and supports we would expect τ to decrease with increasing L/L_{co}, since the plasma loss would increase in proportion to the number of opposed-field coils in operation. Accordingly, the observed decrease in the density-decay constant in the cases $L_{co} = L$, L/2 can apparently be attributed to a situation in which the plasma departs from equilibrium because of the plasma instabilities within the entire confinement region (in the region bounded by the $\psi = 0$ surface). In the case $L_{co} = L/2$ the loss of equilibrium due to the instabilities is less important, and in the case $L_{co} = L/4$ it is essentially negligible. The $\tau = f(L/L_{co})$ curve apparently reaches saturation because the plasma loss at the coils and at their supports becomes significant when four opposed-field coils are activated although the plasma is in stable equilibrium. Further evidence for this suggestion is the observation that when four opposed-field coils are activated the initial plasma-density level in the trap is roughly half that for the case in which fewer coils are turned on.

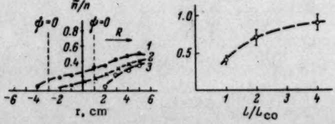

Fig. 3. a: Density-fluctuation level as a function of the radius: 1) $L_{co} = L$; 2) $L_{co} = L/2$; 3) $L_{co} = L/4$; b: Lifetime as a function of L_{co}/L.

Figure 4 shows the plasma stability in the toroidal field as a function of the connection length. The oscillograms in Fig. 4 are obtained during a single pulse by two probes at the same point in the plasma cross section but in diametrically opposite cross sections of the torus. The corresponding field configurations and probe arrangements are shown at the left of each of the oscillograms. If a given connection length ($L_{co} = L/4$; Fig. 4a) is imposed on the plasma at the probe positions, the probe signals are nearly identical, displaying no fluctuations. If the connection length is increased at the position of one of the probes ($L_{co} = 3L/4$; probes II and I; Figs. 4b and 4c, respectively), the plasma becomes unstable in these regions, while a local plasma stability is observed in regions with a shorter connection length ($L_{co} = \frac{1}{4}L$; probes I and II; Figs. 4b and 4c, respectively). The connection length is thus the decisive parameter governing the plasma stability in a toroidal field with a heliotron configuration.

Figure 5a shows density profiles of the plasma in the cross section corresponding to the position of one of the

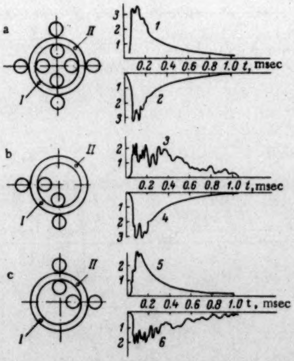

Fig. 4. Oscillograms illustrating the suppression of the flute instability as a function of connection length. 1) Probe II ($L_{co} = L/4$); 2) probe I ($L_{co} = L/4$); 3) probe II ($L_{co} = 3L/4$); 4) probe I ($L_{co} = L/4$); 5) probe II ($L_{co} = 3L/4$); 6) probe I ($L_{co} = 3L/4$).

opposed-field coils; these profiles are obtained by a probe inserted into the plasma through diagnostic part 16 in Fig. 1. This cross section corresponds to the position of the magnetic well, which is formed by the superposition of the toroidal confining field and the field of the opposed-field coil. The vertical lines show the positions of the $\psi = 0$ surface in this cross section. The arrow shows the direction of the radius of curvature of the torus.

This density profile is a typical equilibrium profile for a poloidal heliotron configuration, for which the quantity $U = -\int(dl/B)$ reaches a minimum at the $\psi = 0$ surface.[4] The oscillograms in Fig. 5b (1-3) illustrate the plasma decay at various points of the equilibrium radial profile. Oscillogram 1, obtained at point I (Fig. 5a), illustrates the absolute local stability of the plasma in the min-B region. Oscillograms 2 and 3 are obtained in the plasma bridge, in the magnetic flux linking the opposed-field coil (points 2 and 3 in Fig. 5a). A probe placed at the $\psi = 0$ surface in the bridge region reveals a plasma density equal to half the density at the same surface in the region of the absolute min B (as is evident from the radial distributions in Fig. 5a) and reveals fluctuations in the plasma density in the bridge region. However, these measurements are not correct, since the plasma dimension is comparable to the plasma thickness in the bridge, so that there could be a local decrease in the plasma density due to plasma loss at the probe. Local density perturbations caused by the probe can also cause fluctuations. However, we do not rule out the existence of plasma instabilities in the bridge region, even in the absence of density perturbations caused by the probe. The observed fluctuations in the bridge can be explained in the following manner: The plasma sheath is very thin in this region, and the plasma can be stable only on the $\psi = 0$ surface, whose width is of the order of the Larmor diameter. Accordingly, there are high density gradients ($\nabla n/n \sim \rho_i^{-1}$), which cause instabilities with a typical scale length $\gtrsim \rho_i$. Accordingly, even if the instabilities arise outside the $\psi = 0$ surface, they can fill the entire plasma volume in the bridge. A probe moved beyond the $\psi = 0$ surface from the plasma displays characteristic density spikes (oscillogram 3 in Fig. 5), which can be interpreted as corresponding to plasma ejection from the confinement region across the magnetic lines of force. The effect of plasma instabilities in the bridge on the plasma lifetime requires further study and will not be discussed here.

In other experiments we study the plasma lifetime in the field formed with four opposed-field coils; under these conditions the plasma is both in equilibrium and stable in the toroidal regions. We find the density decay constant as a function of the average ion energy and the field. These experiments are carried out with an initial plasma density $n \sim (2-4)\cdot 10^{12}$ cm^{-3}, at ion energies $W_i = (5-50)$ eV, and fields $H_{tor} = (0.6-4)$ kOe.

The plasma lifetime in this system, governed by the charged-particle loss at the supports of the opposed-field coils, can be evaluated on the basis of the following assumptions.

We assume that the plasma loss from the trap is due solely to the presence of holes in the null magnetic field (region 9 in Fig. 1), through which the plasma particles impinge on the magnetic flux linking the opposed-field coils (in the bridge region), where they can interact with the supports.

The particle behavior at the magnetic nulls is assumed to be nonadiabatic. Particle scattering by a magnetic null leads to equiprobable departure from the null along lines of force of the linking magnetic flux and along lines of flux of the basic confining field. Since the plasma in the cross sections under the opposed-field coils is localized near the field nulls, the probability for motion to a bridge after a single collision with a field null is $p_1 = 1/3$ for each individual charged particle of the confined plasma.

The particles moving along a bridge return to the field null and are not lost if they meet an obstacle, such as a coil support, along their trajectory in the bridge. The probability for the loss of a single particle after a single trip along the magnetic flux around the opposed-field coil (p_2) can be defined as the ratio of the azimuthal width of the bridge subtended by the supports to the total azimuthal dimension of the bridge. The resultant probability for the loss of a single charged particle after it has been scattered once by a field null is the product of probabilities p_1 and p_2.

We now assume that the plasma-loss rate is proportional to $p_0\nu_{i0}$, where $p_0 = p_1p_2$ and ν_{i0} is the rate with

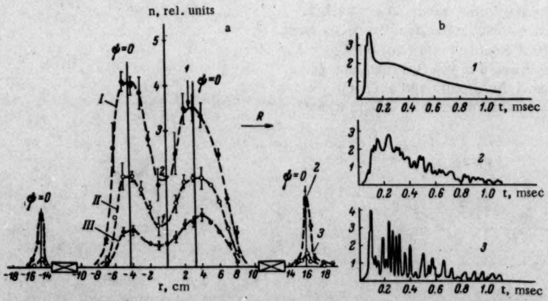

Fig. 5. a: Radial density profiles above an opposed-field coil. I) 200 μsec after the beginning of injection; II) after 400 μsec; III) after 600 μsec. b: Oscillograms of the ion probe current.

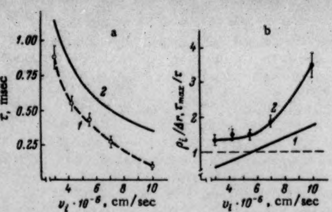

Fig. 6. a: Plasma lifetime as a function of the ion velocity. 1) Experimental; 2) calculated. b: 1) The quantity $\rho_i/\Delta r$ as a function of the ion velocity; 2) τ_{max}/τ as a function of the ion velocity.

which ions interact with the field nulls. We define ν_{i0} as $\nu_{i0} = v_i/L_{co}$, where v_i is the ion velocity and L_{co} is the distance between the opposed-field coils (or the distance between the field nulls). The plasma lifetime governed by the loss at the supports of the opposed-field coils and evaluated on the basis of these arguments is

$$\tau_{\max} = \frac{L_{co}}{v_i p_0}. \quad (1)$$

Curve 1 in Fig. 6a shows the experimental functional dependence $\tau = f(v_i)$; curve 2 shows the lifetime corresponding to loss at the supports of the opposed-field coils as a function of the ion velocity calculated from Eq. (1). Figure 6b shows two curves: Curve 1 is the ratio of the ion Larmor radius ρ in the bridge to the minimum distance from the $\psi = 0$ surface to the housing of the opposed-field coil, Δr; curve 2 shows the ratio of the calculated lifetime τ_{max} (which is apparently the maximum possible lifetime for the given system) to the experimental lifetime τ. From the curves in Fig. 6 we see that τ approaches τ_{max} when the Larmor radius does not exceed Δr. The maximum plasma lifetime determined from the geometric parameters of the system and Eq. (1) is not reached. The slight discrepancy between τ and τ_{max} at $\rho_i < \Delta r$ implies additional loss, not associated with the loss at the supports; however, this additional loss is much less important than that at the supports (an evaluation of this loss yields a plasma lifetime, calculated from the known values of τ and τ_{max}, on the order of 3.5 msec at an ion energy of 5-7 eV). Accordingly, the plasma loss from the trap at low ion energies is governed by the loss of charged particles to the supports of the opposed-field coils; at high ion energies, in which case the ion Larmor radius is comparable to or greater than the distance from the $\psi = 0$ surface in the bridge to the opposed-field coils, the plasma loss increases because of the ion loss at the coils.

This latter conclusion is also supported by the functional dependence of the decay constant on the field in the system. Figure 7 shows the $\tau \sim f(H_{tor})$ functional dependences obtained at various times: Curve 1 corresponds to 500 μsec after the beginning of injection, while curve 2 corresponds to 1500 μsec after the beginning of injection. These functional dependences are obtained with an initial plasma density of $n \sim 10^{12}$ cm^{-3} and with an average ion energy of $W_i \sim 7$ eV. We see that τ is noticeably a function of H in weak fields and that the functional dependence $\tau \sim f(H_{tor})$ becomes less pronounced in the strong fields (with $\rho_i < \Delta r$) or at later times. The increasing functional dependence in the earlier stages and in the case of weak fields can be attributed to a reduction of the particle loss at the opposed-field coils because of the reduction in the particle Larmor radius. The functional dependence of τ on time in the case of weak fields apparently results from the decrease in the average energy of the plasma ions as time elapses because the most energetic ions (for which $\rho_i \gg \Delta r$) are lost from the plasma first, at the coils and at their supports. The weak functional dependence $\tau \sim f(H)$ at later times is apparently due to a spread of the particles with respect to Larmor radius or to a reduction in the size of the magnetic hole through which the particles enter the bridge.

CONCLUSION

On the basis of these experiments we can draw the following conclusions.

1. A plasma equilibrium can be established in a toroidal magnetic field without a rotational transform if the field has a heliotron configuration.

2. The parameter governing the stability of an equilibrium plasma in a toroidal heliotron field is the connection length.

3. Suppression of the flute instability within the $\psi = 0$ surface in the toroidal regions requires a connection length no longer than one fourth the length of the system.

4. If the plasma is in a stable equilibrium within the $\psi = 0$ surface, its confinement is governed by the loss of charged particles at the supports of the opposed-field coils, which produce the heliotron configuration, provided that the average Larmor radius of the confined particles is smaller than the distance from the $\psi = 0$ surface to these coils. Otherwise (with $\rho_i \gg \Delta r$), ion loss at these cells can become significant.

5. In all the situations studied here, including that in which the ion Larmor radius is much smaller than the distance from the $\psi = 0$ surface to the coils, the maximum possible plasma lifetime for the given system is not achieved. This result implies an additional loss of charged particles (other than the loss at the supports). There are various possible mechanisms for this additional loss: First, there are the plasma instabilities observed at the boundary of the $\psi = 0$ surface, which are clearest in the plasma bridge, in the magnetic flux linking the opposed-field coils. Second, there can be particle collisions in the bridge, where the thickness of the plasma sheath is of the order of the ion Larmor diameter, and a single ion–ion collision can displace an ion from the $\psi = 0$ surface by a distance of the

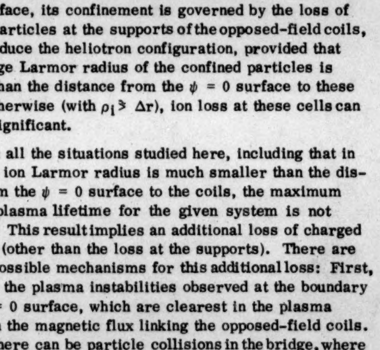

Fig. 7. Plasma lifetime as a function of the intensity of the confining field. 1) 500 μsec after the beginning of injection; 2) 1500 μsec.

order of the Larmor radius, causing it to strike an opposed-field coil.

If an effective method is found for suppressing the effect of the supports on the plasma lifetime in systems with internal conductors (e.g., through the use of magnetically shielded supports[12] or through the compensation of the loss at the supports by repeated injections[6,7]), the plasma loss due to the observed instabilities will dominate the situation. A study of the mechanisms responsible for the additional loss and quantitative estimates for these loss mechanisms are an important and necessary future step in the study of plasma confinement in a heliotron magnetic field.

The decay of an injected plasma [$n \geq 2 \cdot 10^{13}$ cm^{-3}, $n(T_e + T_i) \simeq 5 \cdot 10^{14}$ eV/cm^3] has been studied in a toridal trap with a poloidal heliotron configuration. The decay constant is found to be a function of the magnetic field H, the plasma density n, and the size of the regions in which the lines of force have an unfavorable curvature, L_{co}. This functional dependence, which can be written as $\tau \sim H/nl_{co}$, is attributed to the stabilizing effect of the poloidal heliotron configuration on the instabilities due to the toroidal nature of the system. The decay constant for the plasma density is τ = 0.5-1 msec and, in the case $L_{co} = L/4$ is in order-of-magnitude agreement with the lifetime calculated from the measured flux of ions to the supports and coils of the opposed magnetic field, which are not completely shielded magnetically.

The Pluton toroidal system is described and experimental results on the confinement of an injected plasma with the parameters $nT \sim 5 \cdot 10^{12}$ eV/cm^3 and $n \sim 10^{11}$ cm^{-3} are reported in ref. 1. Below we report experimental results on plasma confinement in the Pluton poloidal heliotron with the different initial parameters $nT \sim 5 \cdot 10^{14}$ eV/cm^3 and $n \sim 2 \cdot 10^{13}$ cm^{-3} but with the same confining field (H = 5 kOe). The parameters n and T and thus the parameter $\beta = 8\pi nkT/H^2$ of the confined plasma are increased by applying a guiding magnetic field along the plasma guide section connecting the plasma accelerator with the chamber; this magnetic field significantly reduces the loss at the guide-section walls. Because of the higher density of the confined plasma we are able to use microwave methods to study it; these methods are more accurate and more reliable than probe methods for diagnosing a decaying plasma.

The density of the trapped plasma and its functional dependence on the time are measured by means of microwave interferometers at λ = 4, 8, and 14 mm; the electric vector of the microwave signals is parallel to the external magnetic field. Since the phase shift of the wave transmitted by the plasma is

$$\Delta\varphi \sim \bar{n}l,$$

where $\bar{n}$ is the average density and l is the distance which the wave travels through the plasma, the wave is passed through the plasma twice in order to expand the range of measurable densities. In situations in which the plasma in the trap is opaque to the microwave signals (i.e., λ = 4 and 8 cm^{-3}, respectively), we measure the phase of the wave reflected from the plasma. The microwave signal is directed onto the plasma in cross sections corresponding to diagnostic ports 12 and 10 in Fig. 1 of ref. 1.

EXPERIMENTAL RESULTS

The imposition of an average min B or a connection length is the decisive factor for the plasma stabilization in the toroidal parts of the system. Accordingly, in these experiments we are primarily interested in the plasma decay as a function of connection length.

Figure 1 shows n = n(t) curves obtained for various cross sections of the chamber and for various connection lengths. The curves in Fig. 1a are obtained in a cross section near the injection point (in the cross section corresponding to the position of diagnostic port 12 in Fig. 1 of ref. 1), while the curves in Fig. 1b correspond to a remote cross section (corresponding to diagnostic port 10 in Fig. 1 of ref. 1). Curves 1 and 4 in these figures are obtained in configurations with L_{co} = L/4 and L, respectively. Curves 2 and 3 correspond to configurations with L_{co} = L/2, obtained by turning off poloidal heliotron cells IV and III, respectively (see Fig. 1 of ref. 1). We see that the slope of the curves, which is proportional to the decay constant of the plasma density, is a strong function of L_{co} in the remote cross section but independent of it in the near cross section. The decay constant for the plasma density in the near cross section is lower than that in the remote cross section for any value of L_{co}.

This difference is not due to the initial density of the plasma which fills the toroidal regions corresponding to these cross sections. The difference in the plasma decay is most clearly observed in the configuration with L_{co} = L/4, in which case heliotron cell IV, which lies between the near and remote cross sections, is activated, and the plasma density in the remote cross section falls off be-

Fig. 1. Fig. 2. Neutral-gas pressure as a function of the time. a,b) In the cross section corresponding to the position of diagnostic port 12 in Fig. 1 of ref. 1; c) in the cross section corresponding to diagnostic port 10 in that figure. In parts b and c, curves 1 correspond to the situation during plasma injection, while curves 2 correspond to the situation when only the gas-injection valve operates.

cause of scattering of the plasma by the cell. However, this difference does not vanish when heliotron cell IV is turned off, and the corresponding toroidal regions are filled with plasma of the same density.

The most probable assumption which we can make regarding the observed difference in the decay behavior is that there is an inhomogeneous distribution of the neutral gas which enters the plasma volume from the plasma accelerator and which reduces the plasma decay constant because of recombination or charge exchange. Using a pulsed gauge, whose operation is described elsewhere,[2] we evaluate the neutral gas pressure in various cross sections of the trap. This gauge is removed from the magnetic field to avoid an effect of the plasma particles on the gauge indications. Figure 2 shows the neutral gas pressure as a function of the time in the near (Fig. 2, a and b) and remote (Fig. 2c) cross sections.

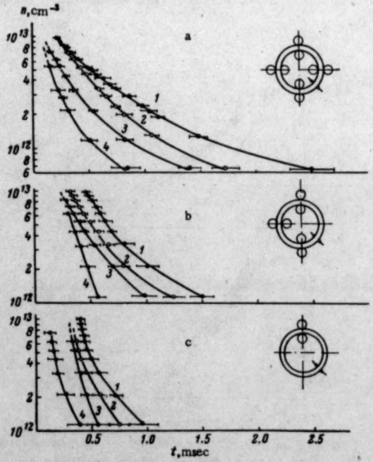

Fig. 3. The function n = n(t) for various values of L_{co} and for various values of the toroidal field. a, b, c) L_{co} = L/4, L/2, and L, respectively. H, kOe: 1) 5.0; 2) 3.0; 3) 2.0; 4) 1.0.

Figure 2a illustrates the behavior of the neutral gas pressure in the near cross section during injection of plasma into the trap. We see that the pressure in the near cross section begins to increase at the time corresponding to that at which the injected plasma arrives at the trap. Figures 2b and 2c show the pressure in the near and remote cross sections, respectively, over a shorter time interval. Curves 2 in Figs. 2b and 2c show the pressure as a function of the time for the case in which only a single pulsed valve of the accelerator is in operation, while curves 1 correspond to plasma injection from the accelerator. The difference between the behavior of the pressure during injection of the plasma and that when only the gas-injection valve operates can be attributed to the contribution of the neutral gas ejected from the chamber walls by high-energy plasma particles in the region in which the plasma enters the system. It is difficult to evaluate the absolute neutral gas pressure since we do not know the nature of the gas ejected from the chamber walls. Because of the delay in the arrival of the neutral gas in the remote cross section, the influence of this gas on the plasma decay there is apparently weak so we assume that n = n(t) obtained in the remote cross section give a correct qualitative idea of the confining properties of the poloidal heliotron configuration.

Figure 3 shows n = n (t) curves for various fields and various field configurations, characterized by different connection lengths. Comparison of Figs. 3a, 3b, and 3c clearly reveals a decrease in the confinement time with increasing connection length. We also see that the decay rate is a function of the intensity of the toroidal field and of the plasma density for a given value of L_{co}. Figure 4 shows the decay constant τ for various values of L_{co} which were calculated from these curves. For L_{co} = L/4, Fig. 4 shows two functional dependences: curve 1, for the density decay from $5.5 \cdot 10^{12}$ to $1.7 \cdot 10^{12}$ cm^{-3}; and curve 5, for that from 10^{12} to $6 \cdot 10^{11}$ cm^{-3}. To summarize these results we can write the decay constant of a dense plasma ($n \geqslant 2 \cdot 10^{12}$ cm^{-3}) as a function of n, H, and L_{co} as

$$\tau \sim \frac{H}{nL_{co}}$$

and attribute the decay to the gravitational-dissipative instability[3] of a collisional plasma for which $\lambda_{ei} \leqslant L_{co}$; the growth rate of this instability,

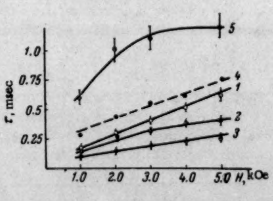

Fig. 4. Decay constant as a function of the value of the toroidal field. 1-3) L_{co} = L/4, L/2, L, respectively; 4) calculated from the measured particle flux to the opposed-field coil; 5) L_{co} = L/4 for decay over the range $6 \cdot 10^{11}$ cm^{-3} $\leq n \leq 10^{12}$ cm^{-3};

$$\mathrm{Im}\left(\frac{\omega_{bo}}{\omega_{Bi}}\right)=\left(\frac{en}{aB}\right)\left(\frac{k_{\perp}}{k_{\parallel}}\right)^{2}\frac{\rho_i^2}{R}\frac{n'}{n}, \qquad (1)$$

is proportional to L_{co}^2/H if the wavelength of the perturbation in the longitudinal direction is governed by the connection length ($\lambda_{\parallel} = 2L_{co}$).

However, as L_{co} is reduced we see from (1) that the plasma lifetime against the gravitational-dissipative instability increases in proportion to L_{co}^{-2}. The plasma loss at the opposed-field coils (which produce the heliotron configuration) and at the supports for these coils increases linearly with decreasing L_{co} (the connection length is inversely proportional to the number of opposed-field coils in operation and is defined by $L_{co} = L/k$, where L is the circumference of the system and k is the number of opposed-field coils in operation). Accordingly, with $L_{co} = L/4$ we would expect a significant decrease in the contribution of the gravitational-dissipative instability, so that the plasma decay would be governed primarily by particle loss at the opposed-field coils and their supports.

We measure the ion flux to the frame of one of the opposed-field coils; curve 2 in Fig. 5 shows the flux to the coil frame along with that to the conductor and the supports as a function of the field intensity. Curve 1 shows the ion flux to the coils without the conductor and supports (which are insulated from the plasma). We see that the particle flux to the coil in the case of the insulated conductor and supports is essentially the same as that in the absence of insulation. This result is evidence that the plasma particles are lost at the coil along its entire perimeter and that only a slight fraction of the plasma particles are lost at the conductor and supports (the fraction is proportional to the part of the coil perimeter occupied by the conductor and supports). Accordingly, under these experimental conditions the opposed-field coils are not completely shielded magnetically from contact with the plasma. The inverse proportionality between the ion current to the coil frame and the field intensity can be explained in the following manner: Because of the small distance between the $\psi = 0$ surface in the plasma "bridge" (in the magnetic flux linking the opposed-field coil) to the coil housing, and because of the low field intensity in the plasma bridge, the plasma ions can strike the coils as they move along lines of force in the bridge. The thickness of the plasma sheath in the bridge is on the order of two Larmor diameters, falling off with increasing field intensity. The number of ions whose Larmor diameter is comparable to or greater than the distance from the $\psi = 0$ surface to the coil housing decreases in proportion to the change in the Larmor diameter. The linear functional dependence $\tau \sim f(H)$ can be attributed on the basis of these measurements of the ion flux to the coil in the case $L_{co} = L/4$ to plasma loss at the opposed-field coils. However, the presence of neutral gas in this system and the inhomogeneity of the profiles of the plasma and neutral-gas densities along the perimeter of this system prevent final conclusions regarding the contribution of particle loss at the coils and that of loss due to the toroidal nature of the system. Estimates show a correspondence between the experimental lifetime and the lifetime calculated from the measured flux and an average plasma density assumed equal to the density in the remote cross section, where the measurements were carried out (curve 4 in Fig. 4). On the other hand, the probe measurements show that the plasma is not unstable in the toroidal regions within the $\psi = 0$ surface if $L_{co} = L/4$. We can therefore assume that the functional and quantitative dependence $\tau \sim f(H)$ in the configuration with $L_{co} = L/4$ is governed primarily by the loss of plasma particles at the opposed-field coils and its supports, which are not completely magnetically shielded under the given experimental conditions.

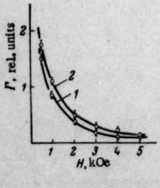

Fig. 5. Ion flux to the opposed-field coil. 1) Insulated current conductor and coil supports; 2) no insulation.

As was mentioned above, the weak magnetic shielding of the opposed-field coils is due to the weakness of the opposed field and the correspondingly small distance from the $\psi = 0$ surface to the opposed-field coil. In addition, the magnetic insulation of the opposed-field coils could be disrupted by neoclassical plasma diffusion to the coils in the plasma bridge. If the plasma dimensions in the bridge is $2\rho_i$ and if $T_e \sim T_i$, the particle flux to the coils due to neoclassical diffusion is

$$nv_r = D_{ei}\frac{du}{dr} \simeq \rho_e^2\nu_{ei}\frac{n}{2\rho_i} = \frac{1}{2}\sqrt{\frac{M}{m}}\rho_e\nu_{ei}n.$$

The particle flux to the coil due to neoclassical diffusion also corresponds in magnitude to the experimental flux; this flux turns out to be proportional to H^{-1} and to the plasma density n. Then we can attribute the functional dependences $\tau \sim f(H)$ and $\tau \sim f(1/n)$ to neoclassical diffusion in the bridge.

CONCLUSIONS

On the basis of these experiments we draw the following conclusions:

1. The decay constant of a plasma held in equilibrium by plasma limiters of a poloidal heliotron magnetic configuration is governed by the connection length; this result is quantitative evidence that toroidal drift and the plasma instabilities due to the toroidal nature of the system are stabilized efficiently by the poloidal heliotron configuration.

2. At all connection lengths we find the decay constant to be a function of the field intensity and the plasma density. This functional dependence, which can be written qualitatively as $\tau \sim H/nL_{co}$ can be attributed to the gravitational-dissipative instability of the plasma in the field regions with an unfavorable curvature of the magnetic lines of force if the dimensions of these regions, L_{co}, are large enough.

3. If the connection lengths are short so that the relative contribution of the gravitational-dissipative

instability to the plasma decay must be significantly reduced (because of $\mathrm{Im}\,\omega_p \sim L_{co}^2$), no significant plasma instabilities are observed in the toroidal regions, and we assume that the observed decay is due to plasma loss at the opposed-field coils, which are weakly shielded magnetically in these experiments.

4. The weak magnetic shielding of the opposed-field coils is due to the weakness of the opposed field and the short distance from the $\psi = 0$ surface (in the plasma bridge in the magnetic flux linking the opposed-field coils) to the coil housing. The magnetic shielding of the opposed-field coils can also be disturbed because of neoclassical plasma diffusion in the narrow sheath of the plasma bridge.

5. Since the plasma volume contains neutral gas ejected from the chamber walls and coils, and since the opposed-field coils are not completely shielded magnetically, we cannot find quantitative estimates of the relative contributions of these processes to the quality of the confinement of a dense plasma in a poloidal heliotron field. Further experiments should be carried out with stronger opposed fields and with a different method for producing the plasma.

Nonequilibrium ionization in the cathode region of a high-pressure arc

S. P. Reshenov

Moscow Energy Institute

(Submitted April 26, 1973; resubmitted December 18, 1973)
Zh. Tekh. Fiz., 44, 1719-1723 (August 1974)

The electron energy and velocity distribution and the rates of nonequilibrium ionization are calculated in the cathode region of a high-pressure arc. If the plasma temperature is low or if the sheath cooled by the cathode is large nonequilibrium ionization can make an important contribution to the ion current to the cathode.

1. To determine the ion current density to the cathode in the present models of the cathode spot of a high-pressure arc discharge[1,2] it is usually assumed that the ions are emitted by a hot plasma located some distance from the cathode, local thermodynamic equilibrium obtaining. It is noted in ref. 3 that electrons emitted by the cathode and accelerated in the Langmuir sheath can participate in the ionization near the cathode, but the quantitative contribution of this mechanism is still unclear. In the present paper, we estimate the contribution of nonequilibrium ionization of the gas near the cathode in a high-pressure arc with a refractory cathode.

The electron distribution function is usually determined before the rate of nonequilibrium ionization is calculated. Since, according to ref. 3, the ion portion of the current to the cathode is several tens of percent, calculation of the electron distribution function should allow for its energy relaxation due not only to Coulomb interaction between fast and plasma electrons, but also due to inelastic collisions between electrons and neutrals. A similar problem is solved in ref. 4 for the case of a low-voltage arc, where the cathode potential drop is smaller than the first excitation potential. The opposite relationship[3] holds more often in a high-pressure arc and is assumed below.

The electron distribution function in the plasma near the cathode is represented in the form[5]

$$f(\eta,\ \xi)=f_0(\eta)\left[1+\psi(\eta,\ \xi)-\cos\alpha\,\frac{\lambda_y}{L}\,\frac{\partial\psi}{\partial\xi}\right], \tag{1}$$

where

$$\xi=\frac{x}{L};\quad L=\sqrt{\frac{\eta_k\lambda_k\lambda_y}{3}};\quad \eta=\frac{eU}{T_e};\quad \eta_k=\frac{eU_k}{T_e},$$

x is the distance to the cathode; λ_y and λ_k are the electron mean free paths for scattering by atoms and electrons; α is the angle between the normal to the cathode and the electron velocity vector; eU is the electron energy; U_k is the potential drop in the sheath near the cathode, and

$$f_0(\eta)=n_e\left(\frac{m_e}{2\pi T_e}\right)^{3/2}e^{-\eta}.$$

The correction $\psi(\eta,\ \xi)$ is determined by the solution of the equation[4]

$$\frac{\partial^2u}{\partial\xi^2}+\frac{\partial^2u}{\partial\varepsilon^2}-\left[\theta(E)\delta+\frac{1}{4}\right]u-\delta(1-\nu_1)e^{-\varepsilon/2}\theta(\varepsilon)=0 \tag{2}$$

with the boundary conditions

$$\left.\begin{aligned}\xi=0,\quad &\frac{\partial u}{\partial\xi}=0; && \varepsilon<\varepsilon_k,\\ &-a(\varepsilon)\frac{\partial u}{\partial\xi}=\varphi(\varepsilon), && \varepsilon>\varepsilon_k,\\ &\xi=\infty,\ u=0, &&\end{aligned}\right\} \tag{3}$$

where $u=\psi e^{-\varepsilon/2}$; $\varepsilon=\eta-\eta_b$; $\eta_b=eU_b/T_e$; $\delta=\eta_k\lambda_k n_a\sigma(\eta_k)$; U_b is the excitation potential of the first excited atomic level; $\nu_1=n_1/n_{1p}$; $n_{1p}=(g_1/g_0)n_a e^{-eUb/Te}$; n_a and n_1 are the densities of the normal and excited atoms; $\sigma(\eta_k)$ is the excitation cross section of the first excited atomic state for an electron energy equal to eU_k;

$$\theta(\varepsilon)=\begin{cases}1 & \text{for}\quad \varepsilon>0,\\ 0 & \text{for}\quad \varepsilon<0;\end{cases}$$

$$\varepsilon_k=\eta_k-\eta_b;\quad a(\varepsilon)=\frac{4\eta\lambda_y e^{\varepsilon/2}}{3L(\varepsilon-\varepsilon_k)},$$

$$\varphi(\varepsilon)=\Theta\exp[-(\beta-1)(\varepsilon-\varepsilon_k)];\quad \Theta=\frac{4j_{ek}\beta^{3/2}}{en_e v_e}e^{\eta_k},$$

$$\beta=\frac{T_e}{T_k};\quad v_e=\sqrt{\frac{8T_e}{\pi m_e}},$$

j_{ek} is the electron current density to the cathode; T_e and T_k are the temperatures of the plasma electrons and the cathode.

The boundary condition for $\xi=0$ and $\varepsilon>\varepsilon_k$ is approximate. It is obtained from an exact expression[5] if the following inequalities are satisfied: $(\varepsilon-\varepsilon_k)\ll\eta_k$, $a(\varepsilon)\gg1$ and $\varphi(\varepsilon)\gg1$; this is usually true in the neighborhood of the point $\varepsilon=\varepsilon_k$ for small ξ for gases with large U_b.

In the right-hand side of Eq. (2) the last term in the first approximation can be neglected since the energy range $\psi\gg1$ is of interest in practical problems. From the physical point of view this means that processes involving production and loss of fast electrons are not included in the interactions between plasma electrons and excited and normal atoms.

The solution of Eq. (2) with boundary conditions (3) is found by dividing the entire energy range into three intervals: 1) $\varepsilon<0$, 2) $0<\varepsilon<\varepsilon_k$, 3) $\varepsilon>\varepsilon_k$; and by using the Fourier cosine transform in the variable ξ. As a result, we have

$$\varepsilon<0;\quad \frac{\partial^2\Phi_1}{\partial\varepsilon^2}-p\Phi_1=0, \tag{4}$$

$$0<\varepsilon<\varepsilon_k;\quad \frac{\partial^2\Phi_2}{\partial\varepsilon^2}-p_1\Phi_2=0, \tag{5}$$

$$\varepsilon>\varepsilon_k;\quad \frac{\partial^2\Phi_3}{\partial\varepsilon^2}-p_1\Phi_3-\sqrt{\frac{2}{\pi}}\left.\frac{\partial u}{\partial\xi}\right|_{\xi=0}=0, \tag{6}$$

whose solutions under the continuity condition $\psi(\eta,\ \xi)$ and its first energy derivative at the limits of the intervals are

$$\Phi_1(\varepsilon,\ k)=\frac{Me^{-p_1\varepsilon_k+p\varepsilon}}{(p_1+p)(\gamma+p_1)^2}, \tag{7}$$

$$\Phi_2(\varepsilon,\ k)=\frac{Me^{-p_1(\varepsilon_k-\varepsilon)}}{2p_1(\gamma+p_1)^2}\left(1+\frac{p_1-p}{p_1+p}e^{-2p_1\varepsilon}\right), \tag{8}$$

$$\Phi_3(\varepsilon_1,\ k)=M\left[\frac{e^{-p_1\varepsilon_1}}{2p_1(\gamma+p_1)^2}\left(1+\frac{p_1-p}{p_1+p}e^{-2p_1\varepsilon_k}\right)\right. +$$

$$+\frac{2\gamma e^{-p_1\varepsilon_1}}{(\gamma^2-p_1^2)^2}\left(1-e^{-\varepsilon_1(\gamma-p_1)}\right)-\varepsilon_1\frac{e^{-\gamma\varepsilon_1}}{\gamma^2-p_1^2}\Bigg], \qquad (9)$$

where

$$p=\sqrt{k^2+\frac{1}{4}},\quad p_1=\sqrt{p^2+\delta}+\frac{1}{4},\quad \gamma=\beta-\frac{1}{2},$$

$$M=\sqrt{\frac{2}{\pi}}\frac{3L\Theta}{4\lambda_y\eta}e^{-\varepsilon_k/2};\quad \varepsilon_1=\varepsilon-\varepsilon_k.$$

In determining the Fourier cosine transforms Φ_1, Φ_2, and Φ_3, the terms η and M are assumed to be constant. This procedure corresponds to neglecting terms of the order of T_k/eU_k compared to unity.

2. The excitation rate of the lower excited state is found from

$$z(\xi)=\frac{n_e v_e}{\lambda_n}e^{-\eta\delta}\int_0^\infty e^{-\varepsilon/2}\varepsilon\eta u(\varepsilon,\xi)\,d\varepsilon, \qquad (10)$$

where λ_n is the electron mean free path for an exciting collision at an electron energy $eU = eU_k + T_e$. The integral excitation rate in the range $0 < x < L\xi$ is determined from

$$Z(\xi)=\frac{eL}{j_{ek}}\int_0^\xi z(\xi)\,d\xi. \qquad (11)$$

With allowance for (8)-(10), the expression for $Z(\xi)$ becomes

$$Z(\xi)=\frac{2\lambda_k}{\pi\lambda_n}\eta_k\int_0^\infty R(k,\varepsilon_k,\beta,\delta)\frac{\sin k\xi}{k}\,dk, \qquad (12)$$

where

$$R(k,\varepsilon_k,\beta,\delta)=\frac{\beta^2}{2p_1(p_1+\gamma)^2}\Bigg\{\frac{\varepsilon_k}{p_1-\frac{1}{2}}\left[1-\frac{1-e^{-\left(p_1-\frac{1}{2}\right)\varepsilon_k}}{\varepsilon_k\left(p_1-\frac{1}{2}\right)}\right]$$
$$+\frac{p_1-p}{\left(p_1+\frac{1}{2}\right)(p_1+p)}e^{-p_1\varepsilon_k}\left[\frac{1}{p_1+\frac{1}{2}}-\left(\varepsilon_k+\frac{1}{p_1+\frac{1}{2}}\right)e^{-\varepsilon_k\left(p_1+\frac{1}{2}\right)}\right]$$
$$+\frac{4p_1\gamma}{(\gamma-p_1)^2}\left[\varepsilon_k\left(\frac{1}{p_1+\frac{1}{2}}-\frac{1}{\beta}\right)+\frac{1}{\left(p_1+\frac{1}{2}\right)^2}-\frac{1}{\beta^2}\right]$$
$$+\left(1+\frac{p_1-p}{p_1+p}e^{-2p_1\varepsilon_k}\right)\frac{\varepsilon_k}{p_1+\frac{1}{2}}\left[1+\frac{1}{\varepsilon_k\left(p_1+\frac{1}{2}\right)}\right]$$
$$-\frac{2p_1(\gamma+p_1)}{(\gamma-p_1)\beta^2}\left(\varepsilon_k+\frac{2}{\beta}\right)\Bigg\}.$$

If the ionization is predominantly cascade in nature, and the redistribution of atoms between the upper excited states and ionization from excited states are due to plasma electrons, then the relation found for $Z(\xi)$ can be used to estimate the upper limit of the ionization rate.

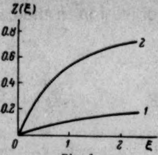

Fig. 1

Figure 1 gives $Z(\xi)$ for two values of δ with $\varepsilon_k = 1$ and indicates that with increasing δ the ionization rate increases and the ionization region as a whole moves toward the cathode. When $\delta > 1$, the linear dimension of the nonequilibrium ionization region in the direction perpendicular to the cathode becomes almost $L' = \sqrt{\lambda_y/3n_a\sigma(\eta k)}$. Figures 2 and 3 give the total excitation rate1) (Z_∞) as a function of δ for $\varepsilon_k = 1$ and as a function of ε_k for $\delta = 0.1$, 1.0. In all cases the maximum value of Z_∞ is of order unity; for a cathode fall of the order of the first excitation potential each electron exiting from the cathode cannot experience more than one excitation event.2)

Table 1 illustrates the contribution of nonequilibrium ionization to the ion current to the cathode for different temperatures of the plasma near the electrode. The calculations have been performed for argon at an initial atomic density of $2.69 \cdot 10^{19}$ cm^{-3}, corresponding to a cold pressure of 1 atm, with $\varepsilon_k = 1$. The equilibrium electron density is determined from the Saha equation

$$\frac{n_e n_i}{n_a}=\frac{2g_i}{g_a}3\cdot10^{21}T_e^{3/2}e^{-\frac{eU_i}{T_e}}, \qquad (13)$$

where n_e and n_i are the electron and ion densities, g_a and g_i are the statistical atomic and ionic weights, and U_i is the ionization potential. The limiting value of the fraction of ion current to the cathode provided by nonequilibrium ionization was determined, as in ref. 6, by

$$\frac{\mu_n}{1-\mu_n}=Z_\infty, \qquad (14)$$

where $\mu_n = j_i/j_p$; j_i and j_p are the ion and discharge cur-

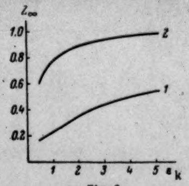

Fig. 3

rent densities to the cathode.

The flux of ions to the cathode in the case of equilibrium ionization and the corresponding value of the ion fraction of the current μ_p are determined from

$$j_i = \frac{en_i}{4}\sqrt{\frac{8T_e}{\pi m_i}}, \tag{15}$$

where m_i is the ionic mass.[3)]

According to the results of the calculation shown in the table, if the temperature of the hot plasma near the cathode does not exceed 1 eV or the longitudinal dimension of the plasma region cooled by the cathode and located between it and the hot plasma is of the order of L', then nonequilibrium ionization can make an important contribution to the ion current to the cathode. It should be noted that at low plasma temperatures, due to the small density of plasma electrons, ionization of the excited state is provided by fast (emission) electrons. It is not difficult to show that in this case the limiting value of Z_∞ is 0.5 and that of μ_n corresponds to 1/3. In this case, however, the contribution of nonequilibrium ionization near the cathode to the thermal plasma is comparatively large. We note also that with intense nonequilibrium ionization near the cathode and a low plasma temperature the density of plasma electrons can appreciably exceed the value obtained from the Saha equation. However, this cannot lead to a substantial decrease in the nonequilibrium ionization rate since it is the primary cause of the increase in the concentration of plasma electrons. In conclusion, it should be noted that the above considerations as to the contribution of nonequilibrium ionization near the cathode to a thermal plasma are preliminary in nature. Further refinement of the situation requires that one take into account the effect of transitions between excited atomic states on the ionization rate and on relaxation of the electron distribution function, and also determine the temperature distribution and plasma electron density in the cathode region.

[1)] The value of Z_∞ is determined from (11) for $\xi \to \infty$.

[2)] In individual cases, Z_∞ exceeds unity by an amount T_k/T_e. This occurs because $\sigma(\eta_k)$ is assumed constant when determining $\psi(\eta, \xi)$, while the linear dependence of the cross section above the excitation threshold is used to obtain Eq. (12).

[3)] When calculating μ_p, the characteristic discharge current density in the cathode spot is taken[3] to be $j_p = 5 \cdot 10^4$ A/cm^2.

Quantum electronics

Plasma dynamic lasers

S. A. Reshetnyak and L. A. Shelepin

(Submitted September 4, 1973)
Zh. Tekh. Fiz., 44, 1724-1732

In the rapid expansion of a dense, highly ionized plasma in the plasma laser, the electron gas is cooled, the plasma recombines, and lasing occurs on atomic transitions. A method of calculating these is developed using quasistationary analytic population distribution functions over discrete levels. A quenching effect is considered for a hydrogen plasma and a radiative mechanism for emptying the lower laser level is analyzed. The possibility of an effective collision mechanism for lithium, helium, and beryllium plasmas is pointed out which would permit the use of large plasma volumes for generation. The dependence of population inversion on a number of parameters is studied.

1. INTRODUCTION

There has been a rapid growth in research on gasdynamic lasers, in which lasing occurs by virtue of vibrational–rotational transitions in molecules (primarily CO_2). Several such lasers have been developed; among them is the electrogasdynamic laser, in which a discharge is used to increase the efficiency. High powers have been obtained in the continuum regime.

Plasma dynamic lasers, in which a population inversion is created on atomic transition in plasma expansion, have not been developed to as great a degree. The plasma dynamic laser is evaluated in ref. 1, where the possibility of creating a population inversion as a result of recombination in adiabatic expansion of a highly ionized plasma (field free or magnetized) is considered.

Experimentally, a population inversion has been observed[2] in a plasma jet expanding through a nozzle in argon, between the lower 5p levels and 4p levels, and in helium, between levels with n = 4 and n = 3 (n is the principal quantum number). Spectroscopic measurements[3] in a hot high-pressure arc in mixtures of helium and methane or argon and methane which expand in a nozzle yield observation of a population inversion in the neutral carbon line corresponding to the transition $2p^{21}S_0 \rightarrow 2p3s\,{}^1P_1^0$ (λ = 2478.6 Å). In addition population inversion is observed in neon[4] and in regions of low electron density in hydrogen.[5,6]

A theoretical treatment of the relaxation processes in plasma expansion is carried out in refs. 7-10. The numerical calculations of refs. 9 and 10 show the possibility of obtaining a population inversion on a neutral nitrogen line (λ = 1745 Å) and in lines of neutral xenon (7p–5d, 4*f*–5d).

The significance of plasma dynamic lasers (compared with usual gasdynamic lasers) lies, first of all, in the possibility of extending the wavelength to the visible and ultraviolet regions of the spectrum. However, there are important difficulties, connected with the rate of relaxation of atomic systems, the complexity of analysis of inversion in plasma jets, and the choice of optimal conditions and materials.

The purpose of the present paper is to present a computational design method for plasma dynamic lasers based on quasistationary analytic population distribution functions, and, to show that in such lasers a collisional mechanism for emptying the lower level can work efficiently, permitting the use of large volumes for efficient lasers.

2. POPULATION OF ATOMIC LEVELS IN PLASMA EXPANSION. COMPUTATIONAL METHOD

We consider electron–ion recombination due to cooling of the electrons as a plasma expands. It is assumed that the plasma is initially in thermodynamic equilibrium at an electron temperature, T_e. At some point the ionization of the plasma begins to deviate from the equilibrium value. In the flow a population inversion can develop between the discrete atomic (ionic) levels in the recombining plasma.

In a general analysis of inversion in expansion of a plasma it is necessary to solve simultaneously the equations for population relaxation, electron temperature, and gas dynamics. We shall assume that the characteristic time for changes in the electron temperature, T_e, is much greater than the time for establishment of a quasistationary distribution.[9] Thus, a quasistationary distribution of excited atomic states exists.

In order to present the clearest explanation of this new computional method for plasma dynamic lasers, we have not considered in any detail the questions of gas dynamics and recombination heating of electrons; rather, we have assumed T_e and N_e to be given functions of time. (The calculation of T_e and N_e is similar to that for ordinary gasdynamic lasers.) Emphasis is placed on the quasistationary population distribution functions.

We consider the system of equations for population balance over the discrete levels of an atom:

$$\left.\begin{aligned} \frac{dN_{nl}}{dt} + N_{nl}\operatorname{div}\mathbf{v} = N_e \sum_{n'l' \neq nl} [V(n'l',\, nl)\, N_{n'l'} \\ - V(nl,\, n'l')\, N_{nl}] \\ + \sum_{E_{n'l'} > E_{nl}} A(n'l',\, nl)\, N_{n'l'} - \sum_{E_{n'l'} < E_{nl}} A(nl,\, n'l')\, N_{nl}, \\ \frac{dN}{dt} + N\operatorname{div}\mathbf{v} = 0, \end{aligned}\right\} \quad (2.1)$$

where N_{nl} and E_{nl} are the population and energy of the nl-th energy level (n is the principal quantum number, and l is the orbital quantum number), $V(nl,\, n'l')$ is the transition probability from states nl to $n'l'$ due to atomic collisions with electrons as averaged over a Maxwellian electron distribution, $A(nl,\, n'l')$ is the radiative transition probability from nl to $n'l'$ per unit time, N_e is the electron density, and v is the hydrodynamic expansion velocity of the plasma.

Substituting

$$N_{nl} = N g_{nl} \exp\left(-\frac{E_{nl}}{kT_e}\right) f_{nl} \qquad (2.2)$$

(where g_{nl} is the statistical weight of the level nl and k is Boltzmann's constant) and using the relation between forward and reverse transitions, we obtain

$$f_{nl}^{(1)} = \frac{1}{N_e}\frac{df_{nl}}{dt} = \sum_{n'l' \neq nl} V(nl,\ n'l')(f_{n'l'} - f_{nl}) \qquad (2.3)$$

for the case of a dense plasma, in which radiative decay can be neglected.

The system of Eqs. (2.3) is formally identical to the system of equations considered in ref. 11, where the distribution function, N_{nl}, is obtained for constant N and T_e in the "single-photon approximation" for n, including optically allowed transitions, and assuming a Boltzmann distribution in l. Using the results of ref. 11 and considering the energy levels of lithium, we have

$$N_{nl} = N_{2s} g_{nl} \exp\left(-\frac{E_{nl}}{kT_e}\right)(1 + \beta_{ns}^1 \varkappa), \qquad (2.4)$$

$$\beta_{ns}^1 = \sum_{m=2}^{n-1} \frac{1}{V^*(ms,\ m+1p)}\left(1 + \sum_{i=3}^{m}\prod_{k=i}^{m} \frac{V(ks,\ k-1p)}{V^*(k-1s,\ kp)}\right), \qquad (2.5)$$

and

$$\varkappa = \frac{1}{N_e}\frac{d}{dt}\ln\frac{N_{2s}}{N} = \frac{f_{2s}^{(1)}}{f_{2s}}; \quad (E_{2s} = 0,\ g_{nl} = 2l+1). \qquad (2.6)$$

Here,

$$V^*(ms,\ m+1p) = V(ms,\ m+1p)\exp\left(\frac{E_{m+1p} - E_{m+1s}}{kT_e}\right)$$

are the effective ionization probabilities for the transition [ms → (m + 1) s], and s, p, d, . . . are the spectroscopic notation for the orbital quantum number l.

The terms with second, third, etc., derivatives can be neglected if

$$\left|\frac{f_{2s}^{(2)}}{f_{2s}^{(1)}}\right| \ll \frac{\exp\left(\frac{E_{ns}}{kT_e}\right)}{g_{ns}\beta_{ns}^1} \quad (n = 3,\ 4,\ \ldots). \qquad (2.7)$$

We consider recombination for $N_i = N_e$ and for times beginning at which the population distribution function, Eq. (2.4), deviates from the Boltzmann case ($\beta_{ns}^1 \varkappa \gg 1$) while the population of the ground state of lithium, N_{2s}, exceeds significantly the population of the excited states, being equal to the neutral density ($N_{2s} = N_0 = N - N_e$). That is, we assume the following inequalities:

$$\frac{1}{\beta_{ns}^1} \ll \varkappa \ll \frac{\exp\left(\frac{E_{ns}}{kT_e}\right)}{g_{ns}\beta_{ns}^1} \ (n = 3,\ 4,\ \ldots). \qquad (2.8)$$

Introducing the ionization, $x = N_e/N$, and combining the distribution function obtained in Eq. (2.4) and the Saha distribution for upper levels ($n \geq n_0$), we obtain the following equation for the ionization:

$$N_{2s}\varkappa = \frac{K(T_e)}{\beta_{n_0s}^1(T_e)} N_e^2 \ \text{or} \ \frac{dx}{dt} = -\frac{K(T_e)}{\beta_{n_0s}^1(T_e)} N^2 x^3, \qquad (2.9)$$

where

$$K(T_e) = \frac{1}{Z_1}\left(\frac{2\pi\hbar^2}{mkT_e}\right)^{3/2}\exp\left(\frac{I}{kT_e}\right)$$

is the ionization equilibrium constant, z is the statistical sum for the lithium ion, I is the ionization potential of lithium, m is the mass of the electron, and ħ is Planck's constant.

3. RECOMBINATION OF A HYDROGEN PLASMA. RADIATIVE MECHANISM FOR POPULATION INVERSION

A number of simple features in the change of the population distribution function in expansion are evident in a hydrogen plasma. The expression for the relaxation factor, Eq. (2.5), for hydrogen can be written in the form

$$\beta_{n_0}^1 = \sum_{m=2}^{n_0} \frac{\exp\left(\frac{E_m}{kT_e}\right)}{g_m V(m,\ m-1)} \sum_{k=1}^{m-1} g_k \exp\left(-\frac{E_k}{kT_e}\right). \qquad (3.1)$$

Substituting in Eq. (3.1), using the equation for the probabilities V (m, m − 1) (cf. ref. 12), and limiting discussion to low recombination temperatures (such that $\sum_{k=1}^{m-1} g_k \exp(-E_k/kT_e) \simeq 1$, we have

$$\beta_{n_0}^1 = \frac{10^7}{1.73}\left(\frac{kT_e}{R}\right)^{1/2}\exp\left(\frac{R}{kT_e}\right)\sum_{m=2}^{n_0}\frac{(2m-1)^4}{[m(m-1)]^5}\,\frac{\exp\left(-\frac{R}{kT_e m^2}\right)}{U\left(\frac{E_{m,\,m-1}}{kT_e}\right)}, \qquad (3.2)$$

where R is the Rydberg constant, $U(x) = 1 + x\,\mathrm{Ei}(-x)\exp x$, and $\mathrm{Ei}(-x)$ is the exponential integral.

The summation in Eq. (3.2) has a sharp maximum in m: for small m the first terms in the summation are small because of the smallness of the exponential factor, resulting from the large distance between neighboring energy levels; for large m these are small because of the higher transition probabilities, V (m, m − 1). The term with $m = m^*$, which makes the basic contribution to the sum Eq. (3.2), corresponds to the so-called "bottleneck" in the energy level spectrum of the hydrogen atom. This bottleneck has an important effect on the entire recombination process.

By finding the extremum in m in the term following the summation in Eq. (3.2) it is possible to find the location of the bottleneck in the spectrum of energy levels of hydrogen for two limiting cases of the function U (x). For $x \ll 1$, U (x) = 1, and m^* is the root of the equation

$$\frac{R}{kT_e} = \frac{m^2}{2(2m-1)(m-1)}[18m^2 - 18m + 7], \quad m^* \simeq \frac{1}{3}\sqrt{\frac{2R}{kT_e}}.$$

For $x \gg 1$, U (x) = 1/x, and m^* is a root of the equation.

Evaluation of the sum in Eq. (3.2) by means of an electronic computer shows that for temperatures in the interval 0.1 eV ≤ kT_e ≤ 1.2 eV the factor $\beta_{n_0}^1$ is well approximated by an analytic expression of the form

$$\beta_{n_0}^1 = (1.4 \pm 0.2) \cdot 10^8 T_e^4(\mathrm{eV}) \exp\left(\frac{R}{kT_e}\right). \quad (3.3)$$

The lower the electron temperature, the higher the bottleneck. The bottleneck m = m* divides the energy level spectrum into two parts. The population distribution function for energy levels which lie below the bottleneck $[\beta_n^1 \simeq \exp(E_n/kT_e)/g_n V(n, n-1)]$ deviates strongly from equilibrium. For energy levels above the bottleneck $(\beta_n^1 \simeq \beta_{n_0}^1)$ we have almost a Boltzmann distribution in equilibrium with the continuous spectrum. Thus, the boundary level n_0 must be chosen to be higher than the bottleneck so that the magnitude of n_0 will not affect the results of the calculation.

Substituting Eq. (3.3) in Eq. (2.9) we obtain the following equation for ionization:

$$\frac{dx}{dt} = -bN^2 T_e^{-11/2}(\mathrm{eV}) x^3, \quad b = 2.4 \cdot 10^{-28}. \quad (3.4)$$

We assume that the density of heavy plasma particles N and the electron temperature T_e change according to the law

$$\left.\begin{aligned} N &= N_0\left(\frac{t_0}{t}\right)^\alpha, \\ T_e &= T_{e0}\left(\frac{t_0}{t}\right)^\beta \; (\alpha, \beta > 0, \; t > t_0) \end{aligned}\right\} \quad (3.5)$$

during expansion, where N_0 is the initial plasma density, T_{e_0} is the initial electron temperature, α and β are given parameters, and t_0 is the time scale for changes in N and T_e.

Integrating Eq. (3.4) and taking Eq. (3.5) into account yields

$$x^2 = \frac{x_0^2}{1 + \frac{\xi}{\varepsilon}\left[\left(\frac{t}{t_0}\right)^\varepsilon - 1\right]}, \quad \xi = \frac{2bt_0 N_0^2 x_0^2}{T_{e0}^{11/2}}, \quad (3.6)$$

where x_0 is the initial ionization level of the plasma and $\varepsilon = (11/2)\beta - 2\alpha + 1 \neq 0$.

It is clear from Eq. (3.6) that for $\varepsilon > 0$ the ionization of the plasma approaches zero as $t \to \infty$, and that for $\varepsilon < 0$, the plasma expands to infinity (partially ionized i.e., quenching) with a residual degree of ionization given by the equation

$$x_\infty = \frac{x_0}{\sqrt{1 + \frac{\xi}{\varepsilon}}}. \quad (3.7)$$

It is clear that the residual ionization is greater for a higher initial electron temperature and smaller for a higher initial plasma density and characteristic scale change in density and electrom temperature.

For spherical $(N \sim t^{-3})$, cylindrical $(N \sim t^{-2})$, and plane $(N \sim t^{-1})$ adiabatic expansion of gas into a vacuum with equal electron and ion temperatures $T \sim N^{\gamma-1}$ (γ is the adiabatic index), quenching will be observed in spherical expansion for $\gamma < 1\ 10/33$, cylindrical for $\gamma < 1\ 3/22$, and finally, planar, for $\gamma < 1\ 2/11$.

The ionization equation [Eq. (2.5)] then yields an expression for the recombination coefficient with constant N and T_e:

$$\gamma = -\frac{1}{N_e^2}\frac{dN_e}{dt} = bT_e^{-11/2}(\mathrm{eV}) N_e. \quad (3.8)$$

Within the given range of temperatures T_e and for electron densities $10^{13} \leq N_e \leq 10^{16}$, the recombination coefficients evaluated according to Eq. (3.8) are only two or three times smaller than those obtained by numerical calculation in ref. 13. In addition, Eq. (3.8) is exactly the same as the expression for the recombination coefficient obtained by numerical calculations of relaxation in a lithium plasma in ref. 14.

In recombination of an arbitrary atomic plasma, Eq. (3.4) and Eq. (3.8) can be used provided the bottleneck in the energy level spectrum which defines the recombination rate is located in a region of hydrogen-like levels. The more the energy spectrum of the atom is hydrogen-like, the better Eq. (3.4) represents the recombination process. As T_e is decreased the bottleneck shifts to the region of hydrogen-like levels. Thus, for small T_e the conditions for applicability of Eq. (2.5) improve. If the spectrum differs strongly from that of hydrogen, then the sum in Eq. (2.5) must be analyzed as a function of T_e.

In investigating the possibility of obtaining an inverted population, we now consider radiative decay in expansion of an optically thin hydrogen plasma. In such a plasma, as has been shown theoretically[12] and confirmed experimentally,[5,6] a population inversion can arise by virtue of a rapid depletion of the lower laser levels caused by the high probability of radiative decay.

Carrying out calculations analogous to those in ref. 11, we obtain the following expression for the distribution function with radiative decay taken into account:

$$N_n = N_1 g_n \exp\left(-\frac{E_n}{kT_e}\right)(Q_1^n + \delta_n^1 x), \quad (3.9)$$

$$Q_m^n = \prod_{k=m}^{n-1}\left(1 + \frac{A(k+1, k)}{N_e V(k+1, k)}\right)^{-1} \; (Q_1^1 = 1), \quad (3.10)$$

$$\delta_n^1 = \sum_{m=2}^{n} \frac{\exp\left(\frac{E_m}{kT_e}\right)}{g_m V(m, m-1)} Q_{m-1}^n \sum_{k=1}^{m-1} g_k \exp\left(-\frac{E_k}{kT_e}\right). \quad (3.11)$$

The radiative decay of the levels has been considered subjected to

$$\sum_{k=n}^{n_0} \sum_{m=1}^{n-1} A(k, m) N_k \simeq \sum_{m=1}^{n-1} A(n, m) N_n = A(n) N_n,$$

where A (k, m) is the probability of radiative decay of level k to level m per unit time. The expression for A(n) can be found, for example, in ref. 12.

For reasonably large electron densities, $N_e \gg A \cdot [m^*/V(m^*, m^*-1)]$, the location of the bottleneck in the energy level spectrum of hydrogen and Eq. (3.4) (for the degree of ionization) are unchanged. For the population of levels below the bottleneck the sum in Eq. (3.11) can, as before, be terminated by the last term with m = n. At temperature of recombination $\sum_{k=1}^{m-1} g_k \exp(-E_k/kT_e) \approx 1$ we obtain an expression for the inversion of population between neighboring levels of the hydrogen atom; then

$$\frac{N_{n+1}}{g_{n+1}}-\frac{N_n}{g_n}=\varkappa N_1\left(\frac{Q_n^{n+1}}{g_{n+1}V(n+1,\ n)}-\frac{Q_{n-1}^{n}}{g_nV(n,\ n-1)}\right),\ n=2,\ 3,\ \ldots. \tag{3.12}$$

It follows from Eq. (3.12) that a population inversion can be realized in a hydrogen plasma by radiative emptying of the lower level alone if

$$N_e<\frac{g_nA(n)-g_{n+1}A(n+1)}{g_{n+1}V(n+1,\ n)-g_nV(n,\ n-1)}. \tag{3.13}$$

The upper limit on the electron density and the requirement that the optical thickness of the plasma be small indicate that the use of a hydrogen plasma in a plasma dynamic laser is not promising.

4. COLLISIONAL MECHANISM FOR POPULATION INVERSION

In contrast with hydrogen, in which population inversion occurs by a radiative mechanism, a collisional mechanism due to recombination branching can occur in more complex atoms (ions).

We consider population inversion between the 4p and 3s levels of a lithium plasma based on the population distribution function, Eqs. (2.4)-(2.6), obtained earlier.

Noting that the probability of ionization of the ground state of the lithium atom $V^*(2s, 3p) \ll V(3s, 2p)$, from Eqs. (2.4) and (2.5) we have

$$\frac{\Delta N}{g}=\frac{N_{4s}}{g_{4s}}-\frac{N_{3p}}{g_{3p}}=\varkappa N_{2s}G(T_e), \tag{4.1}$$

where

$$G(T_e)=[3V(3p,\ 2s)]^{-1}\left[\frac{V(3s,\ 2p)}{3V(4p,\ 3s)}-\exp\left(-\frac{E_{3p}-E_{3s}}{kT_e}\right)+\exp\left(-\frac{E_{4s}-E_{3s}}{kT_e}\right)\right].$$

The function $G(T_e)$ depends on the energy spectrum of the atom and the associated transition probabilities. Using the cross section for inelastic collisions between atoms and electrons calculated in ref. 15, it can be shown that for low recombination temperatures $G(T_e)$ is essentially constant and that the inverted population as a function of time, initial electron temperature, and plasma density is determined by the factor $\varkappa N_{2s}$.

If the bottleneck in the energy level spectrum of the lithium atom lies in the region of hydrogen-like levels, then the factor $\varkappa N_{2s}$ can be calculated using Eqs. (2.6) and (3.4):

$$\varkappa N_{2s}=\frac{\xi}{2t_0}f\left(\frac{t}{t_0}\right),\quad f(z)=\frac{z^{\varepsilon-1}}{1+\xi\varepsilon^{-1}(z^{\varepsilon}-1)}\ (\varepsilon\neq 0). \tag{4.2}$$

Analysis of the behavior of $f(z)$ leads to the conclusion that the inverted population at the start of plasma expansion increases with time if $\xi < \varepsilon - 1$. The time $t = t^*$ at which the inverted population reaches a maximum value is given by

$$\frac{t^*}{t_0}=[(\varepsilon-1)(\varepsilon-\xi)\xi^{-1}]^{1/\varepsilon}, \tag{4.3}$$

and the corresponding maximum inverted population is given by

$$\left(\frac{\Delta N}{g}\right)_{\max}=\left(\frac{\varepsilon-1}{2t_0}\right)^{\varepsilon-1/\varepsilon}\left(\frac{\xi}{\varepsilon-\xi}\right)^{1/\varepsilon}G(T_e). \tag{4.4}$$

Thus, the larger the initial plasma density, the more rapidly the inverted population reaches its maximum and the larger the maximum value.

The dependence of $\Delta N/g$ on time is shown in Fig. 1. The expansion of the plasma is modelled using a cylindrical ($\alpha = 2$) expansion with an adiabatic index, $\gamma = 16/11$, $N_0 = 4 \cdot 10^{14}$ cm^{-3}, $T_{e0} = 0.4$ eV, and $t_0 = 2.5 \cdot 10^{-5}$ sec. The initial growth in $\Delta N/g$ is explained by an increase in the recombination flux to discrete levels due to cooling of the electrons. The fall in inverted population occurs because of the decrease in recombination flux and the decrease in density as the plasma expands.

An examination of the dependence of $(\Delta N/g)_{\max}$ on T_{e0} shows that there are optimum initial electron temperatures, T_{e0}^{opt}. The existence of these T_{e0}^{opt} can be explained as follows: as T_{e0} becomes larger, the initial degree of ionization of the plasma and the electron density become greater; however, the recombination flux which populates the higher discrete levels decreases at higher T_{e0}. The optimum electron temperature can be found using the condition $\partial\xi/\partial T_{e0} = 0$ or $11/4T_{e0} = \partial(\ln x_0)/\partial T_{e0}$. Taking $(1 - x_0)/x_0^2 = K(T_{e0})N_0$, we have

$$\frac{2}{11}\left(\frac{I}{kT_{e0}}-\frac{5}{4}\right)=\frac{y}{1+2y-\sqrt{1+4y}},\quad y=K(T_{e0})N_0. \tag{4.5}$$

Here, I is the ionization potential of the atom and $K(T_{e0})$ is the ionization equilibrium constant.

The results of a calculation of optimum initial electron temperatures as a function of the initial density of a lithium plasma are shown in Fig. 2. It is clear that these T_{e0}^{opt} values lie within a relatively narrow range of electron temperatures and increase as N_0 increases.

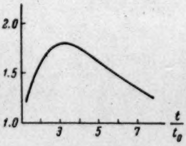

Fig. 1. Time variation of the inverted population during expansion of a lithium plasma. $N_0 = 4 \cdot 10^{14}$ cm^{-3}, T_{e0} = 0.4 eV, $t_0 = 2.5 \cdot 10^{-5}$ sec, α = 2, γ = 16/11.

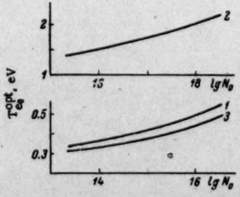

Fig. 2. Dependence of optimum initial electron temperatures on the initial density of lithium (1), Be II (2), and orthohelium (3) plasmas.

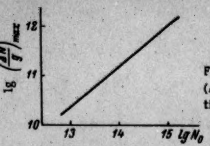

Fig. 3. Maximum inverted population, $(\Delta N/g)_{max}$, as a function of the initial density (for lithium).

Taking the dependence of $T_{e_0}^{opt}$ on N_0 into account we also obtain the inverted population, $\Delta N/g$, as a function of N_0. This function is shown in Fig. 3 on a logarithmic scale and is almost a straight line. Thus, as the initial plasma density increases the inverted population, $\Delta N/g$, increases according to a power law, $\Delta N/g \propto N_0^q$, where q is the slope of the curve (for lithium q = 0.87), to the limits of applicability of this theory, which are defined by Eq. (2.8).

Similar calculations can be carried out in the second ionization region of the atom if the plasma consists of singly and doubly charged ions. Estimates for Be II (a lithium-like ion) show that at $t^* = 2.6\, t_0$, $(\Delta N/g)_{max} = 4.6 \cdot 10^{11}$ cm^{-3} for $N_0 = 3.6 \cdot 10^{16}$ cm^{-3}, $T_{e0} = 1.6$ eV, and $t_0 = 10^{-5}$ sec. The optimum electron temperatures as a function of initial density, N_0, are given in Fig. 2.

The optimum electron temperatures for He I (Fig. 2) have been calculated using the metastable 2^3S state of orthohelium as a ground state. For $N_0 = 2.2 \cdot 10^{14}$ cm^{-3}, $T_{e0} = 0.35$ eV, and $t_0 = 10^{-5}$ sec, the maximum population inversion between the 4^3S and 3^3P levels is reached when $t^* = 6t_0$, and $(\Delta N/g)_{max} \simeq 7 \cdot 10^{11}$ cm^{-3}.

Analysis of the population distribution function for parahelium shows that inversion between the 3^1S and 2^1P, and 4^1S and 3^1P levels is not observed. This is connected with the presence of the highly excited metastable 2^1S state in parahelium. During recombination the 2^1S state is repopulated while the population of the lower laser levels, 2^1P and 3^1P, increases.

If the plasma expands from an orifice (slit or nozzle) with characteristic dimension *a*, then the scale of change in the density and electron temperature, t_0, is of order *a*/v, where v is the plasma flow velocity from the orifice. Then the distance from the orifice at which the inverted population reaches a maximum is approximately equal to $a(t^*/t_0)$, i.e., the greater the plasma flow velocity from the orifice, the greater the inverted population and the earlier it reaches its maximum value.

Hence, on the basis of examples using lithium, beryllium, and helium plasmas, we see a distinct possibility of realization of a collisional mechanism and of the use of large plasma volumes for lasing. This suggests a promising outlook for plasma dynamic lasers. The method developed here can be used for further analysis of optimum regimes in plasma jets and calculations of specific systems with different plasma compositions.

Effect of plasma parameters on emission in an ion laser

I. E. Sakharov, V. V. Ermolin, and S. V. Shatalin

M. I. Kalinin Leningrad Polytechnic Institute

(Submitted July 13, 1973)
Zh. Tekh. Fiz., 44, 1733-1739 (August 1974)

The plasma parameters (electron temperature, density) and the laser emission in a discharge in argon are studied experimentally. The parameter range studied includes a region in which the degree of ionization is near unity. The discharge is produced in a tube 6 mm in diameter and 1 m long in a long-pulse regime (100 μsec) at currents up to 600 A at pressures $2 \cdot 10^{-2}$ to 10^{-1} torr. The high degree of ionization permits observations up to electron temperatures of ~ 20 eV. The pressure range varies from $3 \cdot 10^{14}$ to $1 \cdot 10^{15}$ cm^{-3}. The data yield the optimum values of plasma parameters from the standpoint of laser emission. It is proposed that one of the mechanisms which limits the growth of laser emission with discharge current is an instability observed in these experiments.

INTRODUCTION

In recent years considerable success has been achieved in increasing the power of ion lasers. In particular, a power of 175 W has been obtained from an argon laser in the cw mode.[1] Analysis of the operation of ion lasers shows that in the discharge regimes characteristic of maximum output power the degree of ionization of the gas is rather high. Thus, in ref. 2 the degree of ionization is 0.2 to 0.3 at a current density of 500 A/cm^2. That the degree of ionization of the gas in the discharge region near the axis can be very high is also shown by the authors of refs. 1 and 3.

The transition to a high degree of ionization ($\alpha \sim 1$) changes significantly the properties of the discharge.[4] In particular, the electron temperature is not determined by the balance of charged particles and can increase rapidly as the discharge current is increased. This implies a possible extension of the range of electron temperatures over which lasers operate to very much higher values. Nevertheless, in the literature, investigations of the dependence of laser emission properties on the mean electron energy are limited to values $T_e \leq 10$ eV, i.e., to values close to the temperature determined by the charged particle balance. Hence, it is of interest to relate the properties of laser emission to the parameters of a plasma which is fully ionized.

In the present paper the dependence of the emission from an argon ion laser on the discharge parameters (current density and gas pressure) and on the plasma parameters (the density and average electron energy) is studied. The experiments are carried out in a quasistationary regime (long current pulses) in a weakly ionized plasma and a highly ionized plasma. This means the electron temperature varies from 3-4 eV to ~20 eV.

EXPERIMENTAL ARRANGEMENT

The experimental arrangement consists of a modification of an earlier apparatus.[4] The present apparatus differs from the earlier one in that it has plane-parallel quartz plates mounted at the Brewster angle at its ends and is located within an optical resonator. A circuit to measure the laser output power and apparatus for optical spectrum analysis are added.

The subject of this investigation is the laser emission from a plasma column produced in a quartz tube 6 mm in diameter and approximately 1 m long by means of a pulsed current whose magnitude is variable between 50 and 600 A. The minimum pressure of argon fill gas at which it is possible to obtain stable pulses for all values of discharge current is $2 \cdot 10^{-2}$ torr. The pulse source is a modulator with an artificial delay line, which delivers a pulse up to 12.5 kV 100 μsec long to a matched load. The discharge current is controlled by simultaneous variation of the load and matching impedances.

The long pulse regime is chosen for the following reasons. On one hand, the discharge must last significantly longer than the characteristic time required to establish the plasma parameters, which, under the present experimental conditions, is of the order of 10 μsec. On the other hand, the change in volume density of heavy particles (total density of ions plus atoms) due to gas breakup must be insignificant during the discharge. If this is so, then it is possible to use an easily measured quantity, the initial gas density, to calculate the degree of ionization. The characteristic breakup time, estimated from the speed of sound in the apparatus and the plasma parameters, is of the order of 1 msec. Thus the current pulse length is taken to be 100 μsec.

The basic plasma parameter measurements are carried out using a double probe (electron temperature from the slope of the curve and density from the ion saturation current); when a bias magnetic field is used a diamagnetic signal probe (product of electron density and temperature) is used. In addition, there are antennas and horns to detect low-frequency noise and microwave emission. Optical spectra are observed using an STÉ-1 spectrograph, and the laser output power is measured using a system of calibrated absorbers with a calibrated photodetector.

DEPENDENCE OF OUTPUT POWER ON DISCHARGE PARAMETERS

Analysis of oscilloscope traces shows that the relaxation times are less than 15-20 μsec, after which such variables as the discharge current, longitudinal field, potential drop across the discharge, diamagnetic signal, and probe current remain essentially constant over the remainder of the pulse. Nevertheless, the experiments show that the laser output is not stationary. The laser output as a function of time is a curve with several maxima. The first maximum corresponds to the time at which the discharge is initiated and has the form of a narrow peak. Its appearance is associated with the excitation of

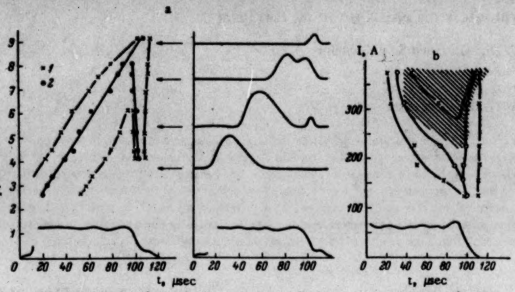

Fig. 1. Variation in time of output pulses relative to discharge current pulse as a function of a) pressure, p (discharge current I = 310 A), and b) discharge current (pressure p = 4.5 · 10^{-2} torr). The points 1 correspond to edges of pulses, and points 2 to maxima of pulses.

ionic levels in the unformed discharge. Since information on the plasma parameters at these times is lacking, this peak is not discussed. The second maximum is observed when the discharge current is essentially constant (current plateau). Its height and displacement in time relative to the beginning of the discharge depend on the discharge current and argon pressure. The third maximum corresponds to the time interval during which the discharge current is falling (the current fall time is approximately 10 μsec). Sometimes it is possible to see these maxima even when there is no plateau pulse. Below we call this the "fall" pulse. When this pulse follows a plateau pulse we call it the secondary fall pulse.

The output characteristics and location of the maxima as functions of gas pressure are shown in Fig. 1a. To the right of the figure is a schematic representation of the oscilloscope traces obtained for a single value of the discharge current (I = 310 A, which corresponds to a current density of 1100 A/cm^2) but different pressures. The lower curve represents the time variation of the discharge current. A more detailed picture of the change in the time of the edges of the observed pulses (experimental values denoted by crosses)and of the maxima (dots) as the pressure is changed are shown in the left half of Fig. 1a. It is clear that at high pressures only a single fall pulse is observed. Then, depending on the reduction in pressure, the plateau pulse blends with a secondary fall pulse. Later, the two pulses occur separately, and at low pressures only a plateau pulse, strongly shifted to the beginning of the current pulse, occurs. We note that small shifts in the fall peak correspond to large changes in the optimum current, i.e., the instantaneous value of the current at maximum (laser) output power. Diagrams similar to Fig. 1a are obtained for different values of the current, but the absolute value of the shift in the output pulse on the plateau relative to the beginning of the current pulse depends on the current.

A diagram which shows the change in the time of the output peaks as a function of the current is shown in Fig. 1b. A single fall pulse occurs at low currents and a plateau pulse shifted toward the beginning of the current pulse is observed at higher discharge current.

In addition to observing the time of occurrence of the peaks, we also study the spectral composition and power of the laser emission at the maxima. It should be noted that the Q factor of the optical resonator is very low (because of the construction of the experimental apparatus). Thus, the output power data should be considered only as an indication of optimum discharge and plasma parameter regimes. More than 98% of the power is in the λ = 4880 Å line. Emission at λ = 5145 Å is observed at several currents (~ 100 A) and pressures (2.5-4 · 10^{-2} torr). Emission at λ = 4765 Å is recorded when the discharge is initiated. The experimental data are sufficient to determine the maximum plateau output power and fall power as functions of discharge current and pressure. Emission is observed for pressures from the minimum possible (2 · 10^{-2} torr) up to 10^{-1} torr and for currents from 50 to ~ 400 A. In each case the dependence on current is obtained for 10 values of the pressure, and the dependence on pressure for eight values of current. The results of such experiments averaged over three series are shown in Fig. 2 as equal power contours with pressure and discharge current as coordinates. The diagram corresponds to plateau emission. The diagram for fall emission is similar. It is shown here because its interpretation is unreliable due to the difficulty of comparing the instantaneous discharge parameters with the plasma parameters in an unstable portion of the current pulse.

DEPENDENCE OF OUTPUT POWER ON PLASMA PARAMETERS

In order to study the dependence of laser output power on electron temperature and density it is necessary to establish the relation of these parameters to the discharge current and filling pressure. As has been indicated earlier, double probes and the diamagnetic signal are used for this purpose. It should be noted that it is not possible to obtain information about the plasma parameters for all discharge parameter ranges over which coherent emission is observed. In particular, noise appears at very high currents, making measurement difficult.

The electron temperature is determined from the slope of the probe volt–ampere characteristic. The error is ~30%. The electron temperature and saturation currents are used to find the density. The errors connected with the assumptions made in treating the data (in particular, the assumption concerning the form of the radial density distribution and the method of averaging the current along the length of the probe) can be significant. Estimates show that these errors have a systematic character and lead to the conclusion that a constant coefficient (which lies between 0.5 and 2) must be introduced into each value of the density. In experiments with a weak magnetic field (when the probe measurements are still accurate but a diamagnetic signal can be obtained) the results of probe and diamagnetic measurements agree within the limits of error.

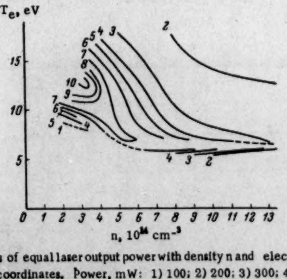

Fig. 4. Lines of equal laser output power with density n and electron temperature T_e as coordinates. Power, mW: 1) 100; 2) 200; 3) 300; 4) 400; 5) 450; 6) 500; 7) 550; 8) 600; 9) 620; 10) 640. The dotted curves correspond to unreliable experimental data.

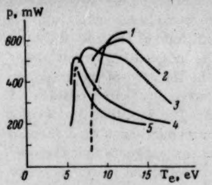

Fig. 5. Dependence of laser output power P on electron temperature T_e for various densities n. n · 10^{14} cm^{-3}: 1) 3; 2) 4; 3) 5; 4) 8; 5) 10. The dotted portions of the curves are those for which experimental data are unreliable.

The results of measurements of electron temperature and charged particle density as a function of discharge current and pressure are shown in Fig. 3 in the form of a diagram constructed by interpolation of experimental data. In this figure the numbers on the left next to the dotted lines correspond to T_e, and the numbers to the right (solid lines), to the electron density. The rapid growth in electron temperature as the current increases at low pressures is due to the transition to a high degree of ionization. These measurements provide information about the direct dependence of output power on the plasma parameters. In Fig. 4 equal power contours are shown in the output power as a function of electron temperature for various densities. As the density is decreased the optimum electron temperature is shifted to larger values. As this occurs the laser output power increases.

The dependence of power on density at constant temperature (obtained, as are the curves of Fig. 5, from the intercepts of the contours of Fig. 4) is shown in Fig. 6. The optimum density is lower for a higher electron temperature. For $T_e \geq 13$ eV the output maximum apparently occurs at densities lower than the minimum density obtained in these experiments.

PLASMA OSCILLATIONS

In the experiments, under certain conditions low- ($\omega \sim 1$ -10 MHz) and high- ($\omega \sim 10^{11}$ Hz) frequency oscillations are observed simultaneously. The low-frequency noise is picked up by probes in the plasma and by external antennas in the shape of spiral sections enclosing the apparatus or of bulk sensors (small plates) located on the outside wall of the discharge tube. Microwave oscillations are detected by a horn with a two-millimeter detector. In all cases the signal is fed directly to the input of an oscilloscope without preamplification.

The oscillations are observed immediately following the plateau laser pulse. A growth in the amplitude of the oscillations coincides with a decrease in laser output power. During the time interval in which high-amplitude

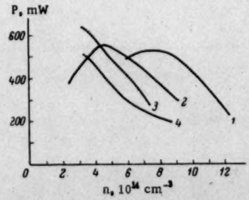

Fig. 6. Dependence of laser output power P on density n for various values of electron temperature, T_e. T_e, eV: 1) 6; 2) 9; 3) 13; 4) 16.

oscillations are observed there is no laser emission. The reduction in the oscillation amplitude at the end of the current pulse coincides with the increase in output power associated with "fall" peak. The location of the noise on the time axis for various discharge currents is indicated in Fig. 1b by the shaded region. The fact that the development of an instability leads to a reduction in or disappearance of laser emission in all cases suggests that the oscillations represent a limitation on output power at large discharge currents.

Apparently, the observed bell-shaped form of the plateau output pulse (absence of a step) is associated with the fact that the oscillations of the plasma damp out the laser emission before it reaches the level which might be expected for a given electron temperature and density in the absence of oscillations. From this standpoint the reduction in output power for large T_e and n (Fig. 4) or large currents (Fig. 2) can be explained by an increase in the amplitude of the oscillations and a corresponding earlier quenching of the output pulse.

The dotted line of Fig. 2 denotes the lower boundary of the currents at which intense oscillations are observed. From this figure it is clear that the oscillation regime coincides approximately with the region in which the output power decreases with increasing current.

There is another (circumstantial) argument to indicate that the oscillations tend to inhibit the laser action.

Measurements of the density for various argon pressures suggest constructing lines of equal degrees of ionization on diagrams analogous to Figs. 2 and 4. One such line (for a degree of ionization equal to 0.3) is shown in Fig. 2 by a dot–dash line. Clearly, it coincides with the location on the diagram of the optimum values of the current. In other words, for all pressures the output begins to decrease with increasing current until a given, fairly high degree of ionization is attained. It should be noted that this value, as well as the density, is known to within a factor of 2: It also characterizes the degree of ionization averaged over the cross section. Thus, near the axis of the apparatus the degree of ionization can exceed 0.3.

Neither the absorption of radiation nor the destruction of the inverted population by electron impact is related unambiguously to the degree of ionization; on the other hand several plasma instabilities (such as the two-stream instability due to runaway electrons) require nearly complete ionization (which can occur near the tube axis under the present experimental conditions). An explanation of the nature of the observed instabilities and the mechanism by which the plasma oscillations affect the laser output power awaits further investigation.

We note that under the present experimental conditions the limitation on and drop in laser power with current cannot be due to the causes discussed in ref. 1, but are due specifically to the reduction in density of the heavy particles due to displacement of the gas. On the other hand, in the same work, the author noted the presence of instabilities (at currents slightly exceeding the optimum value). Intense oscillations and their effect on laser output power in the cw mode were observed in ref. 3.

CONCLUSION

An experimental study of laser emission from a highly ionized argon plasma with density $3 \cdot 10^{14}$–$1 \cdot 10^{15}$ cm^{-3} and temperature 3 to 20 eV shows that the optimum value of the mean electron energy depends on the density and that this optimum value shifts to larger values as n decreases. When n changes from $\sim 1 \cdot 10^{15}$ to $3 \cdot 10^{14}$ cm^{-3}, $T_{e\,opt}$ increases from 6 to 12-13 eV.

As the density increases the output power (corresponding to the optimum T_e in the observed parameter range) increases monotonically. Hence, the optimum density value is apparently less than $3 \cdot 10^{14}$ cm^{-3} and the corresponding $T_{e\,opt}$ exceeds 13 eV.

It is observed that the optimum value (with respect to emission) of the discharge current for various pressures corresponds to a constant value of the degree of ionization averaged over the cross section. The probable reason for the reduction in output power as the current exceeds the optimum value is the oscillation of the plasma observed in these experiments.

The authors thank V. E. Golant, A. P. Zhilinskii, and A. É. Fotiadi for valuable comments.

Self-excited waveguide buncher

N. M. Gavrilov and A. V. Nesterovich

(Submitted May 14, 1973; resubmitted December 28, 1973)
Zh. Tekh. Fiz., 44, 1740-1742 (August 1974)

The possible use of longitudinal beam instability in a slow wave system for a phase bunching before injection into a linear accelerator is analyzed.

The acceleration efficiency of linear particle accelerators can be increased by preliminary phase bunching by means of klystron and waveguide bunchers with constant or varying phase velocity in the beam direction equal to or higher than the particle velocity.[1]

The use of such bunchers assumes the use of separate power supplies that are synchronized with the power supplies of the accelerator sections.

We propose here and analyze the possibility of bunching based on the interaction of particles with the backward wave excited in a slow-wave system by a beam moving at a velocity higher than the phase velocity of the wave, by analogy with backward-wave tubes. A backward-wave tube is known to produce a bunched beam at the exit from the structure. Such a buncher does not require a separate power supply, since the bunching results from power drawn from the beam.

The buncher and accelerator sections can be synchronized by supplying a signal from a stable master oscillator to the input of the "backward-wave" tube. The signal from such an oscillator can be used for a number of accelerator stages. Systems are available for increasing the frequency stability and the output power.[2]

The efficiency of this bunching method is analyzed on the basis of the theory of nonlinear interactions,[3] which gives the most complete information about the phase and energy characteristics of the beam. A unique feature of this system, which distinguishes it from backward-wave tubes, is the existence of high currents and voltages, characteristic of the injectors for linear electron accelerators. A computer is used to solve the generalized equations resulting from the nonlinear analysis of the oscillator by the Lagrange method in a one-dimensional system; Fourier analysis is used to calculate the space-charge field.

The calculations reveal the following general features:

1. In a structure with a constant phase velocity the modulation depth of the beam increases with increasing velocity detuning, but the self-excitation conditions are satisfied for a long structure.

2. The formation of two or more bunches is not observed, implying that such devices can be used for bunching in accelerators. A possible explanation for this behavior is that the bunching occurs in a field which decays to zero, in contrast with the situation in traveling-wave tubes or waveguide bunchers, in which bunches are isolated at high signal levels.

3. An increase in the amplitude of the output signal A(0), in the beam current I_0, and in the characteristic impedence Z_0, correspond to a contraction of the phase spectrum, as does a decrease in the injection voltage V_0.

4. The self-excitation conditions are satisfied for a structure length of $N_S = Z/\lambda_S = 6$-10 (λ_S is the wavelength); at the output about 80% of the particles are bunched into a phase interval shorter than 60°, and the spectral width at half-height does not exceed 20°.

5. A general property is the existence of tails in the accelerating field region in the phase spectra and, at low energies, in the energy spectra. As the structure is lengthened the phase spectra contract, while the energy spectra expand.

As an example, Fig. 1 shows the phase spectra of the particles at the exit from the structure (where the field amplitude vanishes) for two phase-velocity cases for the case of uniform injection; the corresponding energy spectra are shown in Fig. 2. Here b' is the beam radius, f_S is the oscillation frequency, $C = (Z_0I_0/4V_0)^{1/3}$ is the coupling parameter, $y = 2\pi CN_S$ is the normalized length, b =

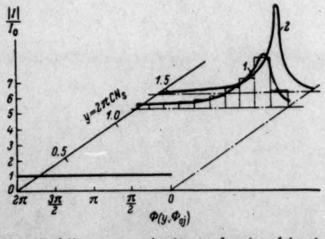

Fig. 1. Normalized linear current density as a function of the electron phase for equilibrium injection. $I_0 = 0.5$ A, $V_0 = 120$ kV, $Z_0 = 40\ \Omega$, b' = 5 mm, $f_s = 3000$ MHz, A(0) = 0.2. 1) b = 0.5, y = 1.2 (the approximating histogram is shown); 2) b = 1.5, y = 1.4.

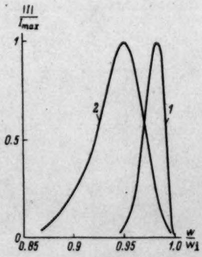

Fig. 2. Energy spectra corresponding to the cases shown in Fig. 1. W_I is the injection energy.

$(u_0-v_0)/Cv_0$ is the velocity-detuning parameter, $A(y) = CV(y)/Z_0I_0$ is the normalized voltage amplitude, $V(y)$ is the voltage across the structure, u_0 is the injection velocity, v_0 is the phase velocity of the unperturbed (cold) wave, $\Phi(y, \Phi_{0j})$ is the phase position of a particular group of charges with respect to the hot wave, and Φ_{0j} is the phase position at the instant of injection.

As a typical example we assume a system with I_0 = 1 A, W_i = 200 keV, b' = 6 mm, f_s = 3000 MHz, Z_0 = 40 Ω (a typical value for structures of the limited-waveguide type), and b = 0.1. We assume that the self-excitation conditions are satisifed when the structure is about 60 cm long; the generated power is almost 10% of the beam power, i.e., 20 kW, and the particles are bunched into a phase interval of 60°.

These results indicate that systems of this kind satisfy the requirements imposed by the prevailing parameters of radio-frequency power supplies (a long pulse and a frequency instability)[4] and by the tolerances involved in the construction of the waveguides[5] and can be used to bunch particles in linear accelerators.

The phase focusing can be improved through the use of well-known methods for increasing the efficiency of TWT devices; in particular, structures with a varying phase velocity can be used. We assume that such a system can be used to achieve a phase bunching no worse than that achieved in most of the existing bunchers, primarily, prebunchers; the system would have similar structural parameters, but would have the important advantage of not requiring a separate power supply.

Furthermore, the beam signal generated in the buncher can be used as a master signal in the accelerator sections.

Self-acceleration of an intense electron beam

I. A. Grishaev, A. N. Dedik, V. V. Zakutin, I. I. Magda,
Yu. V. Tkach, and A. M. Shenderovich

(Submitted June 18, 1973)
Zh. Tekh. Fiz., 44, 1743-1748 (August 1974)

The present work describes an experiment on the self-acceleration of an electron beam in a shock-excited resonator. The experiment is performed at beam energies between 500 and 800 keV and beam current between 5 and 15 kA. The increase of 200-250 keV in the beam energy agrees with the calculations. High-frequency modulation of the current in the resonator walls is observed at high currents.

INTRODUCTION

Self-acceleration with the aid of a resonator is one of the most promising methods of accelerating an intense electron beam.[1-5] The method is based upon shock excitation of a resonator by the beam and the acceleration of the beam in the strong electric fields developed by the shock excitation. Fields excited by the leading edge[1] or trailing edge[2-5] of the beam pulse through the resonator can be used for this purpose.

Earlier papers have reported on theoretical investigations of the self-acceleration of a beam,[1-5] measurements on resonators,[4] and measurements of the accelerating fields which had been excited by a beam of low energy and low intensity.[5] The present work is a description of an experiment on the self-acceleration of an intense electron beam with the aid of a resonator.

1. ACCELERATING RESONATOR

The accelerating system is a resonator (Fig. 1) consisting of a coaxial line with the accelerating gap as a load. A resonator of this type is characterized by the advantage that parameters such as the length of the accelerating gap, the characteristic impedance ρ, and the resonance frequency can be varied independently. In particular, a relatively high characteristic impedance can be obtained with small accelerating gaps. The design calculation for this resonator is based on an equivalent circuit approach and summation of voltage and current waves incident and reflected, in sequence, from the short-circuited end of the coaxial line.[4] The first wave, which is excited by the beam, can be determined from the condition U(t) = ρJ(t), where ρ denotes the characteristic impedance of the resonator and J(t), the beam current.

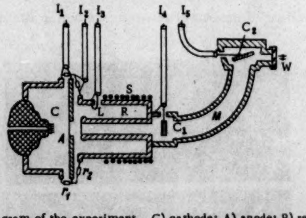

Fig. 1. Diagram of the experiment. C) cathode; A) anode; R) resonator; C_1, C_2) Faraday cylinders; M) magnetic analyzer; W) window through which the light leaves; L) loop for measurement of the field in the resonator; S) solenoid; r_1, r_2) 1/16 Ω resistors for the measurement of the beam current; I_1) current pulse of the gun; I_2) current pulse of the beam in the resonator; I_3) dH/dt pulse in the resonator; I_4) current pulse of the beam from C_1; I_5) current pulse of the beam from C_2.

When the influence of the accelerating gap upon the wave propagation is negligible, the excitation of the coaxial resonator by the beam can be determined by a field approach. This calculation makes it possible to verify the validity of the equivalent-circuit method.

Let us consider a coaxial line which is short-circuited at both ends (Fig. 2). The exciting beam passes through the cross section z = 1/2 and the current density of the beam is

$$j_z = j_\varphi = 0;$$
$$j_r = \frac{\delta\left(z - \frac{l}{2}\right)}{2\pi r} J(r - vt), \qquad (1)$$

where v denotes the beam velocity.

We restrict our considerations to the excitation of TEM waves because TE waves are not excited by a current of the type described by Eq. (1) and because the influence of TM waves is small in cases of practical interest. Let us determine the vector potential A of the excited field in the form of an expansion in eigenmodes:

$$A \equiv A_r(r, z, t) = \frac{1}{r} \sum_{m=0}^{\infty} q_m(t) \sin \frac{\pi m}{l} z. \qquad (2)$$

Substituting Eq. (2) into the wave equation, we obtain

$$\ddot{q}_m + \omega_m^2 q_m = \frac{4c \sin \frac{\pi m}{2}}{l \ln \frac{R}{r_0}} \int_{r_0}^{R} \frac{J(r - vt)}{r} dr, \qquad (3)$$

where $\omega_m = \pi mc/l$.

Solving Eq. (3) and substituting into Eq. (2), we obtain

$$A = \frac{4}{\pi r \ln \frac{R}{r_0}} \int_0^t dt' \int_{r_0}^{R} \frac{J(r - vt')}{r} dr \sum_{m=0}^{\infty} \frac{\sin \frac{\pi m}{2}}{m} \sin \frac{\omega_m}{c} z \sin \omega_m (t - t'). \qquad (4)$$

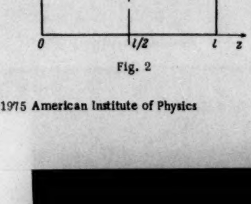

Fig. 2

We are interested in the field at the point $z = l/2$, through which the beam passes. For $t < l/c$, i.e., before the first reflected wave appears, the sum of Eq. (4) is equal to $\pi/4$ or to $-\pi/4$ for various t' values, which, in physical terms, indicates the appearance of a reflected wave. The dt' interval is split into a larger number of terms of alternating signs at greater t values, which in physical terms corresponds to the effect of multiply reflected waves.

We restrict our considerations to the first incident wave ($t < l/c$). According to Eq. (4) the electric field of the first incident wave is (we disregard the influence of space charge)

$$E = -\frac{1}{c}\frac{\partial A}{\partial t} = -\frac{1}{cr \ln \frac{R}{r_0}} \int_{r_0}^{R} \frac{J(r - vt)}{r} dr. \qquad (5)$$

Let us consider a linearly increasing current:

$$J = J_0 \frac{vt + r_0 - r}{t_e v}. \qquad (6)$$

Thus, for $t > (R-r)v$ we have

$$E = -\frac{J_0}{rct_e}\left[t + \frac{r_0}{v} - \frac{R - r_0}{v \ln \frac{R}{r_0}}\right]. \qquad (7)$$

Since it is usually true that $t_e \gg r_0/v$ and $t_e \gg (R-r_0)/v \cdot \ln(R/r_0)$, times $t \gg r_0/v$ and $t \gg (R-r_0)/v \ln(R/r_0)$ are of real interest. The second and third terms in Eq. (7) can be ignored for these times; hence, Eq. (7) coincides with the results of the equivalent-circuit calculation.

According to Eq. (7), the maximum of the retarding voltage is

$$U_{\max} = -\rho J_0 \frac{\Delta t}{t_e}, \qquad (8)$$

where $\Delta t = l/c$.

A calculation similar to the calculation performed here shows that if $t_e/\Delta t$ is an integer, the accelerating voltage has the above value during the flat section of the pulse. When the front does not increase according to a linear law or when $t_e/\Delta t$ is not an integer, the calculations show that U differs from that of Eq. (8), but the difference is not substantial.

When the length of the leading edge of the current pulse is much greater than t_{tr}, the length of the trailing edge, the accelerating voltage is given by Eq. (8) during the trailing edge, but t_e must be replaced by t_{tr}. When t_{tr} is comparable to t_e (and also if the trailing edge is nonlinear), U can differ slightly from U in Eq. (8) as a consequence of the waves which were excited in the resonator by the leading edge.

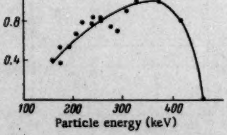

Fig. 3. Spectrum of the accelerator–injector.

Thus, Eq. (8) can be used to estimate the accelerating voltage in both cases.

In the experiments we use a resonator with $\rho = 100\ \Omega$ and $\Delta t = 3 \cdot 10^{-9}$ sec. Calculations with Eq. (8) have shown that the accelerating voltage is $2 \cdot 10^5$ V for $I_0 = 10^4$ A and $t_e = 15 \cdot 10^{-9}$ sec (or $t_{tr} = 15 \cdot 10^{-9}$ sec).

2. METHOD OF THE MEASUREMENTS

Figure 1 shows the experiment. After passing through the grid anode (A), the beam from an injector enters the accelerating gap, excites the resonator, and is accelerated, entering the magnetic analyzer M, in which the beam energy is measured with the aid of a Faraday cylinder C_2.

A direct acceleration, high-current linear accelerator is used as the injector.[6] Measurements are made at accelerator-beam energies between 500 and 800 keV and beam currents I_0 of 5-15 kA in the resonator. Figure 3 shows the spectrum measured in one mode of operation of the injector; the spectrum is obtained from the voltage pulses derived from Faraday cylinder C_2.

The pulses of the beam current in the gun and of the beam current in the resonator are measured with 1/16 Ω resistors r_1, r_2 (Fig. 1) in the form of loops that go around the flanges on which resistors, 1 Ω each, are uniformly distributed on a circle. The design of these loops allows undistorted measurements of pulse fronts of about 1 nsec.

It follows from theoretical considerations that the current pulse in resistor r_2 has both the same amplitude and the same form as the current pulse of the beam. As a matter of fact, by summing the series in Eq. (4) and by differentiating with respect to z, we find that the sum of the oppositely directed currents over the walls of the tube is at the point $z = 0$ (Fig. 2) (for any t and not only for $t < l/c$).

$$J_{\text{wall}} = \frac{1}{\ln \frac{R}{r_0}} \int_{r_0}^{R} J(r - vt) \frac{dr}{r}.$$

In cases of practical interest, in which the beam cur-

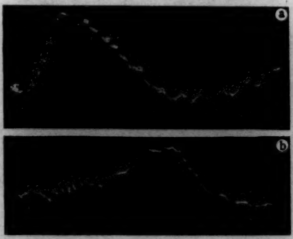

Fig. 4. Beam current pulses in the resonator. A sinusoidal voltage with a frequency of 100 MHz is used for the time scale.

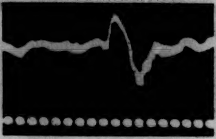

Fig. 5. Voltage pulse derived from the loop (L) in the resonator. Time marks every 20 nsec.

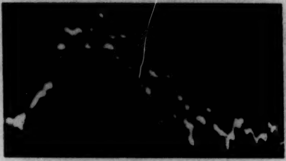

Fig. 6. Current pulse in resistor r_2; the current pulse is modulated by a high frequency.

rent changes only slightly during the time of flight from r_0 to R (see Sec. 1), we find from Eq. (9) that $I_{wall} \approx I$.

Figure 4 shows typical oscillograms of the current pulse of the beam in the resonator.

The beam–current pulses beyond the resonator and beyond the magnet are measured with the aid of cylinders C_1 and C_2, which provide nansecond time resolution. The ends of cables I_4 and I_5 have no load resistances so that the total charge absorbed by the cylinders can be measured. Moreover, a SnS scintillation layer is applied to cylinder C_2 so that visual observation of the electron beam is possible.

3. EXPERIMENTAL RESULTS

Three series of measurements were made to observe the accelerated particles. In the first two of these series, the resonator is initially shorted out and the maximum beam energy is determined by varying the field in the magnet (M); the resonator is then shorted out again and the maximum beam energy is determined again. The electrons are detected on the basis of the luminescence radiation emitted from the scintillating layer applied to C_2. In the first series, in which the anode–cathode gap of the electron gun has a width of 6 mm, an increase in the maximum beam energy from 750 keV to 1 MeV is observed, i.e., the energy increase amounts to 250 keV. In the second series, in which the cathode–anode gap has a width of 4 mm and the initial energy amounts to 550 keV, an energy increase amounting to 200 keV is observed. The accelerating gap of the resonator is 12 mm in these measurements, i.e., the strength of the accelerating field is about 200 kV/cm.

The values which are obtained for the energy increase agree with the theoretical values at this amplitude (10-15 kA) and the form (Fig. 4) of the pulse of the beam current at which the measurements are made [see the above estimate with Eq. (8)].

In the third series, in which the total charge absorbed by cylinder C_2 is measured, a greater energy increase amounting to 500-1000 keV is observed. However, these results are not reliable in view of the strong induction, which resulted in a charging of C_2 even without a beam. The form of the pulse of the beam current is not fixed in this series.

Excitation of the resonator by the beam is observed during the measurements of the first and second series (these observations are made with the loop L of Fig. 1). Both amplitude and shape of the excited magnetic field pulse (Fig. 5) coincide with the calculated values. Moreover, a breakdown of the resonator is observed after passage of the beam, which means that the electric field excited by the beam is very strong.

A high-frequency modulation of the current pulse in the walls of the resonator is detected in the experiments and recorded with the r_2 resistors (Fig. 6). The modulation frequency is close to the double eigenfrequency of the resonator, being about 300 MHz. Modulation occurs at a current in excess of 6 kA and the amplitude of the modulation increases with increasing current.

As has been mentioned above, in the specified-current approximation the shape of the current pulse in r_2 coincides with the shape of the current pulse of the beam. Accordingly, the modulation indicates that feedback in the beam–resonator system exists. The feedback may be related to the development of a longitudinal instability discussed in ref. 7.

CONCLUSIONS

We have established that the self-acceleration of an intense electron beam in the kiloampere range is possible by a shock excitation of a resonator. The resulting increase of 200-250 keV in the beam energy agrees with the theoretical values. Both the excitation of the resonator and the acceleration are observed in the case of a relatively short leading edge and a long trailing edge of the current pulse of the beam (Fig. 4a), as well as in the case of a long leading edge and a relatively short trailing edge of the current pulse (Fig. 4b). Thus, two acceleration mechanisms are observed: in the first case, the self-acceleration of Eq. (1) and, in the second case, the acceleration developing upon interruption of the beam.[2-5] The two mechanisms are simultaneously effective in certain cases. (A short communication on the main results of this experiment has been published in ref. 8.)

General

Secondary-electron energy in a resonance discharge in a three-electrode system

Yu. A. Kulikov, V. V. Ogienko, and Yu. M. Trifonov

(Submitted September 24, 1973; resubmitted January 16, 1974)
Zh. Tekh. Fiz., 44, 1749-1752 (August 1974)

The energy with which the secondary emitters are bombarded by electrons from a secondary-electron-resonance discharge has been studied experimentally in the microwave range in the primary and secondary discharge zones. The discharge is excited in a three-electrode system in which the microwave voltage between one of the emitters and the anode is much lower than the anode potential, which is positive with respect to the emitters. The envelope of the energy spectrum of the electrons bombarding the emitters has a clearly defined peak corresponding to resonance electrons. A large fraction of the electrons from the emitters have energies approximately equal to the resonance value.

The excitation range for secondary-electron-resonance discharges in three-electrode systems has been studied theoretically and experimentally[1,2] for the case in which the microwave voltage applied between one of the emitters and the anode is much lower than the anode potential, which is positive with respect to the emitters. It has been shown that such a discharge in a three-electrode system differs in several fundamental ways from a similar discharge in a high-frequency gap. For example, in a three-electrode system with a constant anode voltage considerably higher than the microwave amplitude the phase condition for excitation is a weak function of the microwave voltage, being governed primarily by the constant anode voltage, the microwave frequency, and the interelectrode distances. The range of favorable starting phases, from which electrons are pulled toward the phase of a resonant electron, is much broader and varies over the volume.

In a three-electrode system, as in a high-frequency gap, the mechanism responsible for the excitation and the maintenance of the secondary-electron-resonance discharge is related to the possible formation of an electron "packet" centered around a resonant electron. Below we report on an experimental study of the energy spectrum of electrons in the packets formed in a secondary-electron-resonance discharge.

The energy spectrum is studied in the microwave range with the apparatus described in ref. 1, supplemented with a two-electrode electron-velocity analyzer. Figure 1a shows the electrodes of the apparatus and the velocity analyzer. The apparatus includes secondary emitters 1 and 2, 10 mm in diameter, with focusing electrodes 7, used to confine oscillating electrons in the interaction region. Anode 3, a quarter-wave cup, is at the end of an open coaxial line; it has a drift tube 10 mm in diameter and 8 mm long. Emitter 1 is at the end of the central conductor of the coaxial line along which the microwave power is supplied to the interaction region. The emitters are 28 mm apart. At the centers of emitters 1 and 2 there are circular apertures 0.4 mm in diameter. Behind the emitters are collectors 4 and 5, Faraday cups with entrance apertures 1.5 mm in diameter. The leads to the analyzer, on the microwave-line guide, lie within the central conductor of the coaxial line. The operating principles of the analyzers are described in refs. 3 and 4. The analyzers are calibrated by recording the retardation curves for an electron flux with a known energy distribution.[3] The secondary emitters 1 and 2 are foils of a Pt−Ba alloy.[5] Electron collectors 4 and 5 contain heaters 6, used to activate the emitters; these also provide the heating needed to produce the thermionic current required to calibrate the analyzers. After calibration we are able to study the electron energy spectrum in the secondary-electron-resonance discharge without any problem. Figure 1b shows the calibration curves. The scatter in the calibration curves in the region up to $U_r = -50$ V is due to secondary emission from the edges of the aperture. In our case this region is not important, so no special measures are used to eliminate the error in this region. The experiments are carried out under pulsed conditions with cold emitters; the chamber pressure does not exceed 10^{-6} torr. The microwave pulses are 30 μsec long. The klystron operates at 850 MHz. The pulse repetition frequency is 50 Hz. The microwave voltage between emitter 1 and anode 3 is determined as in ref. 1, but the power absorption in the discharge is taken into account.

Figure 2a shows the currents of emitters 1 and 2 at $P_{ref} = 1.8$ kW, and the change in the reflected microwave power within the primary and secondary discharge zones.

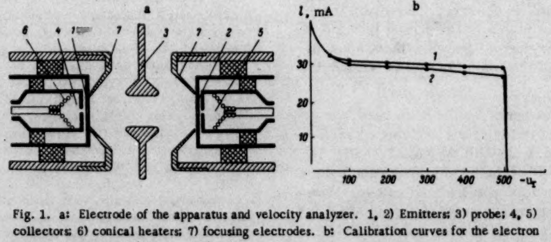

Fig. 1. a: Electrode of the apparatus and velocity analyzer. 1, 2) Emitters; 3) probe; 4, 5) collectors; 6) conical heaters; 7) focusing electrodes. b: Calibration curves for the electron velocity analyzers. 1) I_{an-em_1}; 2) I_{an-em_2}.

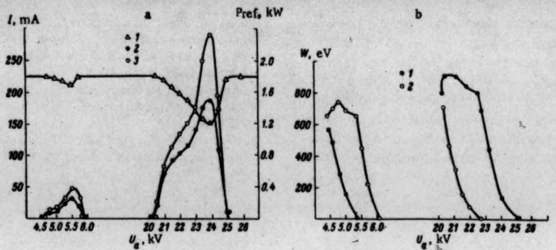

Fig. 2. a: Emitter currents and reflected power in the primary and secondary discharge zones. 1) P_{ref}; 2) I_{em2}; 3) I_{em1}. b: Energies at which the emitters are bombarded by resonant electrons in the primary and secondary discharge zones. 1) W_{em1}; 2) W_{em2}.

The microwave voltage between emitter 1 and the anode varies from 900 to 640 V within the primary discharge zone as a result of power absorption by the discharge, and it varies from 900 to 800 V in the secondary discharge zone. Retardation curves are taken for three values of the anode voltage in each zone. Graphical differentiation of the retardation curves yields the curves in Fig. 3, which show the electron energy spectra.

It follows from the results in Fig. 3 that the electron energy distribution in a secondary-electron-resonance discharge in a three-electrode system has a clearly defined peak. In the primary discharge zone for the electrons bombarding emitter 1 the peak of the energy distribution occurs at a position nearly independent of the anode voltage; for electrons bombarding emitter 2 it shifts toward lower energies between the beginning and end of the zone (Fig. 3a). In the secondary discharge zone (Fig. 3b) we find the opposite pattern: The position of the energy-distribution peak shifts toward lower energies for the electrons incident on emitter 1 and remains relatively constant in the bombardment of emitter 2. We also see that the scatter in electron velocities increases with increasing anode voltage.

In discussing the experimental results we use the prediction of the elementary theory of ref. 1 regarding the energy with which an emitter is bombarded by a resonant electron as a function of the anode voltage. Figure 2b shows this functional dependence, obtained for emitters 28 mm apart, F = 850 MHz, and a microwave voltage of 1 kV between emitter 1 and the anode. Here, W_1 is the energy with which emitter 1 is bombarded and W_2 is the energy with which emitter 2 is bombarded. The energy of a resonant electron incident on emitter 2 falls off rapidly from the beginning of the primary discharge zone to its end, vanishing at U_a = 22.7 kV. The energy with which emitter 1 is bombarded by a resonant electron is roughly constant up to U_a = 22.7 kV; then it falls off to zero at the end of the zone. Here, U_a = 20.4 to 22.7 kV is the range of the two-surface discharge, and U_a = 22.7 to 25.2 kV is the range of the single-surface discharge from the side of emitter 1. For the secondary zone the energy of the resonant-electron bombardment of the second emitter displays a behavior opposite that for the first emitter. Comparison of the results in Figs. 3 and 2b shows that the displacement of the energy-distribution peaks for electrons incident on emitters 1 and 2 corresponds to the functional dependence on the anode voltage of the energy with which the emitters are bombarded by resonant electrons in both the primary and secondary zones. Similar results are obtained at other microwave power levels. On the basis of these results we conclude that the peak of the energy distribution is formed around the resonance value, confirming arguments regarding the resonant nature of the discharge in a three-electrode system. In our apparatus we do not observe a transition from a two-surface

discharge to a single-surface discharge, probably because the transit angles are not the same for electrons starting from the center and the periphery of the emitters, because the potential dips in the anode drift tube. In this connection we do not rule out the possibility that two-surface and single-surface discharges exist simultaneously at the end of the zones; this could explain the increase in the electron velocity scatter toward the end of the zone.

Microcells in cold cathodes

N. P. Kozlov, A. A. Lyapin, and V. I. Khvesyuk

N. É. Bauman Moscow Higher Technical School

(Submitted April 26, 1973)
Zh. Tekh. Fiz., 44, 1753-1757 (August 1974)

An approximate method for analysis of a cold cathode is proposed; this method can be used to determine the basic parameters of the cathode region. Results calculated for a mercury cathode are reported. Analysis of the original system of equations shows that the allowed cell currents lie in a narrow range which is a function of the thermal and emission properties of the cathode material and of the cross section for inelastic electron–atom interactions.

We propose here an approximation method for analyzing a cold cathode which can be used to determine the basic parameters of the cathode region: the current density j, the electronic fraction of a current s, the temperature of the cathode surface T, the density of neutrals n_g, and the electric field E as a function of the characteristics of the material (the heat of vaporization, the thermal conductivity, the cross section for excitation to a metastable level, the work function, etc.), the current in the microscopic cell I, and the cathode potential drop V_C. A similar method could be based on a common analysis of the processes in the cathode region and in the cathode. The system of equations describing these processes is given in ref. 1.

The solution of the equations describing the processes in the cathode region yields equations relating the cathode potential drop and the electric field at the cathode surface to the dimensions of the cathode zones:[2]

$$V_c - V_m = \frac{1}{2} A a^2, \tag{1}$$

$$E = \frac{1}{2} A a, \tag{2}$$

$$A^3 = -\frac{2(1+s) M (n_g \sigma_m 4\pi j)^2}{e \ln\left(3 - \frac{2}{s}\right)} \left[3 - \frac{2}{s} - s\left(3 - \frac{2}{s}\right)^{3/2}\right],$$

$$a = -\frac{1}{2 n_g \sigma_m} \lg\left(3 - \frac{2}{s}\right),$$

where V_m is the potential for the excitation of a cathode atom to the metastable level, M is the mass of this atom, and σ_m is the cross section for the excitation to the metastable level.

Working from the results of ref. 2, we take account only of the surface heat source. We assume that the heat flux q is supplied over the surface of a hemisphere of radius b. Then, in the steady-state approximation the surface temperature for a semiinfinite cathode is

$$T = \frac{b}{\lambda} q, \tag{3}$$

where λ is the thermal conductivity and

$$b = \left(\frac{I}{\pi j}\right)^{1/2}. \tag{4}$$

The heat flux q is determined from the energy-balance equation at the cathode:[3]

$$q = (1-s)(V_i + V_c - \varphi) j + W_{st}. \tag{5}$$

It is legitimate to use the steady-state approximation, since the experimental lifetimes of the microspots[4] τ are much longer than the characteristic times for the establishment of a steady-state temperature distribution, given by[5]

$$\tau^* = \frac{cb^2}{\lambda},$$

where c is the specific heat.

Evaporation is calculated on the basis of the Langmuir equation, which has been shown[6,7] to hold in the case of high vapor concentrations above the surface:

$$G = 0.0583\beta \sqrt{\frac{A}{T}} \exp\left(-\frac{\Lambda}{T}\right), \tag{6}$$

where β is a constant, A is the molecular weight of the cathode atoms, and Λ is the reduced heat of the vaporization. The emission equation is the Fowler–Nordheim equation:[8]

$$j_e = 1.395 \cdot 10^6 \frac{E^2}{\varphi} \exp\left[-\frac{1.19 \cdot 10^9 \varphi^{3/2}}{E} \theta(y)\right], \tag{7}$$

where θ(y) is the Nordheim function and

$$y = \frac{2.09 \cdot 10^{-5} E^{1/2}}{\varphi}. \tag{8}$$

In the calculation we use equations relating the cathode erosion G and the ion-current density j_i to the density of neutrals:

$$j_i = \alpha e n_g v_i; \tag{9}$$

$$G = M n_g v_g, \tag{10}$$

where α is the degree of ionization in the cathode region,

$$v_i = \left(\frac{eV_c}{2M}\right)^{1/2}$$

is the ion velocity, and

$$v_g = \left(\frac{kT}{2\pi M}\right)^{1/2}$$

is the velocity of the neutrals, assumed to be equal to the thermal velocity.

To determine the electric field we use the Mackeown equation[9] instead of Eq. (2),

$$E^2 = 16\pi \left(\frac{m_e}{2e}\right)^{1/2} V_c^{1/2} \frac{j}{1 - \frac{j_i}{j_e}} \left[\left(\frac{M}{m_e}\right)^{1/2} \frac{j_i}{j_e} - 1\right], \tag{11}$$

since these equations give approximately the same values of E, and the use of Eq. (11) simplifies the calculations.

This system of equations is highly nonlinear and cannot be solved analytically in general form. We used the circumstance[1] $f = 1 - s \leq 0.1$ to simplify Eqs. (1) and (11).

To analyze this system of equations we substitute (10) into (6), finding

$$n_g = \frac{0.1463\sqrt{A}}{\sqrt{kMT}} \exp\left(-\frac{\Lambda}{T}\right), \qquad (12)$$

where k is the Boltzmann constant.

Substituting Eqs. (5) and (4) into (3), we find

$$n_g = \frac{7.25 \cdot 10^{8} \lambda^{4/3} M^{1/3}}{\sigma_m^{2/3} \alpha^{1/3} V_c^{1/6} I^{2/3} (V_i + V_e - \varphi)^{4/3} (V_e - V_m)^{1/2}} T^{4/3}. \qquad (13)$$

Equations (12) and (13) are shown graphically in Fig. 1. We see that there are two possible solutions to the problem; in a previous paper[10] we only found solution I. This solution is stable, but the characteristic density and temperature are too high [$n_g \sim 10^{22}$ cm^{-3}; $T \sim (3\text{–}6) \cdot 10^3$ °K]. Solution II is unstable. It has been shown[4,11] that an internal instability is associated with processes at a cold cathode; thus, solution II may, in fact, reflect the actual situation.

We have carried out calculations for a mercury cathode, assuming $V_c = 10$ V, $I = 0.08$ A (ref. 4), and $\varphi_{eff} = 2$ eV. We choose the condition $\varphi_{eff} < \varphi$, which takes account of the effect of the local fields (solution II): $j = 1.55 \cdot 10^6$ A/cm^2, $n_g = 4.2 \cdot 10^{20}$ cm^{-3}, $E = 1.55 \cdot 10^7$ V/cm, $f = 0.11$, $\alpha = 1.6 \cdot 10^{-2}$, and $T = 1.3 \cdot 10^3$ °K.

We see from Fig. 1 that a solution does not exist for certain values of the initial parameters, since the corresponding curves do not have intersections. The condition for the existence of a solution is found by equating Eqs. (12) and (13) and their derivatives with respect to the temperature; it is

$$\alpha I^2 = \frac{1.06 \cdot 10^{-34} \lambda^4 M \Lambda^7}{\beta^3 \sigma_m^2 V_c^{1/2} (V_i + V_e - \varphi)^4 (V_e - V_m)^{3/2}}. \qquad (14)$$

The free parameters are V_c and I; however, since V_c is known quite well from experiment,[4,12] we turn to a determination of the allowable range of cell currents I. We see from (13) that there is a certain minimum current I_{min} below which no solution exists for Eqs. (12) and (13). An equation for I_{min} is obtained from the general solution of the system of equations, taking condition (14) into account:

$$\lg A_2 - \frac{3}{2}\lg A_1 + \lg I_{min} + \frac{1}{2}\lg n_{ge} = \frac{2.58 \cdot 10^{8} \varphi^{3/2} I_{min}}{B_1 A_1^{3/4} n_{ge}^{1/2}} \theta(y),$$

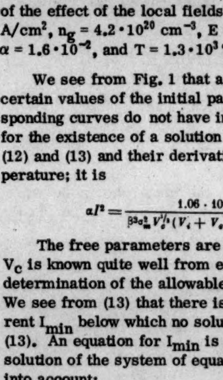

Fig. 1. Typical shapes of the calculated curves. 1) Eq. (12); 2) Eq. (13).

where n_{ge} is determined from

$$\frac{7}{4}\lg n_{ge} + \frac{3}{4}\lg A_1 = -\lg A + \frac{3}{4}\lg B - \frac{0.435\Lambda B^{3/4}}{n_{ge}^{3/4} A_1^{3/4}},$$

$$\lg A = -18.346 - \lg\beta,$$

$$A_1 = \frac{1.44 \cdot 10^{-18} \lambda^{4/3} M^{1/3} \Lambda^{7/3}}{\beta \sigma_m^{2/3} V_c^{1/6} (V_i + V_e - \varphi)^{4/3} (V_e - V_m)^{1/2}},$$

$$\lg A_2 = \lg B_2 - 9.778,$$

$$B = \frac{2.2 \lambda^{4/3} M^{1/3}}{\sigma_m^{2/3} V_c^{1/6} (V_i + V_e - \varphi)^{4/3} (V_e - V_m)^{1/2}},$$

$$B_1 = 3.31\sqrt{V_c},$$

$$\lg B_2 = 16.693 + \frac{1}{4}\lg V_c - \lg\varphi + \frac{1}{2}\lg M + \lg\sigma_m + \frac{3}{4}\lg(V_e - V_m),$$

θ(y) is the Nordheim function, and

$$y = \frac{9.35 \cdot 10^{-3} B_1^{1/2} A_1^{3/4} n_{ge}^{1/4}}{I_{min}^{1/2} \varphi}.$$

If we assume further that (12) does not hold at high vapor concentrations above the surface and that the equation corresponding to (12) is such that a solution of Eqs. (12) and (13) exists for any T, there is still a lower boundary on the cell current, determined from the condition

$$n_g < n_{solid}.$$

The upper limit on the cell current is determined from the obvious condition $\alpha \leq 1$:

$$\frac{7}{4}\lg n_{gr} = -\lg A_3 + \frac{3}{4}\lg B - \frac{1}{2}\lg I_{max} - \frac{3.37 \cdot 10^4 \Lambda B^{3/4}}{n_{gr}^{3/4} I_{max}^{1/2}},$$

where h_{gr} is found from

$$\lg B_2 + \frac{1}{2}\lg n_{gr} = \frac{1.55 \cdot 10^{13} \varphi^{3/2}}{B_1 n_{gr}^{1/2}} \theta(y),$$

$$\lg A_3 = \lg A - 4.889;$$

$$y = \frac{1.21 \cdot 10^{-7} B_1^{1/2} n_{gr}^{1/2}}{\varphi}.$$

For a mercury cathode and under the conditions given above, we find the following limits on the cell current: $I_{min} = 0.043$ A and $I_{max} = 0.42$ A.

On the basis of this discussion we can draw the following conclusions:

1. The calculated results agree with the data of several experimental papers with regard to current density,[13] relative ion current,[14,15] and density of neutrals.[16]

2. The range of currents I over which a solution exists is narrow and is a function of the thermal and emission characteristics of the cathode material. We note that the experimental cell currents of refs. 4, 17 lie within the range found here.

3. As the thermal conductivity λ increases, the current range shifts toward larger values, also in agreement with experimental data.[4]

4. A reduction of the heat of vaporization Λ shifts the current range toward lower values.

5. If a film cathode is used (or, correspondingly, if

the thermal conductivity λ is reduced), the I range is shifted toward lower values.[4]

6. As the cross section for excitation to a metastable level σ_m is increased the current range shifts toward lower values.

Evaporation rates of the system ZrC + x% W for the temperature range 2300-3000°K

N. M. Karnaukhova, V. A. Luknitskii, and I. A. Maslov

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted March 19, 1973)
Zh. Tekh. Fiz., 44, 1758-1764 (August 1974)

The evaporation rate of solids in vacuum is measured by letting the test substance condense onto a water-cooled metal collector whose removable part is an aluminum foil. The collector and the condensate are irradiated by neutrons in a nuclear reactor; after the irradiation the condensate is removed in a mixture of nitric and hydrofluoric acids. Evaporation rates are measured for ZrC, W, and ZrC + x% W (x ≃ 10 and 30%). The amounts of zirconium (according to ^{95}Zr) and tungsten (according to ^{187}W) are determined from direct γ spectrometry of the solution. For the compounds ZrC + x% W a radiochemical procedure is proposed for separation; the procedure involves extraction with α-benzoinoxime in chloroform. The evaporation experiment is carried out in a metal apparatus at 10^{-7}-10^{-8} torr, with the mass composition of the residual gases being monitored. The emissivities of the evaporating substances are measured under the vacuum conditions.

INTRODUCTION

Measurements of the evaporation rates of refractory materials based on zirconium carbide are of considerable practical interest because of the proven and potential technological applications of these materials – in thermionic convecters, protective coatings, etc. One such promising material is the compound ZrC + x% W, in which tungsten is used to reduce the evaporation rate of the carbide.

If pure tungsten is used in a study of the evaporation rate of such materials in vacuum as a function of the tungsten content, as in our case, in which this content is varied from 0% to 100% (by weight), special precautions are necessary.

First, any trace of moisture leads to a gas-transport reaction in which tungsten is transported from relatively hot regions to relatively cool regions.[1] Accordingly, experiments of this type must be carried out in a high vacuum and the mass composition of the residual gas must be monitored for water, oxygen, and organic matter.

Second, accurate measurement of the temperature of a particular sample requires knowledge of its emissivity, which is a function of the composition of the material and, probably, the residual gas composition. It follows that the emissivity must be measured under experimental conditions designed to eliminate the need for indirect conversions, which lead to errors.

Both these requirements are met by the apparatus designed for these experiments. Furthermore, since the range of relatively low temperatures which we study (of practical importance in connection with thermionic conversion) is characterized by comparatively low evaporation rates and very small amounts of condensate, the apparatus is designed with provision for the collection of the condensate on the collector and for subsequent neutron-activation analysis of the zirconium and tungsten contents.1)

We have not been able to determine the amount of evaporated material by direct γ spectroscopy because of the significant interference of ^{24}Na formed from the collector material (Al) during the reactor irradiation in the reaction $^{27}\mathrm{Al}(n, \alpha)\,^{24}\mathrm{Na}$. The sodium passes into solution during the scouring of the condensate. Furthermore, the resolution of the NaI(Tl) detector is inadequate for distinguishing the necessary γ lines: those of ^{187}W (480 and 686 keV), ^{95}Zr (750 keV), and ^{97}Zr (666 and 750 keV). We therefore use a radiochemical method for separating the radioactive Zr and W isotopes.

EXPERIMENTAL APPARATUS AND PROCEDURE

The experimental apparatus is designed for operation in a vacuum of 10^{-7}-10^{-8} torr (most of the measurements are carried out at a residual gas pressure $< 10^{-7}$ torr); at these pressures ($P_{O_2} \leq 10^{-8}$ torr) there are no oxides in the vapor phase during the evaporation of tungsten, and only atomic tungsten particles are observed.[3] The metal apparatus is made of stainless steel with six removable flanges with copper seals. The system of traps and valves provides complete isolation of the working chamber from oil vapor after the general degassing by heating, which is carried out for 7-8 h at 330°C. The vacuum is monitored by LT-2, LM-2, and IM-12 gauges and an RMO-4S omegatron gauge. The temperature is measured through a glass window, which is covered in the intervals between temperature measurements by an internal shutter or by the collector itself.

Rods of the material being tested (1.5-1.7 mm in diameter and 40 mm long) are mounted on water-cooled copper leads with tungsten tips, through which heating is car-

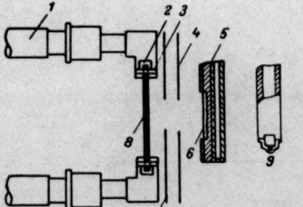

Fig. 1. The evaporation apparatus. 1) Cooled heater-current leads; 2) tungsten tips; 3) tantalum clamp; 4) tantalum shield; 5) cooled copper collector disk; 6) aluminum collector; 7) additional W shield; 8) test rod; 9) device for attaching the test rod to the current lead (view along the rod axis).

ried out by current at the line frequency. Two shields (tungsten and tantalum) with irises are used to cut out the flux of evaporated material from the central part of the rod, which exhibits a temperature drop of less than 20°.

Figure 1 shows the evaporation apparatus.[2] The collector is aluminum tape (99.999% pure), 80 mm long, 30 mm wide, and 0.09 mm thick, pressed against a copper half-cylinder cooled by running water.

A special mechanism makes it possible to carry out the evaporation four times on different parts of the tape (an individual spot of condensate has dimensions of 8 × 16 mm), and the collector can be moved aside for the time required to bring the apparatus to working conditions and for the time required to measure the temperature.

The rod temperature is measured at intervals of 10-20 min and held constant within ± 20° during an experiment.

At the end of an evaporation cycle (consisting of four exposures for a single temperature), the aluminum tape with the deposit of evaporated material is sent to a VVR-M reactor for neutron irradiation and for subsequent activation analysis.

The evaporation rate is calculated as in ref. 2.

Before the irradiation the collector tape is rolled up into thin aluminum foil (0.02 mm thick) and placed in a container unit. Up to 16 collectors are irradiated simultaneously in a single container unit. Reference samples packed in quartz ampoules are irradiated along with the collectors. For the case of Zr these reference samples consist of $5 \cdot 10^{-3}$g of zirconyl chloride ($ZrOCl_2 8H_2O$), and in the case of tungsten they consist of $2 \cdot 10^{-6}$g of tungstic acid (H_2WO_4).

After irradiation in a vertical reactor channel [flux $(3\text{-}5) \cdot 10^{13}$ neutrons/($cm^2 \cdot sec$) for 24 to 100 h], the radioactive zirconium and tungsten isotopes are separated radiochemically. The condensate is scoured in a Teflon cup in 2-3 ml of a mixture consisting of 2 parts of HNO_3 (1:1) and 1 part of concentrated HF. First, 0.2 ml of the tungsten-carrier solution (H_2WO_4, 10^{-5} g) is added to the mixture. The collector is cut into the four parts corresponding to the four evaporation exposures, and each part is etched[2)] separately for 1 min. An experimental check shows that the condensate is removed essentially completely by a single etching. The thickness of the film removed in a single etching is about $5 \pm 0.005\mu$ and the same with triple etching.

The Zr and W are separated by an extraction method with α-benzoinoxime in chloroform. The separation procedure used for the case of pure zirconium carbide is described in ref. 4. To the solution of the condensate we add 17 ml of water and 1 ml of concentrated HCl; then the tungsten is extracted twice with 15 ml of a 0.15% solution of α-benzoinoxime in chloroform. The chemical yield[3)] of tungsten in the organic phase is 98%. The zirconium activity is measured in the aqueous phase.

For a quantitative determination of the zirconium content we measure its activity on the basis of the isotopes $^{95}Zr + ^{95}Nb$ (the γ lines at 750 and 770 keV); in the case of tungsten we use the isotope ^{187}W (the γ lines at 480 and 686 keV). The γ activity is measured by a spectrometer consisting of a scintillation unit with a NaI(Tl) crystal (63 × 63 mm in size, having a 9% resolution at the 662-keV line) and an AI-256 multichannel pulse-height analyzer. The count rate − the area of the γ spectral peak − ranges from 2 to 1000 sec^{-1} for the various samples.

Analysis of eight samples (including the cooling of the irradiated samples, the radiochemical separation, and the activity measurements) requires about three days. The samples of the compositions studied are prepared by the powder-metallurgy method from zirconium carbide and "especially pure" tungsten.[4)]

EMISSIVITY MEASUREMENTS

To determine the emissivity we select rods of those lots for which evaporation experiments have been carried out (except for the case of pure tungsten, for which we use the tabulated values[6]) and we construct a "blackbody" of each compound. For this purpose we use an electric-spark method to machine a depression 0.15 mm in diameter and 1 mm deep in the central part of a rod. The actual temperature is measured by training an LMP-066 optical micropyrometer onto the bottom of the depression and the brightness temperature is measured by training it onto the rod surface. All the measurements are carried out in the same apparatus, in the same high vacuum as in the evaporation experiments. An estimate of the error in the measurements of the actual temperature due to the imperfections in the blackbody model[7] shows this error to be less than 1%. The calculations are carried out on the basis of the standard equation.[8] The results are shown in Fig. 2.

We see from these figures that there is a tendency for ε_λ to decrease with increasing temperature for all the materials studied, in agreement with the data for tungsten[6] and zirconium carbide.[8] Then, as the tungsten content is increased, the values of ε_λ for these compositions decrease, approaching the values characteristic of tungsten.[5)] The brightness temperature in these measurements is detected by an OPIR-17 optical pyrometer, and the accuracy of its indications is monitored by means of an LMP-066 micropyrometer. The values of $\varepsilon_\lambda(ZrC)$ and

ε_λ(ZrC + 10% W) are essentially the same. There is some discrepancy between our results and those of ref. 8, probably because of differences in the materials and in the vacuum conditions.

MASS COMPOSITION OF THE RESIDUAL GASES

The residual gases must strongly influence the evaporation of hot metal carbides as a result of the interaction with the surfaces of these carbides.[10]

In the unheated evacuated apparatus, with an oil vapor pump, the pressure in the system is governed primarily by gases containing oxygen (H_2O, CO, CO_2) and by hydrocarbons (C_xH_y); the water content can reach 90% of the total pressure.[11] In working out the heating conditions for our apparatus we study the mass composition of the residual gases under all operating conditions. The partial pressures of the residual gases are measured by an IPDO-1 apparatus with an RMO-4S omegatron gauge. Figure 3a shows a typical residual-gas spectrum, for the heating of ZrC + 10% W. An important change in the mass composition is observed near the beginning of an exposure.

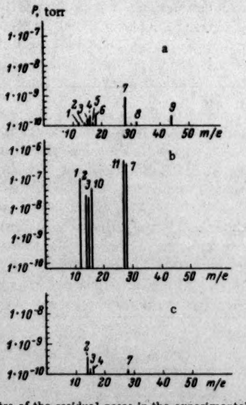

Fig. 3. Mass spectra of the residual gases in the experimental apparatus (ZrC + 10% W). a: Apparatus heated under the oven. $P_{res} = 6 \cdot 10^{-8}$ torr, T = 293°K, ZrC + 10% W. b: Sample heated to 2480°K. $P_{res} = 18 \cdot 10^{-5}$ torr. c: Vacuum conditions at the time of the measurements for exposures. $P_{res} = 4 \cdot 10^{-8}$ torr, T = 2480°K. 1) C^+; 2) N^+, CH_2^+; 3) CH_3^+; 4) O^+, CH_4^+; 5) OH^+; 6) H_2O^+; 7) N_2^+, CO^+; 8) O_2^+; 9) CO_2^+; 10) CH_4, 11) $C_2H_3^+$.

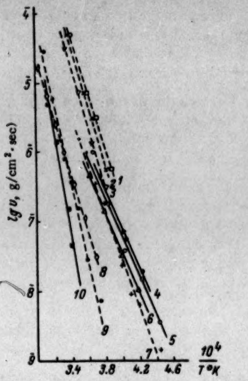

Fig. 4. Evaporation rates of ZrC, W, and samples made from them. 1) ZrC (ref. 9); 2) ZrC + 10% (ref. 9); 3) ZrC + 30% W (ref. 9); 4) ZrC (this work); 5) ZrC + 10% W (this work); 6) ZrC + 30% W (this work); 7) ZrC (ref. 10); 8) W (ref. 6); 9) W (ref. 12); 10) W (this work).

For example, masses at 17, 18, 32, and 44 (OH^+, H_2O^+, O_2^+, CO_2^+) are not observed; the peaks with masses of 14, 15, 16, and 28 (N^+, CH_2^+, CH_3^+, O^+, CH_4^+, N_2^+, CO^+) remain considerably lower than those according to the corresponding data of ref. 10. We see that our experiments have been carried out under qualitatively better vacuum conditions, with a higher total vacuum.

EXPERIMENTAL RESULTS AND DISCUSSION

The experimental results are shown in Table 2 and Fig. 4; the figure also shows data of other investigators.

Analysis of these results reveals that zirconium carbide evaporates fastest. The composition with 30% tungsten displays an evaporation rate about half as large over the temperature range studied. The lowest evaporation rate is of course that of tungsten.

Our values for the evaporation rates of ZrC, ZrC + 10% W, and ZrC + 30% W are considerably lower than the values of ref. 9; this result is to be expected since our measurements are carried out in a considerably higher vacuum. The results of ref. 10, found under relatively better vacuum conditions, show better agreement with the present results.

The discrepancy between the line slopes, which give the heats of vaporization, can also be attributed to differences in the vacuum conditions (the pressure and the mass composition of the residual gases), and perhaps to differences in the chemical compositions of the materials studied. It is interesting to note the clearly defined tendency for the residual gas pressure to affect the slopes of the lines for pure tungsten and the slopes of the lines for the compositions including zirconium carbide in opposite manners.

In the former case, as the pressure is reduced [10^{-5} torr (ref. 6), $8 \cdot 10^{-7}$ torr (ref. 12), and $1.4 \cdot 10^{-7}$ torr (the

present experiments)], the line slope increases. In the latter case [$(1\text{–}2)\cdot10^{-5}$ torr (ref. 9), $4\cdot10^{-7}$ torr (ref. 10), and 10^{-7}–10^{-8} torr (the present experiments)], we find the opposite tendency. While in the case of tungsten this tendency could be interpreted as a change in the evaporation mechanism, from oxide evaporation to evaporation of the pure metal, with a corresponding increase in the heat of vaporization, in the case of the materials based on zirconium carbide the data available allow us only to note a significant change in the evaporation process as the vacuum in the evaporation apparatus is improved.

---

[1] A similar procedure for ZrC evaporation in a vacuum of 10^5–10^6 torr has been described previously.[2]

[2] Before the deposition, the collector surface is treated with similar threefold etching.

[3] The authors thank G. I. Karazhanova, who was very helpful in solving the chemical questions.

[4] The samples have been synthesized at the State Institute of Applied Chemistry and graciously furnished by R. G. Avarbé and T. A. Nikol'skaya, whom the authors thank. The synthesis procedure is described in ref. 5. The chemical composition of the original samples is shown in Table 1. The sample porosities were 16% for ZrC, 7% for ZrC + 10% W, and 5% for ZrC + 30% W.

[5] In light of these results we note that the literature reveals significantly different results[9] for "poor vacuum conditions" for the analogous materials: $\varepsilon_\lambda = 0.51$ for ZrC + 10% W and $\varepsilon_\lambda = 0.53$ for ZrC + 30% W.

Mass-spectrometer study of the ion composition of a glow discharge

N. P. Egorov and V. N. Komarov

L. Ya. Karpov Scientific-Research Physicochemical Institute, Moscow

(Submitted April 9, 1973)
Zh. Tekh. Fiz., 44, 1765-1769 (August 1974)

The composition of the beams and the ion composition have been studied in the negative glow of glow discharges in nitrogen, mixtures of nitrogen with helium and argon, air, and carbon dioxide. The discharges are studied over the pressure range 0.1-0.8 torr and at current densities ~ 10^{-4} A/cm². The experimental apparatus and procedure are described. A KM-1 quadrupole mass spectrometer is used as mass analyzer. A system of grids is used to study the energy distribution of the ions emitted from the discharge tube. The ions are extracted from the negative glow through an aperture in the anode. The extraction mechanism is discussed.

We report here on a study of the ion composition in the cathode region of a glow discharge. A mass-spectrometer method has been developed for this purpose. The literature reveals several cases[1-13] in which the positive-ion composition in a dc discharge has been studied by mass-spectrometer methods. The work can be divided into two groups: 1) studies of channeled beams;[7-10] 2) study of the positive column, the negative glow, and the Faraday dark space.[1-6,11,12] In a study of channeled beams the ions are extracted through an aperture in the cathode; in studies of the intermediate parts of a discharge the extraction is carried out through an aperture in the side wall of the discharge tube. In the present experiments, in contrast, an analysis of the channeled beams is combined with an analysis of the positive ions in the negative glow. In this procedure the positive ions are extracted through an aperture in the anode, which is in the negative glow (in this case, there is no anode region, positive column, or Faraday dark space). The extraction is assumed to occur as the result of a negative potential drop. The energy spread of the ions emitted from the aperture in the anode is 2-5 eV.

Ions approaching the cathode of a glow discharge have a broad energy distribution (up to several hundred volts). Accordingly, in the study of channeled beams we use a quadrupole mass spectrometer (the KM-1; ref. 14), which has the important advantage of a resolution which is not a function (within a certain range) of ion energy. It is possible to collect efficiently ions with a large energy spread. Other characteristics[15] of the quadrupole mass spectrometer indicate that this type of spectrometer is highly suitable for plasma studies.

Figure 1 shows the experimental apparatus. The ions are extracted through an aperture 0.1 mm in diameter in electrode 3, which can serve as either the anode or the cathode of discharge tube 1. The other electrode, 2, can be moved by means of a magnet. Both electrodes are made of stainless steel and have diameters of 2.2 cm, approximately equal to that of the discharge tube. The discharge tube is made from molybdenum glass. Conical electrode 4 performs accelerating and focusing functions. Grid system 5 is used to record the ion distribution with respect to kinetic energy. Ionization box 6 is used to analyze the neutral component in the discharge. In front of the quadrupole rods 10 are the extracting and focusing irises of the KM-1 quadrupole mass spectrometer. After mass analysis the ion beam strikes secondary electron multiplier 11.

Fig. 1. The experimental apparatus. 1) Discharge tube; 2) movable electrode; 3) electrode with aperture; 4) accelerating and focusing electrode; 5) grids for recording the ion energy distribution; 6) ionization box; 7) heater filament; 8) reflector; 9) extracting and focusing irises of the KM-1; 10) quadrupole rods; 11) secondary electron multiplier.

The analyzer is evacuated by an ÉRA-100 vacuum pump. When the pressure in the discharge cell is in the range 0.2-0.8 torr the corresponding pressure in the analyzer is $5\cdot10^{-6}$-$2\cdot10^{-5}$ torr. The gases and mixtures to be tested are admitted into a chamber having a volume of ~15 liters connected to the discharge. The large volume makes it possible to operate continuously without any appreciable pressure change in the discharge tube due to the escape of gas through the extraction aperture. The pressure in the discharge tube is assumed to be equal to the pressure in the chamber and is measured with an LT-2 thermocouple gauge.

We use technical grade nitrogen, spectrally pure helium and argon, and carbon dioxide.

EXPERIMENTAL RESULTS AND DISCUSSION

Most of the ions in the channeled beams from the discharge in nitrogen are N_2^+ and N^+ ions. There is also a contribution to the ion current with m/e = 14 from N_2^{++} ions, as can be inferred from the existence of ions with kinetic energies higher than the voltage across the discharge tube. We also observe N^{++} and N_3^+ ions and impurity Ar^+ ions. The N_3^+ current is about 1% of the total ion current.

A change in the anode–cathode separation does not affect the composition of the channeled beams until the anode approaches the boundary of the cathode dark space and the negative glow. This observation implies that ions

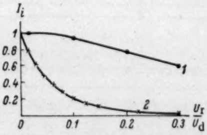

Fig. 2. Reduced ion current J_i in the channeled beam as a function of the retardation potential U_r. The discharge is in nitrogen at a pressure of p = 0.3 torr, and the current density is j = $2\cdot10^{-4}$ A/cm². Here U_d is the voltage across the discharge tube. 1) N^+; 2) N_2^+.

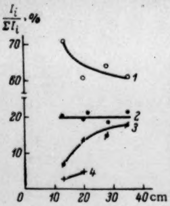

Fig. 3. Relative ion current in the negative glow as a function of the distance between the cathode and the anode. Discharge in nitrogen, p = 0.3 torr, j = $2 \cdot 10^{-4}$ A/cm². The ions are extracted through an aperture in the anode. 1) N_2^+; 2) N^+; 3) N_4^+; 4) N_3^+.

produced in the cathode dark space or in the first part of the negative glow move toward the cathode. Figure 2 shows the ion current as a function of the retardation potential. The distribution of N_2^+ ions with respect to kinetic energy agrees qualitatively with the distribution obtained on the basis of a model in which resonant charge exchange is treated as the decisive factor governing this distribution:[7]

$$\frac{V_c}{N_0}\frac{dN}{dV}=\frac{L}{2l}e^{-\frac{L}{2l}\frac{V_x}{V_c}}, \tag{1}$$

where l is the characteristic length for resonant charge exchange, N_0 is the number of ions coming from the negative glow, L is the length of the cathode dark space, V_c is the cathode potential drop, and V_x is the potential corresponding to the ion energy.

As expected, the width of the distribution is inversely proportional to the pressure ($l \sim 1/p$).

A mechanism which affects the particle energy distribution like resonant charge exchange is gas ionization in the cathode dark space by electrons; furthermore, there is the possible dissociation

$$N_2^+ + N_2 \rightarrow N^+ + N + N_2. \tag{2}$$

The distribution for N^+ ions is broader than that for N_2^+ ions; there are no ions of zero kinetic energy.

The increase in the contribution of the N_2^+ ions to the total ion current from 80% to 90% as the pressure is raised from 0.2 to 0.7 torr may be due to a reduced contribution of process (2) to the observed ion currents. It would be interesting to compare the ion composition in the negative glow with that of the channeled beams. We see from Fig. 3 that in the negative glow there are a large number of N_4^+ ions; the relative number of these ions in the total ion current increases with distance from the boundary of the cathode potential drop into the negative glow. The fact that the weakly bound N_4^+ ion is not observed in the channeled beams is evidently due to its dissociation in collisions with gas molecules in the region in which the electric field is strong.

We have studied the ion composition in discharges in mixtures of nitrogen with argon and helium. We find that in the case of the nitrogen–argon mixture the ratio of the current of Ar^+ ions to the sum of the N_2^+ and N^+ currents in the negative glow agrees well with the ratio calculated from the relative abundances of the two components and the cross sections for ionization by the electron beam. It should also be noted that we have detected ArN_2^+ and ArN^+ ions in the negative glow; the relative concentration of the ArN_2^+ ion increases with distance from the cathode, in agreement with the assumption that this ion is formed in a reaction involving an excited argon atom:[16]

$$Ar^* + N_2 \rightarrow ArN_2^+ + e. \tag{3}$$

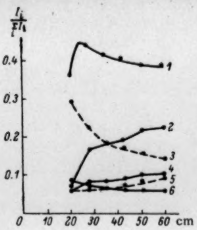

Fig. 4. Relative ion current from the negative glow as a function of the cathode–anode separation. Discharge in carbon dioxide, p = 0.1 torr, j = $2 \cdot 10^{-4}$ A/cm². 1) O_2^+; 2) $H_2CO_2^+$; 3) CO_2^+; 4) H_2CO^+; 5) H_3O^+; 6) CO^+. The HCO^+ currents (~ 0.07 of the total ion current) are not shown, nor are the small currents corresponding to O^+ and C^+ ions.

In the helium–nitrogen mixture the behavior of the ion currents is very different from that in the case just discussed. Near the cathode the ion current is governed primarily by N_2^+ and N^+ ions, even at concentrations on the order of 1%. It is difficult to explain this result under the assumption that the ions are formed only as a result of electron impact. In the negative glow a current of helium ions is detected only near the boundary of the negative glow, and its relative contribution to the total current is an order of magnitude lower than that near the cathode. The ratio of ion currents in the He discharge can be attributed to the contribution of Penning ionization,

$$He^* + N_2 \rightarrow He + N_2^+ + e,$$

or the reaction[17]

$$He^+ + N_2 \begin{cases} \nearrow He + N_2^+, \\ \searrow He + N^+ + N. \end{cases}$$

The positive ions in the carbon dioxide are analyzed at pressures in the range p = 0.1-0.8 torr and at currents in the range 0.08-6 mA. Most of the ions in the channeled beams are CO_2^+, O_2^+, CO^+ and C^+ ions; there are also O^+ (~ 6%) and H_2O^+ (~ 1%) ions. As the discharge current is

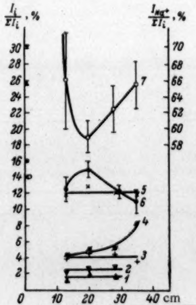

Fig. 5. Relative ion current as a function of the distance to the cathode. Discharge in air, p = 0.3 torr, j = $2 \cdot 10^{-4}$ A/cm². The values for zero distance to the cathode are the ion contributions to the channeled beams. 1) O^+; 2) N^+; 3) N_2O^+; 4) H_3O^+; 5) O_2^+; 6) N_2^+; 7) NO^+.

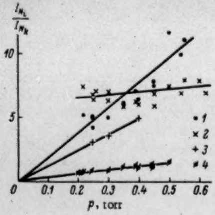

Fig. 6. Ratios of ion currents as functions of the pressure in the discharge tube. Discharge in air, $j = 2 \cdot 10^{-4}$ A/cm². 1) $I_{NO^+}/I_{N_2^+}$; 2) $I_{NO^+}/I_{O_2^+}$; 3) I_{NO^+}/I_{N^+}; 4) $I_{O_2^+}/I_{N_2^+}$.

raised from 0.08 to 2 mA ($p = 0.25$ torr), the relative CO_2^+ contribution falls off from 50% of the total ion current to 20%, while the contributions of O_2^+ and CO^+ increase from 17% to 24% and from 6% to 40%, respectively. Of primary interest in the negative-glow region (Fig. 4) is the intense peak with $m/e = 46$ ($H_2CO_2^+$); this peak is not observed in the neutral composition. In addition to $H_2CO_2^+$ we detected other ions containing hydrogen: H_3O^+, H_2CO^+, HCO^+, and HCO_2^+. We note that, as in ref. 12, at a sufficiently high current density the O_2^+ ions are predominant.

Figure 5 shows the results obtained for discharges in air. Most of the ions in the negative glow are NO^+, N_2^+, O_2^+, H_2O^+, H_3O^+, N^+, O^+, N_2O^+, and Ar^+ ions. As the pressure is raised from 0.3 to 0.6 torr the relative NO^+ current increases from 60% to 80% of the total ion current. The large ratio of the O_2^+ current to the N_2^+ (~ 1, although the mixture contains only ~ 20% oxygen) can be attributed to the formation of O_2^+ in charge exchange $N_2^+ + O_2 \rightarrow N_2 + O_2^+$ or to the consumption of N_2^+ ions in the ion–molecular reaction

$$N_2^+ + O_2 \rightarrow NO^+ + NO.$$

A further contribution to the formation of NO^+ ions probably comes from the reaction

$$N^+ + O_2 \rightarrow NO^+ + O.$$

These mechanisms are consistent with the functional dependences of the relative ion currents on the pressure shown in Fig. 6. In contrast with the case in the negative glow, the intensities of the NO^+, O_2^+, and N_2^+ currents in the channeled beams are about the same (~ 15%), and the N^+ and O^+ intensities increase sharply (~ 30%), probably because of the dissociation of the molecular ions in the high-energy part of the cathode fall.

Energy losses of slow electrons reflected from molybdenum and tungsten single crystals

O. M. Artamonov, B. B. Bolotov, and M. V. Kremkov

A. A. Zhdanov State University, Leningrad

(Submitted August 30, 1973; resubmitted January 3, 1974)
Zh. Tekh. Fiz., 44, 1770-1773 (August 1974)

The energy spectra of scattered electrons and secondary electrons are obtained for various states of the surfaces of the (100) face of Mo and the (110) face of W. A change in the position of the maxima of the energy losses is observed when the single-crystal surfaces are outgassed. Keeping the samples in N_2 or H_2 or in an atmosphere of residual gases increases the intensity of both the elastic and inelastic maxima and, at the same time, raises the work function of the surface.

The energy losses of slow electrons reflected from a surface are of interest for studying the interaction of electrons with a solid and for investigating the energy conditions at the surface of a crystal. Groups of electrons losing an energy of 1.5 or 4.3 eV upon excitation of the energy transitions to subsurface bands are reported in refs. 1 and 2 for the (100) face of W. Similar energy losses at 3.0 and 5.4 eV are observed in ref. 3 in the case of the (110) face of W. Maxima which are associated with the excitation of oscillations of gas molecules adsorbed on the surface,[1] or with the excitation of electron transitions from the levels of adsorbed O_2, CO, and H_2O molecules,[2] or with the excitation of plasma oscillations of the valence electrons of tungsten[4] are identified in the spectra of the energy losses. In investigations of the energy losses of the (100) Mo face, only maxima resulting from the excitation of plasma oscillations[5,6] were detected, although it is shown in ref. 7 that the energy losses are independent of the type of the adsorbed gases.

The goal of the present work is to use the (100) Mo and the (110) W faces of single crystals as examples to show how the energy losses of slow electrons with energies $E_p = 5$-200 eV depend upon the state of the surface.

Molybdenum and tungsten have a volume-centered cubic lattice with similar lattice constants. The energy characteristics of these elements are similar. In particular, the form of the Fermi surface and density of the electron states in the conductivity bands are similar.[8] Consequently, characteristic details in the spectrum of the energy losses of slow electrons (e.g., the maxima resulting from the excitation of plasma oscillations) appear at close values of the energy losses.[4,6,9]

The spectra of the energy losses are recorded with an electrostatic 180° analyzer having a system of retarding three-electrode lenses and an analyzer resolution[10] of 0.15 eV. Both the scattered electrons and secondary electrons are recorded in the direction of the (00) diffraction maximum at an angle of 20° relative to the normal to the surface. The spectra of the energy losses are studied on an outgassed surface of the single crystals, or on surfaces with adsorbed N_2 or H_2 molecules or with adsorbed residual gases. The spectra of the energy losses are also measured in the thermally stimulated desorption in vacuum between $2 \cdot 10^{-6}$ and $6 \cdot 10^{-10}$ torr. The composition of the residual gases is checked with the aid of an IPDO-1 instrument. The spectra reveal CO_2 (18%), CO (40%), H_2O (12%), and H_2 (18%). When the target is cleaned by high-temperature flashes, the CO_2, CO, and H_2 concentrations increase. The state of the surface is monitored by observing changes in the sample work function, which is measured with an accuracy of 0.05-1.1 eV, and by observing changes in the intensity of the maxima of elastically reflected and slow secondary electrons. The relative change in the work function is recorded from the shift of the curves representing the delay of the primary electron current at the target and from changes of the energy interval encompassing the full spectrum of both scattered and secondary electrons relative to the peak of the elastically reflected electrons. The surface which is used on the single crystals is mechanically polished and treated with an electropolishing etching agent. The accuracy with which a crystal face appears on the surface is checked with Laue diagrams, being about 1.5°. Repeated, extended heating to 2000°K by radiation or electron bombardment of the rear surface of the target is used for surface cleaning. The final cleaning step consists of several short high-temperature heating cycles to which the sample is subjected in a vacuum of $1 \cdot 10^{-9}$ torr. The thermal treatment of the target leads to the removal of adsorbed molecules and chemical compounds from the surface but does not render a surface fully cleaned from carbon.[6,11]

The spectra of the slow electrons reflected from the surface are displayed in Figure 1. At energies $E_p = 18$-22 and 70-80 eV, maxima of energy losses with an intensity ratio of genuine secondary electrons to background depending upon E_p appear near the peak of the elastically reflected electrons. The energy losses ΔE_i of the surfaces of the (100) Mo and (110) W faces, which have or have not been outgassed, are listed in Table 1.

The loss value of 9.5 eV in the case of molybdenum corresponds to the approximate excitation energy of a surface plasmon. The excitation energy amounts to 10-11 eV, according to the results of optical measurements[12] of the dielectric constant ε. In the case of outgassed

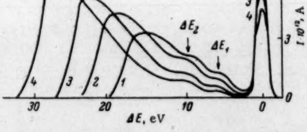

Fig. 1. Spectra of the energy losses of slow electrons reflected from the surface of the (110) faces of W at various energies of the primary electrons. E_p (eV): 1) 18; 2) 22; 3) 27; 4) 33.

TABLE 1

State of the sample's surface	Energy loss (eV)				
	(100) Mo		(110) W		
	ΔE_1	ΔE_3	ΔE_1	ΔE_2	ΔE_3
Surface not outgassed	6.5±0.5	25.5±1.5	6.5±0.5	10.5±0.5	24.0±1.0
Surface outgassed	9.5±0.5	22.0±1.0	5.5±0.5	11.0±0.5	22.5±1.5

tungsten, the loss figure of 11 eV is close to the excitation energy of a surface plasmon; the excitation energy is in approximate agreement with the energy value of 10 eV obtained in ε measurements.[13]

When a molybdenum target is kept for an extended period of time in an atmosphere of residual gases under a pressure of $1 \cdot 10^{-6}$ torr, the ΔE_1 peak is shifted to 6.5 eV and becomes stronger; on the other hand, absorption of N_2 and H_2 under similar pressures only increases the intensity of the maximum, which agrees with the results of ref. 6. A shift of the peak of the surface plasmons toward lower energies in the presence of a layer of adsorbed molecules of residual gases on the surface can be explained by an increase in the ε value of the layer at the metal–vacuum interface[4] or by possible additional energy losses, which are associated with the excitation of electrons from the level of CO and H_2O molecules adsorbed on the surface;[2] these electrons distort the plasmon peak.

Thermal desorption of adsorbed molecules of residual gases shifts the maximum of the surface plasmon toward increased energy losses. The work function $l\Delta\varphi$ of the surface decreases by the value $l\Delta\varphi = -0.3$ eV and passes through the minimum $l\Delta\varphi = -0.6$ eV at a sample temperature of 700°K. The majority of the adsorbed molecules are desorbed at temperatures of 600–800°K when the maximum change of $l\Delta\varphi$ is observed and when the peaks of the elastically and inelastically scattered electrons reach the intensity maxima. CO molecules are the main component of the gas molecules desorbed from the surface. When CO is adsorbed on the (100) Mo face, an increase by 0.35–0.6 eV is observed in the work function of refs. 11 and 15. This observation agrees with the results of our experiments. The desorption of the molecules of the residual gases from the surface of the (100) face of W reduces the work function by 0.5–0.6 eV, whereas adsorption of N_2 on the (110) face of W increases the work function by 0.3 eV and by 0.5 eV in the case of the (100) face of Mo of our experiments. These figures are consistent with the results of other authors.[11,16] When the outgassed target is kept in an N_2 atmosphere or in an atmosphere of residual gases under pressures of $1 \cdot 10^{-6}$ torr, a relatively stronger increase in the intensity of the elastic peak and the peaks of the energy losses is obtained in (100) Mo than in (110) W. The observed shift of the maxima of the energy losses is more pronounced in molybdenum when the target has been outgassed.

The very intensive, broad peak around about 23 eV can be explained[4,6,9] by the excitation of plasma oscillations of hexavalent electrons in the peak of Mo and W. This interpretation of the maximum is confirmed by the change in the intensity of the peak relative to the peak of surface plasmons. At energies E_p up to 100 eV the surface plasma peak has the highest intensity in the spectrum, whereas at higher E_p values the volume peak dominates. The absorption of the molecules of the residual gases on the surface of an outgassed target leads to a shift of the peak of the bulk plasmon toward higher energies, with the shift amounting to 1–2 eV. In the case of polycrystalline tungsten, a similar change is observed in the spectrum by the authors of ref. 17. An additional inelastic scattering of the electrons during their passage through the layer of adsorbed molecules is the most likely explanation.

In the case of the outgassed W surface, a 5.5 eV peak is observed in the spectrum of the energy losses within the range E_p = 18–40 eV. Similar behavior at 5.4 eV is observed in ref. 3 in the case of the (110) face of W. The authors of ref. 3 associate the peak with the excitation of electron transitions in the near-surface conduction band of tungsten.

Our investigations of the spectra of energy losses of slow electrons reflected from the surface of the (100) Mo and (110) W faces show that the state of the surface of a crystal has a strong influence upon the interaction of electrons with solids.

Diffusion and solubility of helium in potassium chloride

A. Ya. Kupryazhkin, P. V. Volobuev, and P. E. Suetin

S. M. Kirov Ural Polytechnical Institute, Sverdlovsk

(Submitted June 26, 1973; resubmitted January 7, 1974)
Zh. Tekh. Fiz., 44, 1774-1778 (August 1974)

The diffusion coefficients and solubilities of helium in potassium chloride crystals have been measured. An experimental apparatus for measuring the diffusion properties of inert gases in ionic crystals is described. Over the temperature range 160-300°C the diffusion coefficient is described by the Arrhenius equation

$$D=3.9\cdot10^{-5}\exp\left\{-\frac{10.6}{RT}\right\}\ \mathrm{cm^2/sec}$$

The solubility is also an exponential function of the temperature in this range:

$$S=2.4\cdot10^{14}\exp\left\{\frac{3.8}{RT}\right\}\ \mathrm{cm^{-3}}$$

All the measurements are carried out at a saturation pressure of 800 torr. The results are compared with experimental data on helium diffusion in sodium chloride. It is concluded that a vacancy mechanism is responsible for the dissolution in these systems.

The more stringent requirements being imposed on the gas permeability of various crystalline materials require a detailed understanding of the microscopic processes involved in the diffusion of gases in solids and of the macroscopic consequences of these processes under various conditions. In particular, it would be difficult to describe the evolution of inert gases from fuel elements in nuclear reactors without an accurate understanding of the diffusion mechanisms and the parameters of the interaction between gas molecules and solids. To acquire this knowledge it is necessary to study the given processes in detail in simple systems by independent methods. One such simple system is that of an inert gas and an alkali halide crystal.

We have been carrying out an experimental study of helium diffusion in potassium chloride by a method involving desorption from previously saturated crystals.[1] This method, in contrast with that in which the inert gas is produced in the crystal through neutron bombardment, does not damage the lattice, so it is preferable. However, since only a few systems have been studied, since the sensitivity is low, and since the background in the chamber in which the sample is saturated is high, we have now improved the apparatus and carried out additional measurements.

Figure 1 shows the experimental apparatus. The sensitive element is differential capacitive gauge[2] 5, whose membranes form the capacitance in high-frequency oscillator 19, which uses a single transistor. The indicating device is a ChZ-11 digital frequency meter. The sensitivity of the measurement circuit is $1.7\cdot10^{-6}$ torr/Hz. The stability with bypass valve 6 open is ±1 Hz over a 10-min period. For increased thermal stability of the measurement circuit the oscillator is mounted directly on the gauge and placed with it in a quiet oil bath 7. During the measurements the reference cavity of the gauge is evacuated continuously by forepump 11 and diffusion pump 10. The pressure in the system is monitored by the ionization tube 20 of vacuum gauge 16 and by oil 8 and mercury 9 gauges.

The apparatus has two chambers 3; one holds the sample, while the other is used to monitor outgassing from the walls. The chambers are made primarily from aluminum, because it is relatively impermeable to gases. Since aluminum conducts heat well, the sample can be heated uniformly. The chamber is connected to the system by means of a conical stainless steel gasket. This connection remains vacuum-tight over the entire operating-temperature range. Both chambers are placed in oven 2, whose temperature is regulated within ±0.1°C by temperature-regulation and -sensing system 17, which receives signals from thermocouple 18, mounted on the oven housing. The temperature is measured by three thermocouples 1 at various points along the length of the chambers. In the measurements the temperature gradient is less than 1°C. Gas is injected from bottle 10 through nitrogen trap 13; the injection is monitored by the spring gauge 12 and mercury gauge 9.

In the experiments we use "pure" KCl crystals sifted through a screen with a mesh size of 0.0125–0.0160 cm. The total volume of the salt is V = 13.6 cm³. Before an experiment the chamber and sample are outgassed continuously for 15 days at the maximum temperature. Then the sample is saturated with the gas to be studied. At time t = 0 the gas is evacuated, and the chamber is connected to the measurement system. Pressure changes in the system change the frequency of oscillator 19, and these latter changes are detected by frequency meter 15. The rate of change of the frequency, which corresponds to the rate of change of the pressure in the chamber, is recorded

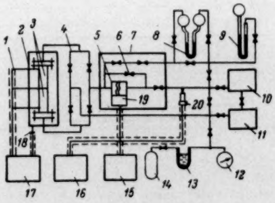

Fig. 1. The experimental apparatus.

over 1 min intervals. Through the use of valves 4, which do not change the volume of the system, the two chambers can be connected separately to the vacuum and measurement units. The outgassing of the empty chamber can thus be monitored at any time. Figure 2 shows typical curves recorded by the measurement system.

We see that the effect of helium dissolution in the chamber walls is small, and after a certain time we find $\Delta f/\Delta t = \text{const}$ for the empty chamber. The value of this constant is an order of magnitude lower than that for a fused quartz chamber.[1] Since the desorption data are generally processed 50 min after the beginning of the measurements, the empty chamber is used solely to monitor the outgassing upon a change in the thermal conditions.

An equilibrium is established between the adsorbed gas atoms and the gaseous phase in the system within $1 \cdot 10^{-12}$ sec (ref. 3). Gas accumulates in the surface layer of the crystal by physical mechanisms; no chemical reactions occur. It is found experimentally that the system obeys ideal laws. The outgassing pressure and the saturation pressure differ by four orders of magnitude. Accordingly, after a certain period of time the outgassing can be described by the first term of the general solution of Fick's second law,[1] obtained under the assumption of an instantaneous desorption reaction at the crystal–vacuum interface,[1] an assumption which is widely used in studies of the diffusion of gases in solids. The behavior of the pressure in the system as a function of the time is given by

$$\frac{dP}{dt}=\frac{1536DSN\bar{a}kT_2}{\pi^4V_2\left[1+\frac{V_1}{V_2}\left(\frac{T_2}{T_1}\right)^{1-\gamma}\right]}\exp\left\{-\frac{3\alpha}{\bar{a}^2}Dt\right\}, \tag{1}$$

where a is the average crystal dimension, P is the pressure, t is the time, k is the Boltzmann constant, S is the solubility, N is the number of salt crystals, V_1 and T_1 are the volume and temperature of the cold part of the measurement system, V_2 and T_2 are the same for the hot part, $\alpha = 8.4$ is the approximation constant, and γ is the thermomolecular pressure-difference constant, calculated for each specific temperature and for each specific pressure range for a connecting-tube diameter of 0.5 cm (see ref. 5).

To check the reproducibility of the results, we have repeated the measurements after one month. Between series of measurements the working chamber is opened to the atmosphere. Figures 3 and 4 show the experimental results for the diffusion coefficient and the solubility; the results of both series of measurements are shown in Fig. 3 to illustrate the reproducibility. We see that the scatter of the points does not exceed the experimental error. The functional dependences of the diffusion coefficient and the solubility of helium in KCl on the temperature at a saturation pressure of 800 torr are

$$\left.\begin{aligned} D&=3.9\cdot10^{-5}\exp\left\{-\frac{10.6}{RT}\right\}\ \text{cm}^2/\text{sec}\\ S&=2.4\cdot10^{14}\exp\left\{\frac{3.8}{RT}\right\}\ \text{cm}^{-3}\,, \end{aligned}\right\} \tag{2}$$

The mean-square relative deviation of the experimental results from Eq. (2) for the diffusion coefficient is 10%, and that for the solubility is 8%.

Unfortunately, we have found no other data in the literature with which to compare our results, so that we can compare our results only with data on helium diffusion in NaCl (ref. 1). It is evident that the diffusion coefficients are described by the same equations in the two cases, while the activation energy of the solubility has different signs in the two cases. A negative value of this activation energy could be attributed to the influence on the overall effect of surface adsorption and dissolution at dislocations and in vacancies of the crystal. However, experiments on the adsorption of inert gases on alkali halide crystals[6] reveal a low adsorption energy even for argon; second, the sign of the energy must be the same, regardless of the sample; and third, the procedure used to process the data completely eliminates this effect, since the lifetime of helium on the surface amounts to a fraction of a second. In the case of dissolution at dislocations, a helium molecule would very probably diffuse along dislocations; since the corresponding diffusion coefficients[7] are one or two orders of magnitude higher than the values which we found,

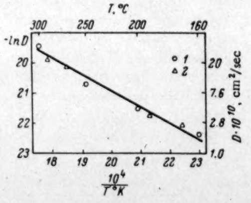

Fig. 3. Diffusion coefficient of helium in KCl as a function of the temperature. 1) First series of measurements; 2) second series.

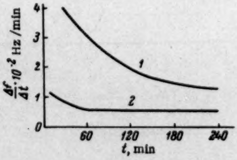

Fig. 2. Experimental rate of change of the frequency of oscillator 19 as a function of the time (T = 163°C). 1) Chamber with salt; 2) chamber without salt.

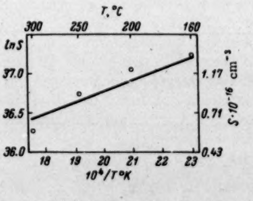

Fig. 4. Solubility of helium in KCl as a function of the temperature.

this mechanism should be more apparent early in the experiment and should also be eliminated in the procedure used to analyze the data.

On the basis of the vacancy mechanism for dissolution we can explain both the negative value of the dissolution energy and the difference between the signs for two crystals. Experimental study of the electrical conductivity[8] has shown that at low temperatures the vacancies are predominantly cation vacancies, resulting from the presence of divalent impurities in the crystals. The concentration of these vacancies is not a function of the temperature. In these systems the energy for the interaction of the inert gas with the ions of the alkali halide crystal can be interpreted by means of a binary-interaction potential, usually the Lennard-Jones 6−12 potential:[9]

$$U(r)=4\varepsilon\left\{\left(\frac{\sigma}{r}\right)^{12}-\left(\frac{\sigma}{r}\right)^{6}\right\}, \tag{3}$$

where σ is the value of r at which U(r) = 0, and ε is the depth of the potential well.

The sign of the energy depends on the distance between the interacting particles. In the case of helium at a cation vacancy we can, in a first approximation, consider only the nearest neighbors, neglecting relaxation of the lattice ions around the vacancy. Then an evaluation of the interaction of helium with the crystal in the case of either lattice reduces to an evaluation of the interaction of helium with chloride ions in the unperturbed lattice. The functional dependence of this energy for a mole of the gas on the distance between the particles should have the same form as the interaction potential, and the energies corresponding to the interaction of helium with the nearest-neighbor ions, corresponding to definite distances, must lie on this curve. In the first case the distance is r_1 = 2.81 Å, and in the second it is r_2 = 3.14 Å; the energies are U_1 = 3.2 kcal/mole and U_2 = 3.8 kcal/mole. Since $\Delta r = r_2 - r_1$ is small in comparison with the width of the potential well, it is reasonable to assume that both points lie on a single branch of the potential curve. Using a linear interpolation between the points, we find

$$\sigma_{He-Cl}=\frac{1}{2}(\sigma_{He-He}+\sigma_{Cl-Cl}), \tag{4}$$

and knowing the ionic radius of chlorine we can evaluate σ_{He-He}. Taking this radius from ref. 10, we find σ_{He-Cl} = 3.0 Å and σ_{He-He} = 2.4 Å. The latter value agrees reasonably with the value obtained from measurements of the viscosity of helium:[9] σ_{He-He} = 2.576 Å. We note that taking account of the relaxation of chloride ions around the helium does not increase the discrepancy between these results by more than 15%.

Even in view of the roughness of the assumptions used, these arguments imply a vacancy mechanism for the dissolution of helium in these systems. In turn, the method used to demonstrate the dissolution mechanism allows us to use data on the solubility of gases in crystals differing by only one ion species to evaluate the parameters of the interaction potentials of the systems.

Pulsed ion beams from a high-current plasma diode

B. A. Tskhadaya, A. A. Plyutto, and K. V. Suladze

(Submitted October 13, 1973)
Zh. Tekh. Fiz., 44, 1779-1780 (August 1974)

In a study of pulsed ion beams in a high-current plasma diode it has been found that an ion beam of $6\cdot10^2$ A is produced when a critical diode current is reached and a discontinuity appears in the plasma. The ion beam has a large energy spread, but the average energy is approximately equal to the initial voltage, $U_0 = 30$-50 kV. The linear functional dependence of the ion-beam current on the critical diode current implies that ion beams with currents of $2\cdot10^4$ A can be achieved at diode currents of 10^6 A.

The present interest in the production of high-current ion beams results from their possible use in thermonuclear research and in producing intense neutron radiation.[1] Ion beams are usually produced by extraction from a plasma surface.[2] New techniques for producing charged-particle beams have led to the concept of preliminary filling of a diode with plasma.[3-6] Ion beams with currents up to 20 A have been produced in diodes in the collapse of the anode plasma when the plasma source is located at the cathode.[7] Pulsed neutral ion beams with considerably higher currents and current densities can be produced if the diode and the drift region are first filled with a plasma from a source located at the anode. The experiments have been carried out in an apparatus similar to that described in refs. 5 and 6.

When an external electric field is applied to a plasma-filled diode (in which the plasma density at the cathode is 10^{13}-10^{14} cm^{-3}), the electron current reaches its critical value in a time $t = 10^{-7}$ sec and is then cut off (Fig. 1a); at this point the voltage across the gap increases sharply[4] to $(1.5$-$2)U_0$ ($U_0 = 30$-50 kV) (Fig. 1b). At this point a discontinuity appears in the plasma,[4,7,8] and an ion beam is produced; it moves in the neutralized state in the drift region. A transverse magnetic field $(2$-$3)\cdot10^2$ Oe is applied to the beam to separate the plasma electrons from the ions near the collector ($l = 50$ mm), which measures the ion current. The ion current appears when the current is cut off (Fig. 1c). The ion current increases linearly with critical electron current. At $I_{cr} = 3\cdot10^4$ A a proton beam of $6\cdot10^2$ A, with an average length of $(3$-$4)\cdot10^{-7}$ sec and a current density of 10^2 A/cm^2, has been achieved (in this case the distance to the collector is 8-10 cm). Oscilloscope and calorimetric measurements of the average ion-beam current yield consistent results. When the collector is moved to 30-40 cm the ion-current signal is delayed by the transit time with respect to the voltage signal.

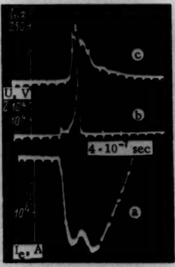

Fig. 1. Oscillograms: a) total diode current; b) voltage across the diode; c) ion current to the collector.

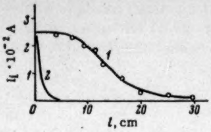

Fig. 2. Profile of the current density along the beam. 1) Experimental; 2) calculated for the case in which the beam is not neutralized.

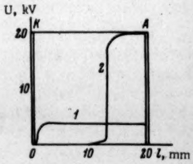

Fig. 3. Potential distribution in the diode. 1) In the initial stage of the increase in the total current; 2) in the stage in which the total current is cut off.

Study of the divergence of the ion beam shows that the collector current varies slightly over the distance 8-10 cm but then falls off (Fig. 2). The divergence angle is below 6° at distances up to 10 cm.

A Thomson mass analyzer is used to study the composition and energy distribution of the particles. The beam is found to be predominantly protons, but charged carbon ions C^{+1}, C^{+2}, C^{+3}, C^{+4} are also observed. The ions have a large energy spread, but the average beam energy is approximately equal to the initial voltage on the capacitor bank, U_0. The maximum proton energy is $\sim(1.5$-$2)U_0$, apparently because of the overvoltage which results from the cutoff of the electron current.

Fast electrons, with energies of 10^3-10^4 eV (at $U_0 = 30$ kV), move in the same direction as the ion beam; the reason is not clear. The energy acquired by these electrons does not significantly affect the calorimetric measurements of the ion current.

On the basis of these experimental results we propose that high-current pulsed ions beams can be produced in the discontinuity in a plasma. This method differs fundamentally from the method in which beams are produced from a plasma boundary, in which case the potential drop occurs between the cathode and the plasma. A state with a cathode potential drop is observed (when the gap is filled with plasma) in the initial stage of the current rise, when the space-charge shell is near the cathode and the voltage drop is $0.2U_0$ (curve 1 in Fig. 3). The appearance of electron-emission centers at the cathode changes this state considerably. The plasma from the emission centers destroys the ion space-charge sheath, and the conductivity near the cathode increases. When the electron current reaches its critical value, a discontinuity occurs in the plasma;[4,7,8] most of the potential drop occurs in this region (curve 2 in Fig. 3). An electron beam,[4] which evaporates the working medium of the source and which generates a dense plasma, is also produced in the discontinuity. As a result, the ion current is an order of magnitude larger than that in ref. 7.

Because of the space-charge neutralization and focusing by the magnetic field of the electron current, the ion beam accelerated in the discontinuity has a high current density and can propagate over a considerable distance in the drift region. The linear functional dependence of the ion-beam current on the critical electron current implies that ion beam currents of $2 \cdot 10^4$ A can be achieved at diode currents of 10^6 A.

The basic advantage of this method of producing an intense ion beam (electrostatic acceleration of ions in the discontinuity) as compared with the electrodynamic method is that the ion energy can be adjusted by changing U_0. It is possible to increase the ion energy to 10^5–10^6 eV.

In conclusion the authors thank I. F. Kvartskhava, V. N. Ryzhkov, and L. P. Skripal' for valuable comments.

Parallel-plate capacitor as a charged-particle spectrometer

Yu. D. Kornyushkin

Leningrad Institute of Precision Mechanics and Optics

(Submitted February 1, 1973; resubmitted February 6, 1974)
Zh. Tekh. Fiz., 44, 1781-1784 (August 1974)

We discuss the possibility of using the uniform electrostatic field of a parallel-plate capacitor for the energy and angle analysis of charged-particle beams in the most general case in which the source of charged particles is in the interelectrode space. We show that there are operating conditions favorable for the energy and angle analysis of a beam of charged particles. We obtain equations and curves for the dispersion in energy and angle. We show the possibility of using the electric method to analyze the angle of emission distribution of charged particles.

Among electrostatic spectrometers the simplest seems to be one employing a parallel-plate capacitor to deflect a stream of charged particles to one plate.[1] Such a device was first discussed in some detail in refs. 2 and 3. In particular, the optimum condition for energy analysis based on the use of first-order focusing was formulated. The analysis of the properties of an electrostatic spectrometer with plane-parallel plates was continued in refs. 4 and 5, and the operating conditions for second-order focusing were found. Subsequently the electron-optical properties of such a spectrometer were investigated in ref. 6 for relativistic particles. Nevertheless the analysis of the electron-optical properties of such a spectrometer performed in refs. 1-6 is still incomplete and the possibility of obtaining the angle distribution of charged particles has not been completely evaluated. In the present paper we investigate the properties of a parallel-plate capacitor used to find the angle distribution of charged particles.

ANALYSIS OF THE OPERATION OF THE CHARGED-PARTICLE SPECTROMETER

The spectrometer consists of parallel plates with a potential difference between them. In the general case a source of charged particles is located in the space between the plates; therefore for a given potential difference between the plates and a given energy $\mathcal{E}_0$ of the charged particles only those particles which leave the source at the angle of emission α (Fig. 1) pass through the point of the exit slit a distance x_0 from the source. None of the other charged particles with different angles of emission pass through the indicated point of the exit slit. It is assumed that the effect of the inhomogeneity of the electrostatic field at the edges of the plates on the charged particle trajectories is eliminated in one way or another. In general the charged particles can move in both decelerating and accelerating fields.

We use the following sign convention for measuring the angles of emission relative to the horizontal line passing through the source; $\alpha > 0$ for angles measured counterclockwise and $\alpha < 0$ for angles measured clockwise (Fig. 1).

We assume that the motion of the charged particles is at all times in the xoy plane and that the space charge density in the interelectrode space is negligibly small. Then the distance between the source of charged particles and the exit slit in the x direction can be found in relative units from the expression

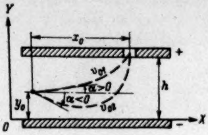

Fig. 1. Schematic diagram of spectrometer.

$$X_0 = 2E_0 \cos\alpha \left[\sqrt{\sin^2\alpha + \frac{1}{a}} - \sin\alpha\right], \tag{1}$$

where

$$X_0 = \frac{x_0}{h}, \quad E_0 = \frac{U_p}{U} > 0, \quad a = \frac{E_0}{1 - Y_0},$$
$$Y_0 = \frac{y_0}{h}, \tag{2}$$

x_0 is the distance from the particle source to the slit in the x direction, y_0 is the distance from the particle source to the lower plate in the y direction, h is the distance between the plates, α is the angle of emission of the particles from the source, U is the potential difference between the plates, and qU_p is the kinetic energy of the particles leaving the source, where U_p is the potential difference and q is the particle charge.

If the beam is monoenergetic Eq. (1) shows that $X_0 = X_0(\alpha)$ can lead to the same value of X_0. Then the conditions $E_0 = \text{const}$, $X_0 = \text{const}$ will correspond to a family of trajectories lying to the left of the limiting trajectory bounding this family on the right and satisfying the condition $X_0 = X_{0\max}$. Therefore charged particles can reach the largest value $X = X_{0\max}$ only for certain angles α_0, which can be found from the extremum condition $(dX_0/d\alpha)_{E=\text{const}} = 0$.

By investigating Eq. (1) at the extremum we find the limiting angle

$$\sin\alpha_0 = \frac{-1}{\sqrt{2 + \frac{1}{a}}}. \tag{3}$$

It is also clear from Eq. (1) that $E = E_0(\alpha)$ is a multivalued function of the angle of emission α ($X_0 = \text{const}$). This means that to one value of E_0 there can correspond various values of α and therefore various trajectories. As in the preceding case, among the possible values of energies and angles there are limits which correspond to a given value of $X_0 = \text{const}$. By using the extremum condition $(dE/d\alpha)_{X_0=\text{const}} = 0$ it can be shown that the limiting angle of emission α_0 is also determined from Eq. (3). In combining the two limiting cases $X_{0\max}$ and $E_{0\max}$ Eq. (3) corresponds to the condition for focusing charged particles in the plane of the exit slit.

It follows from Eq. (1) and Fig. (1) that for any value of $\alpha > 0$ it is possible to choose a value of E_0 such that the charged particles pass through the exit slit; motion of the charged particles is possible for any angles of emission in the range $0 \le \alpha \le \pi/2$. Particles with negative angles of emission move initially in a decelerating field and can reach the plane of the exit slit only for certain angles $\alpha < 0$, since in moving in the decelerating field the charged particles must not strike the lower plate. Then the condition corresponding to the particles not reaching the lower plate can be written as the inequality

$$\sin^2 \alpha_1 \leqslant \frac{Y_0}{a(1-Y_0)}, \tag{4}$$

where for $\alpha_1 < 0$ we have $\sin^2\alpha_0 < \sin^2\alpha_1$, i.e., $E_0 > Y_0 - 1/2$.

Various specific operating conditions can be investigated by an analytic study of Eq. (1).

ANGLE ANALYSIS

The analyzing properties of the spectrometer are determined by the value of the dispersion and the quality of the focusing. Direct differentiation of Eq. (1) gives the following expressions for the energy and angle dispersion:

$$D_E = \frac{\cos\alpha}{a\sqrt{\sin^2\alpha + \frac{1}{a}}}\left[1 + 2a\sin\alpha\left(\sin\alpha - \sqrt{\sin^2\alpha + \frac{1}{a}}\right)\right], \tag{5}$$

$$D_\alpha = \frac{2a(1-Y_0)}{\sqrt{\sin^2\alpha + \frac{1}{a}}}\left[\left(\sin\alpha - \sqrt{\sin^2\alpha + \frac{1}{a}}\right)\cos 2\alpha - \frac{\sin\alpha}{a}\right]. \tag{6}$$

Figure 2 shows curves of Eqs. (5) and (6) for D_E and D_α. It is clear from the curves that in principle two limiting sets of operating conditions are possible, one for angle analysis and one for energy analysis. In the first case the spectrometer is adjusted so that it is insensitive to a change in the energy of the charged particles but very sensitive to a change in the angle of emission α ($D_E \ll D_\alpha$); in the second case the spectrometer must be insensitive to a change in the angle of emission and very sensitive to a change in the energy of the particles ($D_E \gg D_\alpha$).

If the beam is stopped down sufficiently and the operating conditions correspond to a small value of D_α, the absolute resolving power can be found from the expression

$$\Delta U_p = \frac{\Delta x_{\text{out}}}{h}\frac{U}{D_E}. \tag{7}$$

Here it is assumed that $\Delta x_{\text{out}} \gg \Delta x_{\text{in}}$, where Δx_{out} and Δx_{in} are the widths of the exit and entrance slits.

An analysis of the family of curves of D_α shown in Fig. 2 and Eq. (6) shows that the largest angle dispersion occurs at $Y_0 = 0$. In the angle analysis process the energy dispersion D_E must be a minimum in order that the instrument be insensitive to the energy analysis of the charged particles.

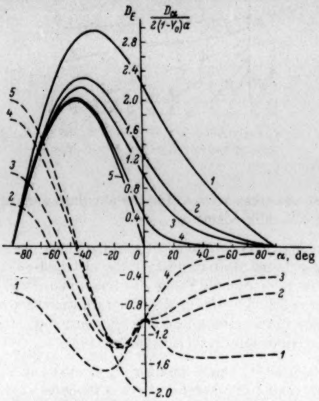

Fig. 2. Curves of energy (solid curves) and angle (open curves) dispersion. a: 1) 0.2; 2) 0.6; 3) 1.0; 4) 5.0; 5) ∞.

The family of curves of D_E in Fig. 2 shows that over a broad range of emission angles α minimum values of D_E exist only for $\alpha > 0$. Consequently the optimum conditions for angle analysis require an accelerating field. Thus it is clear from Fig. 2 that for $a \ge 5$ and $\alpha \ge +25°$ the angle dispersion ($Y_0 = 0$) lies in the range $0.8 \le D_\alpha < 3.4$. Then for $\alpha = 50°$ and $h = 40$ mm $D_\alpha = 60$ mm/rad $= 1.05$ mm/deg, i.e., under these conditions the system is sufficiently sensitive for the angle analysis of a beam of charged particles.

It is frequently necessary to investigate the angle distribution in space of a beam of charged particles in which the energy varies continuously from 0 to qU_p. This case is commonly encountered in the analysis of the interaction of primary charged particles with matter and the study of various characteristics of beams of secondary charged particles. Here it is important that in the range of angles of emission from α to $\alpha + \Delta\alpha$ particles with the largest possible range of energies pass through the exit slit of the spectrometer. The fraction of the spectrum corresponding to the energies of the charged particles which pass through the exit slit is determined from the expression

$$N = \frac{\Delta x_{\text{out}}}{h}\frac{1}{E_0 D_E}, \tag{8}$$

where $N = \Delta U_p/U_p$.

The absolute angle resolving power is given by

$$\Delta\alpha = \frac{\Delta x_{\text{out}}}{h}\frac{1}{D_\alpha}. \tag{9}$$

It follows from Fig. 2 that for $a = 5$ and $\alpha > 35°$, $D_E \le 0.02$. In angle analysis it is expedient to have $Y_0 = 0$, so that $a = E_0 = 5$. For $h = 40$ mm and $\Delta x_{\text{out}} = 4$ mm we find $N = 1$ from Eq. (8). Thus all charged particles in the energy range from 0 to qU_p pass through an exit slit 4 mm wide for $35° < \alpha < 90°$. The substitution of these values

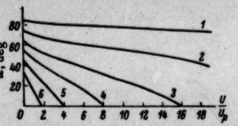

Fig. 3. Angle of emission α as a function of X_0 and E_0. X_0: 1) 0.1; 2) 0.28; 3) 0.5; 4) 0.7; 5) 1.0; 6) 1.5. $Y_0 = 0$.

into Eq. (9) gives $\Delta\alpha = 6'$ for the absolute angle resolving power, which is adequate.

By appropriate choice of spectrometer operating conditions it is possible to analyze the charged-particle distribution in a selected range of emission angles, i.e., to make a detailed analysis of the angle distribution of charged particles for a given initial energy. In many cases this is of considerable experimental interest.

Equation (1) shows that for X_0 = const and Y_0 = const various angles of emission α correspond to various values of E_0. But E_0 can vary not only due to a change in U_p but also because of a change in U – the deflecting potential difference between the spectrometer plates. Hence an angle analysis can be performed by the electric method, in which the continuous variation of U will correspond to a continuous change in the angle of emission α corresponding to the passage of the beam of charged particles through the exit slit.

In the angle analysis it is convenient to have a linear relation between the deflecting voltage and the angle of emission; thus it is expedient to determine the region in which such a relation holds. If the relation $\alpha = \alpha(U)$ is nonlinear it is expedient to approximate the nonlinear relation by some simple function so that the potential difference U can be varied according to that law in the given range of values.

Figure 3 shows curves of $\alpha = \alpha(1/E_0)$, from which the necessary operating conditions for angle analysis can be selected. If the experimental conditions permit U_p = const, $\alpha = \alpha(U)$. The curves of Fig. 3 show that there is an appreciable range within which we can write

$$\alpha = \alpha_i - b_i \frac{U}{U_p}, \tag{10}$$

where α_i and b_i are constants depending on the choice of operating conditions.

Suppose there is a flux of monoenergetic charged particles (U_p = const) in space. By using (10) the angle analysis can be performed rather simply by the electric method. But Eq. (2) shows that a change in U produces a change in E_0 (U_p = const); therefore, according to (5) and (6) the angle and energy dispersions will change. For a monoenergetic beam the change in energy dispersion can be neglected, but the uncontrollable change in angle dispersion can distort significantly the true picture of the angle distribution. Therefore the signal must be corrected to take account of this change. An initial operating point (Fig. 3) should be selected so that measurements can be performed with sufficient sensitivity to the angle of emission over the broadest range of angles α, e.g., $0.5 \le X_0 \le 1.5$.

If the beam of charged particles under study is not monoenergetic the requirements for choosing the operating point are more rigid, since the spectrometer must operate under conditions such that D_E is always small. This condition is satisfied by $a > 1$ and $\alpha > 30°$, and as can be seen from Fig. 3, the possible range of the anglee analysis is appreciably decreased. Thus for $0.7 \le X_0 \le 1.0$ the range of angles of emission relevant to the investigation is of the order of 10°. Therefore in the analysis of the angle distribution over a wide range of angles it is expedient to use a combination of the methods of investigation by mechanically rotating the specimen 10° and then making an angular analysis over a 10° range by the electric method.

Energy exchange between electrons and molecular vibrational states in resonance collisions

A. Kh. Mnatsakanyan and G. V. Naidis

Institute of High Temperatures
Academy of Sciences of the USSR, Moscow

(Submitted January 2, 1974)
Zh. Tekh. Fiz., 44, 1785-1787 (August 1974)

An expression is obtained for the energy exchange between electrons and the molecular vibrational states in resonance collisions when the width of the resonance is much smaller than the vibrational frequency. A comparison is made with conventional expressions for the energy exchange rate in N_2.

In many molecules the excitation of vibrational levels by electron impact is of a resonance character due to the formation, as an intermediate state of the reaction, of an unstable negative ion. The theory of the resonance interaction of electrons with molecules is developed in refs. 1-3; the results of numerical calculations of the cross sections are in good agreement with experiment.[4] In many cases, however, interest centers not so much on the cross constants of the transitions between individual levels, as on the total rate of exchange of energy between the molecular vibrational states and the electrons. In the calculation of an averaged characteristic of the process (averaged with the electrons distributed over energies and the molecules over the vibrational levels) it is possible to utilize less exact values of the cross sections and thereby obtain an analytically simple approximate expression for the energy exchange rate.

1. The rate of exchange of energy between electrons and molecular vibrational states for a Maxwellian electron energy distribution and a Boltzmann distribution over vibrational levels with temperatures T_e and T_v respectively, is given by

$$\omega' N_e \sum_{m,n} (m-n) N_n P_{nm}$$
$$= \omega' N_e N (1-q) \sum_{m,n} (m-n) q^n P_{nm} = \omega' N_e N K (T_e, T_v). \tag{1}$$

Here, $N_n = N(1-q)q^n$ is the population of molecules in the n-th vibrational level,

$$N = \sum_n N_n, \quad q = e^{-\omega'/T_v}, \quad P_{nm} = A \int_0^\infty \varepsilon \sigma_{nm}(\varepsilon) e^{-\varepsilon/T_e} d\varepsilon,$$

is the rate constant of the transition n → m induced by electron impact, $A = \sqrt{8/\pi m_e T_e^3}$, σ_{nm} is the corresponding cross section for the transition, ε and m_e are the energy and mass of the electron, ω is the molecular vibrational frequency and N_e is the electron density.

In the simplest version of the theory, in which the width of the resonance vibrational levels of the ion is regarded as independent of the number of the level, σ_{nm} the cross section for a transition from the n-th vibrational state to the m-th near resonance has the form[2]

$$\sigma_{nm}(\varepsilon) = \frac{\sigma_0}{\varepsilon} \left| \sum_\lambda \frac{\langle n|\lambda\rangle \langle \lambda|m\rangle}{\varepsilon - \varepsilon_0 + n\omega' - \lambda\omega'' + i\frac{\Gamma}{2}} \right|^2, \tag{2}$$

where ε_0 is the energy difference between the ground states of the ion and the molecule, $\langle n|\lambda\rangle$ is the overlap integral for the wave functions of the corresponding vibrational states of the molecule and the ion, ω'' is the ion vibrational frequency, Γ is the width of the resonance, and σ_0 is a normalizing constant, the choice of which is discussed below.

We consider the cases $\omega \ll \varepsilon_0$ (resonance region located far beyond threshold) and $\Gamma/2 \ll \omega$ (a sharp resonance). It is precisely these conditions that are realized for the molecules N_2 and CO. The discussion is restricted to the calculation of the rate constant for energy exchange at high electron temperatures $T_e \gg \omega$. The main contribution to the rate constant then comes from a region close to the resonance region and (2) is valid over the entire energy region. We take $\langle n|\lambda\rangle$ to be the overlap integral of the wave functions for harmonic oscillators with different equilibrium internuclear distances, r_e' and r_e'', and the same frequency $\omega = (\omega' + \omega'')/2$ (following ref. 5, where the absorption cross section of the molecules is averaged over the vibrational distribution).

2. The quantity K can be expressed in terms of an auxiliary function $R(a, b) = \sum_{n,m} a^n b^m P_{nm}$ in the following manner:

$$K = (1-q) \left\{ \frac{dR(q, r)}{dr} \bigg|_{r=1} - q \frac{dR(q, 1)}{dq} \right\}. \tag{3}$$

Expressing the denominators in (2) in the form of integrals of exponentials, setting $\omega' = \omega'' = \omega$, and integrating with respect to ε, we obtain

$$R(a, b) = \sigma_0 A \iint_0^\infty dt\,ds \frac{\exp\left[i\varepsilon_0(s-t) - \frac{\Gamma}{2}(s+t)\right]}{\frac{1}{T_e} + i(s-t)}$$
$$\times S(a e^{-i\omega(s-t)}, b, e^{-i\omega t}, e^{i\omega s}), \tag{4}$$

where

$$S(a, b, c, d) = \sum_{n,m,\lambda,\mu} a^n b^m c^\lambda d^\mu \langle n|\lambda\rangle \langle \lambda|m\rangle \langle m|\mu\rangle \langle \mu|n\rangle.$$

Utilizing the calculational technique described in detail in a previous paper,[5] we write generating function S in the explicit form

$$S(a, b, c, d) = \frac{1}{1-abcd} \exp\left\{ -\Lambda \frac{2 - (a+b)(1+cd) - (c+d)(1+ab) + (a+b)(c+d) - 2abcd}{1-abcd} \right\}. \tag{5}$$

where $\Lambda = \mu\omega/2\hbar\,(r_e^{I} - r_e^{II})^2$ and μ is the reduced mass of the molecule. We note that $S(a, b, c, 1) = \sum\limits_{n,\lambda} (ab)^n c^\lambda \cdot |\langle n|\lambda\rangle|^2 = S_3(ab, c)$, where S_3 is the generating function calculated in ref. 5. It is worth mentioning that Eq. (5) can be of use in a number of other applications.

Inserting (5) and (4) into (3), introducing the variable $u = t - s$, and integrating with respect to s, we obtain

$$K = \frac{\sigma_0 A}{1-q}\frac{\Lambda\omega}{\Gamma(\omega^2+\Gamma^2)} J,$$

$$J = \int\limits_{-\infty}^{\infty} du \frac{(e^{-i\omega u} - q)\,[\omega(1+e^{i\omega u}) + i\Gamma\delta(u)(1-e^{i\omega u})]}{\frac{1}{T_e} - iu}$$

$$\times \exp\left[-\frac{\Gamma}{2}|u| - i\varepsilon_0 u + \Lambda\frac{(e^{-i\omega u}-q)(1-e^{i\omega u})}{1-q}\right], \quad \delta(u) = \frac{u}{|u|}. \quad (6)$$

3. In order to estimate the latter integral, which, in the long run, determines K, we apply the conditions $\Gamma/2 \ll \omega \ll \varepsilon_0$, $\omega \ll T_e$, $\Lambda \sim 1$. Furthermore, we require that $T_v \lessdot T_e$, $T_v \lessdot (\varepsilon_0 + \Lambda\omega)^2/8\omega\Lambda$ ($T_e \lessdot 1.5$ eV for N_2). Then

$$K = \frac{2\Lambda\sigma_0 A\pi}{\Gamma}\frac{(1+p)(p-q)}{p(1-q)}\exp\left(-\frac{\varepsilon_0 + \Lambda\omega\frac{p-q}{p(1-q)}}{T_e}\right), \quad p = e^{-\omega/T_e}. \quad (7)$$

If we neglect the dependence of the exponent of the exponential on q (this dependence is weak for $\Delta\omega \ll T_e$), then K can be expressed in terms of the vibrational energy $\varepsilon_v = q/(1-q)$ in the following manner:[1)]

$$K(T_e, T_v) = K(T_e, 0)\left[1 - \frac{\varepsilon_v}{\varepsilon_e}\right], \quad \varepsilon_e = \frac{p}{1-p}. \quad (8)$$

The normalizing constant σ_0 appears in (2) and (7). When Γ is independent of the number of the level theory[2] gives $\sigma_0 = \pi\hbar^2\Gamma^2/2m_e$. On the other hand the energy exchange rate in N_2 can be normalized using the known[7] value of the total cross section for vibrational excitation by electron impact at its maximum: $\sum\limits_m \sigma_{0m}(2.2\text{ eV}) = 5.5 \cdot 10^{-16}\text{ cm}^2$. The value $\varepsilon_M = 2.2$ eV corresponds to a resonance with $\lambda = 1$ ($\varepsilon_M = \varepsilon_0 + \omega$). Remembering that $\Gamma/2 \ll \omega$, we obtain

$$\sum_m \sigma_{0m}(\varepsilon_M) = \frac{4\sigma_0}{\varepsilon_M\Gamma^2}|\langle 0|1\rangle|^2(1 - |\langle 0|1\rangle|^2). \quad (9)$$

Using the value of $\langle 0|1\rangle$ for harmonic oscillators with equal frequencies, we obtain σ_0/Γ^2, which differs from $\pi\hbar^2/2m_e$ by only 5%. This agreement may be accidental and if the absolute values of the cross sections are available it is better to use them in the normalization.

The cross sections obtained by Chen[2] are averaged in ref. 8 for a Maxwellian electron distribution, and it is shown that for modest n and k the quantity $P_{n+k,\,n}$ is weakly dependent on n and k. The following relation is then derived in ref. 9:

$$\left.\begin{aligned} K(T_e, T_v) &= P_{10}\varepsilon_e(1+\varepsilon_e)\,r_m(p)\left\{1 - \frac{\varepsilon_v(1+\varepsilon_v)\,r_m(q)}{\varepsilon_e(1+\varepsilon_e)\,r_m(p)}\right\}, \\ r_m(x) &= 1 - (m+1)x^m + mx^{m+1}. \end{aligned}\right\} \quad (10)$$

Here, m is the maximum number of transferred photons.

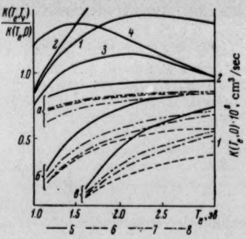

Fig. 1. Rate of energy exchange between molecules and vibrations of electrons $K(T_e, 0)$: 1) Eq. (10), m = 8; 2) Eq. (10), m = 8, approximation of ref. 8 used for P_{10}; 3) Nighan's results;[11] 4) Eq. (7). Ratio $K(T_e, T_v)/K(T_e, 0)$ for various values of vibrational temperature T_v(eV): a) 0.5; b) 1.0; c) 1.5; curves 5) Eq. (10), m = ∞; curves 6) Eq. (10), m = 8; curves 7) Eq. (7); curves 8) Eq. (8).

In ref. 10 use is made of an expression for K obtained on the assumption that only the lowest group of levels, with number up to a certain m, participate in vibrational exchange.

Equations (7), (8), and (10) with m = 8 and ∞ are used to calculate the ratio $K(T_e, T_v)/K(T_e, 0)$ as a function of T_e for various values of T_v. The results of the calculations are presented in Fig. 1. We note that expression (7) obtained in the present paper gives a value for this ratio that lies between the values given by (10) for m = 8 and m = ∞. The figure also gives the absolute values of $K(T_e, 0)$ obtained from (7) and (10) for m = 8 and also from ref. 11, where the cross section is averaged with an electron distribution satisfying Boltzmann's equation. The following values are used for the parameters (7): $\Lambda = 1.65$, $\omega = 0.26$ eV, $\Gamma = 0.15$ eV, $\varepsilon = 1.95$ eV.

We note that (10) and, to a greater extent, the equations of ref. 10 are nonlinear in ε_v, which can give rise to difficulties in the application of these results. Thus, in ref. 10 a study is made of the distribution of N_2 molecules in a discharge. The equation for the vibrational energy, allowing for pumping by electron impact and for the diffusion of vibrationally excited molecules to the walls of the discharge tube, is solved approximately. The use of (8) enables the problem to be solved exactly.

A direct comparison of the results for $T_e \lessdot 1.5$ eV with experimental data is not possible at the present time in view of the lack of experimental data. Preliminary calculations[8,9] for $T_e \lessdot 1$ eV are in satisfactory agreement with experiment (see the discussion in the review article by Mnatsakanyan[12]).

[1)] We note that K depends on T_v in this same manner in the opposite limiting case $\Gamma \gg \omega$, which is realized[6] for the molecules H_2 and CO_2.

Plasma decay instability in crossed fields

V. I. Farenik, V. V. Vlasov, A. M. Rozhkov, and A. A. Kozharin
A. M. Gor'kii Khar'kov State University

(Submitted June 28, 1973)
Zh. Tekh. Fiz., 44, 1788-1789 (August 1974)

An experimental study is made of the nonlinear interaction of characteristic plasma oscillations which obey the decay conditions over a wide range of external fields.

The relative motion between the components of a plasma located in crossed electric and magnetic fields can result in the appearance of various instabilities.[1,2] In the present work an experimental study is made of the excitation and nonlinear interaction of high-frequency ($\omega \gg \omega_{Hi}$, ω_{Hi} is the ion gyrofrequency) longitudinal oscillations in a plasma in external crossed fields, a radial electric field E_r, and an axial magnetic field H.

Oscillations are found to be excited in the plasma with a frequency close to the drift frequency:

$$\omega_0 = k_\varphi V_\varphi, \tag{1}$$

where $k_\varphi = m/r$ is the azimuthal wave number and $V_\varphi = -cE_r/H$ is the electron drift velocity ($E_r < 0$). These oscillations decay into two modes, which satisfy selection rules

$$\omega_0 = \omega_2 - \omega_1, \quad m_0 = m_2 - m_1, \tag{2}$$

where the frequency ω_1 is close to the ion plasma frequency. Plasma heating is observed under conditions of a well-developed nonlinear interaction.

The experiments are performed in the gas discharge with a cold cylindrical diode in an axial magnetic field at a pressure (air) of $(0.25\text{-}5) \cdot 10^{-5}$ mm Hg. The potential difference between the electrodes of the diode $U = \varphi_1 - \varphi_2$ ($\varphi_1 > \varphi_2 = 0$, φ_1, φ_2 are respectively the potentials of the outer and inner electrodes) is varied in the range 0-3 kV. The magnetic field is varied in the range H = 0-3 kOe. The discharge current is varied from 0.5 to 5 mA. The parameters of the plasma and their spatial distribution are determined using movable Langmuir and heated probes. The characteristics of the oscillations of the plasma are determined by means of floating probes.

For values of H and U satisfying the relationship[3]

$$H \geqslant H_{cr} \approx \frac{2c\sqrt{2m_e U}}{r_1\sqrt{e}}.$$

there is formed in the diode at the given pressure a gas-discharge plasma of density $n = 10^8\text{-}10^9$ cm^{-3} ($n_e > n_i$, $n_{e,i}$ are the densities of the components of the plasma) with a temperature $T_e = 20\text{-}100$ eV $> T_i \approx 0.1\ T_e$. The inhomogeneity of the plasma along the radius r is not large:

$$\frac{1}{n}\frac{dn}{dr} \sim \frac{1}{T_e}\frac{dT_e}{dr} \leqslant 1\ \text{cm}^{-1}.$$

The radial electric field in the plasma E_r increases monotonically with radius. The experimentally measured dependence of E_r on U and r can be expressed as $E_r = Ur/A$ V/cm, where $A = 2r_1$ (r_1 is the radius of the outer electrode).

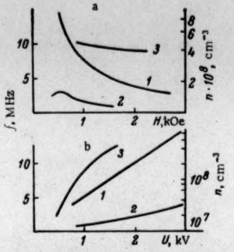

Fig. 1. Experimental plots of oscillation frequencies f_0 (1) and f_1 (2) and plasma density n (3) versus magnetic field intensity H (a) and potential difference across electrodes U (b).

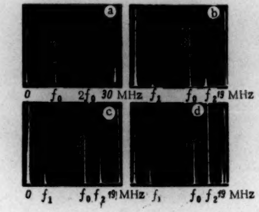

Fig. 2. Spectrograms of observed oscillations for various discharge conditions.

Oscillations are observed in the floating potential and in the discharge current under almost all operating conditions of the discharge. A study of how these oscillations depend on the external parameters of the plasma shows that for $1.1H_{cr} \leqslant H \leqslant 1.2H_{cr}$ only oscillations with a frequency f_0 = 5-15 MHz are excited, accompanied by the appearance of oscillations with frequencies $f_n = nf_0$ (n = 2, 3, 4...). The frequency f_0 is proportional to U/H and is independent of pressure and discharge current. Plots of f_0 versus H and U shown in Fig. 1 agree with (1), while the frequency of the observed oscillations is $\omega_0/2\pi$ with $m = m_0 = 2$. The amplitude of these oscillations increases with increasing magnetic field, up to $H \leqslant 1.2H_{cr}$, and the amplitudes of the higher harmonics nf_0 can be comparable to or greater than the amplitude of the oscillations at the fundamental frequency.

When the amplitude of the drift oscillations reaches the maximum value, frequencies $f_1 \ll f_0$ and $f_2 > f_0$ (Fig. 2b) appear in the spectrum of the plasma oscillations, and under certain discharge conditions the harmonics of these frequencies appear as well. Decay condition (2) holds for these frequencies.[4] As the amplitudes of the oscillations

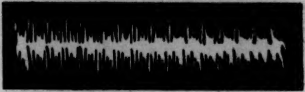

Fig. 3. Oscillogram of plasma oscillations for well-developed three-wave interaction. Sweep length is 10 μsec.

at f_1 and f_2 increase, the amplitude of the oscillations at frequency f_0 decreases. Plots of f_1 versus H and U are shown in Fig. 1. Unlike f_0, the frequency f_1 varies with pressure and discharge current. Simultaneous measurements of f_1 and the density n as a function of the external parameters show that $f_1 \sim \sqrt{n}$. For $n = 4 \cdot 10^8$ cm^{-3} the value of $\omega_{pi}/2\pi \approx 1$ MHz, which is in good agreement with the experimentally observed frequency. The oscillations with frequency f_1 can thus be identified with ion plasma oscillations. As can be seen from Fig. 3, these oscillations are also observed as low-frequency beats between two high-frequency signals at close frequencies.

For all modes of oscillation we measured the phase shift between the signals from probes movable in azimuth. The azimuthal mode numbers satisfy relationship (2): $m = 2$, $m_1 = -1$, $m_2 = 1$. No phase shift is detected along the axis of the system, i.e., the oscillations propagate in a direction perpendicular to the magnetic field.

We note that the harmonics of the oscillations with fundamental frequencies f_0, f_1, f_2 also satisfy the decay condition

$$f_{mn} = nf_0 + mf_1, \quad f_2 \equiv f_{11},$$

the amplitude being the greatest for oscillations with m = n (m and n are the harmonic numbers). In the harmonic spectrum of oscillations of frequency f_{mn}, the amplitude for a well-developed nonlinear interaction is greatest for oscillations with frequency f_{33}.

Under conditions of a well-developed three-wave interaction the elctron temperature reaches a value $T_e \approx 100$ eV, i.e., 5-10 times greater than the value $T_e \approx 10$-20 eV under conditions when oscillations are absent.

We are indebted to K. N. Stepanov for suggesting the problem and for valuable remarks. Thanks are also due to A. G. Pokroev, M. V. Sosipatrov, and M. G. Krivonos for their assistance in setting up the experiments.

Titanium adsorption on tungsten

Yu. K. Ustinov and S. V. Fedichev
A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad
(Submitted January 22, 1974)
Zh. Tekh. Fiz., 44, 1790-1792 (August 1974)

Titanium adsorption on tungsten has been studied by the flash method in a pulsed time-of-flight mass spectrometer. Titanium is found to desorb from two states bound to the tungsten. The first state, an adsorption state, has the following characteristics: $E = 80$ kcal/mole and $C = 10^{13}$ $\sec^{-1}$. The second state is of a diffusive nature, characterized by $E = 25$ kcal/mole and $C = 3 \cdot 10^{3}$ $\sec^{-1}$.

The getter properties of sputtered titanium films are widely used in high-vacuum technology. Titanium is also known to catalyze the formation of methane from molecules containing hydrogen and carbon. To study the simplest reaction, in which methane is formed from hydrogen and carbon dioxide on a titanium catalyst $H_2 + CO \rightarrow CH_4$ we use the thermal-flash method in a pulsed time-of-flight mass spectrometer.[1]

We use titanium films sputtered in high vacuum onto a tungsten substrate, which is neutral with respect to methane synthesis, for better purification of the titanium sorbed gases and for more complete titanium detection during the experiments.

Preliminary experiments on the adsorption of titanium on tungsten are given below.

The substrate is a tungsten ribbon 40 × 0.5 × 0.05 mm; after the appropriate heat treatment, its surface is dominated by the ⟨100⟩ face. The ribbon is heated by electric current. The titanium evaporators are tantalum strips 40 × 0.7 × 0.1 mm in size, to one or both sides of which titanium strips are spot-welded. Figure 1 shows the arrangement of the substrate and evaporators. Fluxes of titanium atoms from the sides of evaporator 3 and the flux desorbed from the substrate can enter the ion source of the pulsed time-of-flight mass spectrometer. Deposition of titanium from evaporator 1 onto the side of the substrate opposite the ion source shows that titanium atoms do not migrate to the opposite side of the substrate (facing the ion source) during the subsequent thermal desorption.

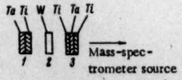

Fig. 1. Arrangement of adsorbent and titanium sputterers with respect to the source of the pulsed time-of-flight mass spectrometer.

The residual pressure in the spectrometer during the experiments is $5 \cdot 10^{-9}$ torr; the residual gases are primarily H_2 and CO, with partial pressures in the ratio 3 : 1. During titanium deposition an appreciable amount of methane appears in the mass spectrum of the residual gases.

The measurement procedure is as follows: The substrate is cleaned by heating to T = 2300°K and then cooled to room temperature. Then a titanium film is deposited on its surface for a certain time t_a, the evaporator is turned off, and the flash occurs. In certain experiments the substrate is cooled to 130°K or heated to 850°K during titanium adsorption. Figure 2 shows the current of Ti^+ ions as a function of the time, i(t), after the beginning of the flash for various titanium-adsorption times. During the flash we observe only the atomic ions Ti^+ and Ti^{++}. The same figure shows the increase in the substrate temperature during the flash, T(t). This functional dependence is determined by the method described in ref. 1.

We note the following features of the i(t) curves: 1) The titanium desorption begins at the same substrate temperature, regardless of the adsorption time t_a. 2) The peaks of the desorption curves, i_{max}, shift toward higher temperatures with increasing t_a. 3) As t_a increases the descending branches of the i(t) curves shift appreciably toward larger values of T, in the manner characteristic of diffusive desorption.

The ion current detected in the mass spectrometer during the flash is proportional to the flux of desorbed titanium atoms, i.e., $i(t) = 1/B\nu(t)$. The proportionality coefficient B is a function of the probability for the ionization of atoms in the ion source, the transmission of the mass spectrometer, and the ion–electron emission yield at the first dynode of the secondary-electron multiplier. The value of B is also a function of the substrate temperature T (it is proportional to $\sqrt{T}$ in the case of a Maxwell energy distribution for the particles), but over a narrow range of T this functional dependence is slight, so

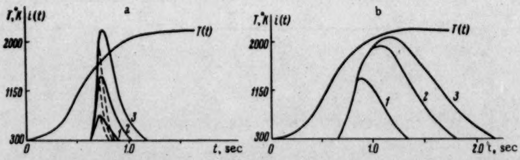

Fig. 2. Curves showing the desorption of titanium from a tungsten surface for various exposure times. a: t_a, min: 1) 0.5; 2) 1.0; 3) 2.0. b: t_a, min: 1) 5.0; 2) 10.0; 3) 20.0.

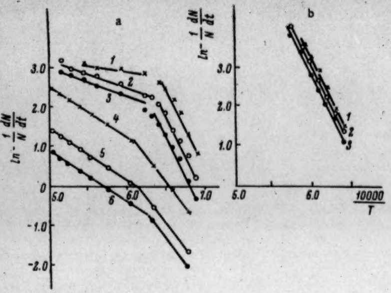

Fig. 3. Arrhenius curves. a: Arrhenius curves for titanium desorption. t_a, min: 1) 0.5; 2) 1.0; 3) 2.0; 4) 5.0; 6) 10.0; 6) 20.0. b: Arrhenius curves for titanium desorption from the first state. t_a, min: 1) 0.5; 2) 1.0; 3) 2.0.

we ignore it. To determine the value of B we use the flux of titanium atoms from evaporator 3 (Fig. 1), calculated from the known values of the titanium vapor pressure.[2]

Under the assumption that the atoms are desorbed according to first-order desorption kinetics, we can write the desorbed flux at any time t after the beginning of the flash as

$$\nu(t) = Bi(t) = -\frac{dN}{dt} = CN\exp\left(-\frac{E}{RT}\right), \qquad (1)$$

where N is the concentration of adsorbed atoms on the surface and E is the desorption activation energy. With E independent of N, we find from (1)

$$N(t) = N_a - B\int_0^t i\,dt = B\int_t^\infty i\,dt, \qquad (2)$$

where N_a is the concentration of adsorbed atoms before the flash at t = 0. For any time t the value of N(t) is proportional to the area under the desorption curve to the right of the i(t) ordinate (Fig. 2). The value of N_a is proportional to the entire area bounded by the desorption curve. The values of N_a, N(t), and dN/dt are found from the experimental i(t) functional dependences.

Comparing for each t the corresponding values of dN/dt and N(t), and using (1), we construct the functional dependences $\ln[(-1/N)(dN/dt)] = \Phi(1/T)$ with E = const; these curves are line segments whose slopes give E and whose ordinate intercepts give the constant ln C. Functional dependences of this type, calculated from the data in Fig. 2, are shown in Fig. 3a. These are approximated by two line segments with different slopes. The two different types of functional dependence imply that there are two different groups of sorbed titanium atoms.

Numerical estimates show that curve 1 in Fig. 2a corresponds to the desorption of a monolayer adsorbed before the titanium flash; correspondingly, curves 2 and 3 are associated with initial coverages greater than a monolayer. During the flash the titanium desorption occurs at T > 1500°K. We propose that as the temperature is raised (before desorption begins) a large fraction of the titanium atoms dissolve in the tungsten lattice. When desorption begins the concentration of adsorbed titanium atoms remaining on the surface is smaller than that corresponding to a monolayer $N < N_0$. Initially, it is these atoms remaining on the surface which are desorbed; their desorption governs the shape of the initial parts of the i(t) flash curves in Fig. 2a and the low-temperature parts of the curves in Fig. 3a. When the concentration of adsorbed atoms has fallen off as a result of the desorption we observe a diffusive flux of atoms from the tungsten lattice to the surface. This assumption is consistent with the fact that a Ti–W solid solution exists in the range[3] 800–1200°K. This second and slower process stretches out the i(t) desorption curves and corresponds to the high-temperature regions in Fig. 3a. During the flash, both processes of course occur at the same time, at different rates, and it is necessary to distinguish between them in order to determine the corresponding kinetic characteristics.

In first-order desorption kinetics, the peak on the desorption curve, i_{max} at T_{max}, is independent of the initial concentration of adsorbed atoms before the flash; under the assumption that the contribution of bulk diffusion is minimal during the desorption of a monolayer (curve 1 in Fig. 2a), we add the symmetric decaying parts (the dashed branches in Fig. 2a) to the desorption curves (rising front) at point T_{max}. In this manner we extract from the i(t) curves the part in which the flash is due primarily to the desorption of adsorbed atoms. After plotting $\ln[(-1/N)(dN/dt)] = \Phi(1/T)$ for these parts from the i(t) curves, we obtain the curves in Fig. 3b, whose slopes are independent of the initial concentration of titanium atoms in the film. The values E = 80 ± 5 kcal/mole and $C = 10^{13}$ sec^{-1} found from these curves are the kinetic characteristics of the thermal desorption of adsorbed titanium atoms from the tungsten ⟨100⟩ face. We recall that the heat of sublimation of titanium is E = 112 kcal/mole (ref. 2).

To test the validity of our method for determining T_{max} we calculate the leading parts of the desorption curves in Fig. 2a by a different method – that proposed by Redhead.[4] We find E = 75 ± 3 kcal/mole, in agreement with the value E = 80 ± 5 kcal/mole found from Fig. 3b.

At large initial concentrations of titanium atoms (corresponding to several monolayers), the slopes of the high-temperature parts of the curves in Fig. 3a apparently correspond to the desorption of dissolved titanium. The kinetic characteristics for the thermal desorption of dissolved titanium, found from the curves in Fig. 3a, turn out to be E = 25 ± 3 kcal/mole and $C = 3 \cdot 10^3$ sec^{-1}.

The parameters characteristic of titanium desorption from tungsten are necessary for studying the production of methane on titanium films deposited on tungsten.

Effect of the radiation density on ion drift velocity in a cadmium–helium laser

G. N. Tolmachev, E. L. Latush, and V. S. Mikhalevskii

Scientific-Research Institute of Physics, Rostov-on-Don

(Submitted October 22, 1973)
Zh. Tekh. Fiz., 44, 1792-1794 (August 1974)

The effect of the radiation density in the cavity of a Cd–He laser on the drift velocity of cadmium ions in the $D_{5/2}$* state is determined. This state is the upper level for the 4416 Å laser transition.

1. The experiments reported here are carried out with an annular cataphoretic cadmium–helium laser with a cavity circumference of 3 m. The cavity is formed by two spherical mirrors (radii of curvature 2 m) and a plane mirror. The discharge tube, 1.8 mm in diameter with an active region 45 cm long, is placed between the spherical mirrors. Two rotatable plane-parallel plates are placed in the laser cavity to introduce a calibrated loss. A mirror system guides the rays moving in opposite directions onto a Fabry–Perot scanning interferometer. The drift velocities of the cadmium ions are measured by the method described in ref. 1, under the discharge conditions optimum for lasing: a helium pressure of 5 torr and a discharge current of 80 mA.

2. The measurements show that the drift velocity of the $D_{5/2}$* Cd II ions is a nonlinear function of the cadmium vapor pressure in the discharge; the functional dependence displays a clear minimum at pressures corresponding to the maximum radiation power.

It is reasonable to suggest that this functional dependence of the drift velocity on the cadmium vapor pressure is related to the power level in the cavity. This assumption is supported by the experimental functional dependence of the cadmium-ion drift velocity on the radiation power at the (constant) vapor pressures and other discharge parameters which are optimum for lasing (Fig. 1). The radiation power is varied by introducing loss in the cavity. It follows from the data in Fig. 1 that an increase in the radiation power in the cavity leads to a significant reduction of the drift velocity.

3. These results can be understood by noting that in the cadmium–helium laser the lifetime of the upper level is long ($\tau \approx 0.6$ μsec) (ref. 2), and this level is populated, according to current ideas, by Penning collisions from the ground state of the atom.[3,4] Since the drift velocity of the atoms is much lower than the ion drift velocity (even zero), a cadmium atom arrives in the upper ionic state with essentially zero average velocity; then it is accelerated in the axial electric field. Since the lifetime of the $D_{5/2}$* ion is long, the average velocity it acquires can be large. However, if the ion moves in the laser field, its lifetime is reduced because of the stimulated emission,[4] so that the velocity which it can reach is reduced.

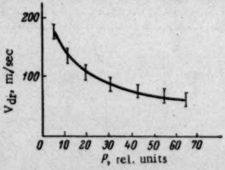

Fig. 1. Cadmium-ion drift velocity as a function of the radiation power in the cavity.

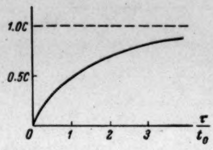

Fig. 2. Position of the maximum of the distribution function, in units of the thermal velocity (C), as a function of the ratio of the lifetime τ to the time required for the establishment of a steady-state ion drift velocity t_0.

4. To show the effect of the laser-radiation field in the cavity on the drift velocity we calculate the ion velocity distribution as a function of the ion lifetime, taking collisions into account. The momentum p of an ion satisfies

$$\frac{dp}{dt} = eE - \delta\langle VQ\rangle N_{He}p. \tag{1}$$

Here, $\delta = M_{He}/M_{Cd}$ is the part of the momentum given up in a collision of a Cd^+ ion with a He atom, Q is the momentum-transfer cross section, V is the relative velocity of the Cd^+ ion and the He atom, N_{He} is the density of helium atoms, and E is the field. The solution of the equation for the directed velocity V_z is

$$V_z = V_{z0} + \frac{eEt_0}{M_{Cd}}\left(1 - e^{-t/t_0}\right), \tag{2}$$

where

$$t_0 = \frac{1}{\delta\langle QV\rangle N_{He}} \tag{3}$$

is the characteristic time for the establishment of a directed ion velocity, and V_{z0} is the initial ion velocity.

The probability for the emission of a photon by an ion in time interval dt a time t after excitation is[5]

$$dW = e^{-t/\tau}\frac{dt}{\tau}, \tag{4}$$

where τ is the ion lifetime.

Solving Eqs. (2) and (4) simultaneously, we find the probability that the directed velocity of the ions will reach the value V_z:

$$dW = \left(1 - \frac{V_z - V_{z0}}{\frac{eEt_0}{M_{Cd}}}\right)^{\frac{t_0}{\tau}-1} \frac{dV_{z0}}{\frac{eE\tau}{M_{Cd}}}. \tag{5}$$

Then the z-velocity distribution function of the emitting ions is

$$F(V_z) = \text{const} \int\limits_{V_z - \frac{eE}{M_{\text{Cd}}} t_0}^{V_z} \left(1 - \frac{V_z - V_{z0}}{\frac{eEt_0}{M_{\text{Cd}}}}\right)^{\frac{t_0}{\tau} - 1} e^{-\frac{V_{z_0}^2}{2kT} M_{\text{Cd}}} \, dV_{z0}. \quad (6)$$

Because of the radiation field there is a change in the lifetime τ; the integral in (6) must be evaluated with this lifetime as a parameter. The distance from the velocity zero to the distribution peak gives the Doppler shift, which is measurable in practice, and the cadmium-ion drift velocity. Figure 2 shows the positions of the ion distribution peaks in units of the most probable thermal velocity $\sqrt{2kT/M_{\text{Cd}}}$, calculated under the assumption that the maximum attainable directed velocity is of the order of the thermal velocity (i.e., under the assumption $t_0eE/M_{\text{Cd}} = \sqrt{2kT/M_{\text{Cd}}} = C$). We see that the distribution peak shifts toward a zero average velocity as the lifetime decreases. This theoretical functional dependence is in qualitative agreement with the experimental data.

Figure 2 also shows that the drift velocity displays a functional dependence on the radiation power in the case in which the ion lifetime is comparable to the time required for the establishment of a steady-state drift velocity. Our estimates show that this condition is satisfied in the Cd−He laser.

This phenomenon is not observed in the argon laser, in which large ion drift velocities are observed,[6] because of the brief lifetime of the excited ion levels and because these levels are populated from the ground state of the ion, rather than the atom.

Accordingly, the drift velocity of the $D^*_{5/2}$ cadmium ions decreases with increasing laser power ($\lambda = 4416$ Å) because the lifetime of these ions is reduced by the stimulated emission; accordingly, the unperturbed ion drift velocities should be measured at low radiation-power levels in such lasers.

This effect can cause a contraction of the emission spectrum of this type of laser, and must be taken into account in analyzing the mode structure. This effect is further evidence that the $D^*_{3/2,\,5/2}$ Cd II levels are populated from the ground state of the atom under optimum conditions. This conclusion agrees with the mechanism of Penning collisions with metastable helium atoms.

It is hoped that future study of this phenomenon can be used to examine the lifetimes and the dynamics of drift velocities under typical discharge conditions.

Dielectric strength of a vacuum gap with electrodes irradiated with He$^+$ and H$^+$ ions

A. P. Solodovnikov and Yu. M. Khirnyi

(Submitted June 25, 1973; resubmitted December 12, 1973)
Zh. Tekh. Fiz., 44, 1795-1796 (August 1974)

The dielectric strength of the vacuum gap between electrodes of metals differing in crystal structure and containing implanted He$^+$ atoms has been studied. The mechanism by which the atoms implanted in the electrodes affect the dielectric strength of the evacuated gap is discussed.

Measurements of the dielectric strength of a vacuum gap with stainless steel electrodes irradiated beforehand with inert-gas and nitrogen ions are reported in refs. 1 and 2. The dielectric strength is determined in ref. 1, where a working hypothesis is also offered for the mechanism for the enhanced dielectric strength of such gaps. Implanted He atoms evidently produce a dense layer of relatively tightly bound atoms at the electrode surface; these atoms stabilize sorption and diffusion processes at the electrodes, inhibiting ionization and bulk processes responsible for the predischarge current. The microscopic surface geometry of the electrodes is assumed to remain essentially constant. Evidence in favor of this assumption is the fact that the greatest increase in the dielectric strength occurs when the electrodes are bombarded with helium atoms rather than heavier ions, which would cause more damage to the metal surface during the bombardment.

We report here a study of the changes in the dielectric strength following helium bombardment of Mg, Al, Ti, Cu, Nb, and Mo electrodes, which have three types of crystal structure and which differ markedly in sputtering coefficient. The dielectric strengths of the gaps are shown in Table 1.

TABLE 1

	Electrodes						
	Mg	Al	Ti	Cu	Nb	Mo	stainless steel
Dielectric strength,	230	240	400	260	310	300	300

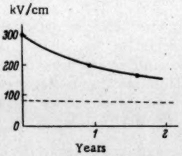

Fig. 1

In all cases at voltages above 200 kV the values of the dielectric strength are corrected to d = 10 mm. The electrodes are bombarded by ions at $E_i = 20$ keV; the total bombardment charge is $Q = 2 \cdot 10^{16}$ ions/cm^2, the optimum value for stainless steel electrodes bombarded by helium.

The dielectric strength is apparently not explicitly related to the type of crystal lattice, because in electrodes made of metal with the same hexagonal lattice – Mg and Ti – the values of the dielectric strength are 230 and 400 kV/cm, respectively.

Nor is the sputtering coefficient (which determines the degree of microscopic working of the electrode surface during the bombardment) the basic reason for the increase in the dielectric strength, since the maximum strength, 400 kV/cm, is obtained for Ti, whose sputtering coefficient is small; for Al, which also has a small sputtering coefficient, the strength is only 240 kV/cm. These experiments of course in no way rule out an effect of the microscopic surface geometry on the predischarge current. Using ions of the same species to bombard the electrodes, and varying the energy, intensity, and bombardment angle, i.e., by changing from ion bombardment to ion etching, one can produce a microscopic geometry such that the dielectric strength of the gap falls below the value characteristic of the unirradiated electrodes; this circumstance is also noted in ref. 3, although that work focused on the electric strength.

With stainless steel electrodes bombarded by He ions the dielectric strength decreases after the electrodes are held for a prolonged period of time under ordinary atmospheric conditions (Fig. 1). This decrease can be explained on the basis of the hypothesized decrease in the density of the layer of implanted He atoms due to diffusion. Hydrogen is known to diffuse more rapidly than inert gases in metals, so we have measured the dielectric strength as a function of the storage time of Ti electrodes bombarded by hydrogen ions in order to determine the role of the change in the density of implanted atoms on the magnitude of the dielectric strength. The extremely small change in the dielectric strength between such electrodes over five months apparently implies that the diffusion of hydrogen ions implanted into a metal by bombardment is not identical to the diffusion of hydrogen dissolved from the gas phase.

Hydrodynamic stability of the Uragan stellarator

V. M. Zalkind, Yu. K. Kuznetsov, V. K. Pashnev, and V. M. Tonkopryad

(Submitted January 28, 1974)
Zh. Tekh. Fiz., 44, 1796-1799 (August 1974)

The hydrodynamic stability of the $l = 3$ Uragan stellarator has been studied by measuring magnetic-field perturbations outside the plasma. A hydrodynamic instability has been studied. The perturbations have the spatial structure m = 1, n = 1. The possible connection between the hydrodynamic perturbations and the macroscopic plasma instability observed for increasing current is discussed.

Investigations of the current-carrying plasma in the $l = 3$ Uragan racetrack stellarator with large shear show[1] that increasing the current to a particular critical value causes an abrupt transition into an unstable regime. This regime is characterized by substantial fluctuations in loop voltage, plasma density, and other parameters, and increased losses of particles and energy from the plasma; therefore, further attempts to increase the energy containment by increasing the introduced power have little effect.

In the present work we investigate the hydrodynamic instability of a current-carrying pinch as one of the most probable causes of the observed effect.

EXPERIMENTAL MEASUREMENT

The main investigations on the Uragan stellarator are carried out in the optimum regime for obtaining the maximum plasma parameters. In this regime the mean radius of the outer unperturbed surface $r_0 = 6.8$ cm (radius of chamber $r_c = 10$ cm) and the rotational transform of the magnetic lines of force, forming this surface, for a single circuit (L = 1035 cm) is $i_0^b = 1.5\pi$. The direction of the ohmic heating current is such as to increase the rotational transform. The pressure of the working gas (helium) is $P = 10^{-4}$ mm Hg. The experiments are carried out with a magnetic field $H_0 \leq 7.2$ kOe.

The critical current is determined mainly by the magnetic field: $J_{cr}(\text{kA}) = 0.4\text{–}0.7\ H_0\ (\text{kOe})$. The coefficient of proportionality varies within the limits 0.4-0.7, depending on the current rise time in the initial phase of the discharge. We obtain the following maximum plasma parameters in the optimum regime: $\bar{n}_e = 8 \cdot 10^{12}\ \text{cm}^{-3}$, $\bar{T}_e = 300$ eV, $\bar{T}_i = 30$ eV.

The hydrodynamic plasma perturbations are studied by measuring magnetic-field perturbations outside the plasma using magnetic probes. Perturbations with m = 1 and n = 0.1, which are most probable under our conditions, can also be measured directly by distributed windings, inductively coupled to the given modes. The probes and windings are located outside the chamber and the helical winding at a distance of 14 cm from the axis. There is also a probe inside the chamber which can be moved in the radial direction. This probe and probes intended for studying the azimuthal structure of the perturbations are located along the straight section of the stellarator, where the shape of the cross section of the plasma is nearly circular because of the presence of the circularizer. In the measurements we process signals with lifetime 0.5-1.0 msec; these satisfy the condition that the process be stationary. The frequency spectrum and spatial structure of the oscillations are determined by correlation measurements.

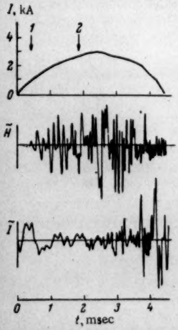

Fig. 1. Oscillograms of the current, oscillations of magnetic field $\tilde{H}$, and oscillations of current $\tilde{J}$. $H_0 = 4.8$ kOe.

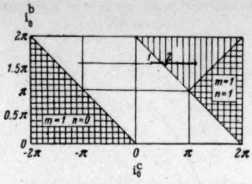

Fig. 2. Diagram of stability of current-carrying plasma in a stellarator with respect to perturbations with m = 1.

MEASUREMENT RESULTS AND THEIR DISCUSSION

Oscillograms that illustrate the hydrodynamic instability are presented in Fig. 1. The figure also shows magnetic-field oscillations (measured by the winding) corresponding to m = 1, n = 1, and the first mode of the helical instability; we also show oscillations of the total current (from the signal output of the Rogowski loop, proportional to J,) using a high-frequency filter. The arrows 1 and 2 indicate the transition to the unstable regime.

On the basis of the theory of hydrodynamic stability of a current-carrying plasma in a stellarator[2] we conclude that the difference between a stellarator and a tokamak in the present context is the additional rotational transform due to the helical windings. Therefore we propose that the theoretical results on the helical instability in a tokamak obtained by Shafranov[3] and other authors apply for a stellarator, if the additional rotational transform is taken into account. The chief parameter determining the stability of a current-carrying plasma is the rotational transform at the surface i_0. To calculate i_0 we use the simple summation of i_0^b and the rotational

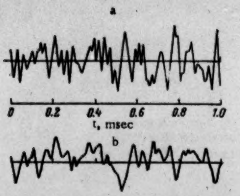

Fig. 3. Characteristic realizations of magnetic-field oscillations: a) inside; b) outside the chamber.

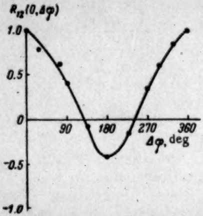

Fig. 4. Azimuthal cross-correlation function of magnetic-field oscillation $R(0, \Delta\varphi) = \langle\tilde{H}_1\tilde{H}_2\rangle/\sqrt{\langle\tilde{H}_1^2\rangle\langle H_2^2\rangle}$.

transform generated by the current $i_0^c = H_\varphi(r_0)L/H_z r_0$. Actually the mean radius of the configuration depends on the magnitude and direction of the current, and i_0 is determined by i_0^b and i_0^c in a more complicated way. However, as is shown by appropriate calculations, under the conditions of our experiments the error in the determination of i_0 due to these effects is less than 10%.

To compare the experimental data on the instability with the theoretical predictions we present a theoretical diagram of the stability of a current-carrying plasma in a stellarator taken from ref. 2 (Fig. 2). Since $i_0^b = 1.5\pi$ in our case, perturbations with $m \geq 2$, which play an important role in Tokamak experiments,[4] should not be excited and the most dangerous mode is the $m = 1$ mode; the region corresponding to this mode is cross-hatched on the diagram (Fig. 2). In the region with cross-hatching ($i_0^c > i_0^b$) an instability is expected for arbitrary values of the distribution over the cross section and the finite plasma conductivity broadens the instability region; the universal condition for suppression of the mode $m = 1$ has the form[3] $i_0 < 2\pi$.

The horizontal line in Fig. 2 shows the range of variation of i_0^c in the experiment, and the values of i_0^c for which oscillations with $m = 1$ arise and a transition to an unstable regime occurs are noted.

In qualitative agreement with the theory, a change in direction of current ($i_0^c < 0$) leads to the suppression of the $n = 1$ mode and the appearance of perturbations with $n = 0$. However, in contrast with the theoretical criterion, the $n = 0$ mode is excited for comparatively small currents ($i_0^c < 0.5\pi$), for which the condition $i_0 = 0$ is not satisfied at the boundary but somewhere within the plasma.

The excitation of the $m = 1$ mode in the fundamental regime is also verified by probe measurements. Characteristic magnetic-field oscillations used for the correlation analysis are presented in Fig. 3. Evidently the oscillations are rather irregular. The conducting chamber distorts the information on the frequency spectrum of the perturbations when the probes are outside the chamber. The measurements with the probe inside the chamber show that the frequency spectrum occupies the range f = 2-20 kHz with maximum power density at f = 8-12 kHz. The growth rates of perturbations corresponding to these frequencies are 5-10 times smaller than the theoretical estimate.[3]

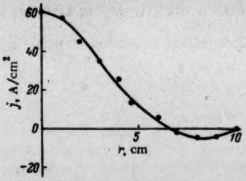

Fig. 5. Current-density distribution along radius, measured by a magnetic probe in an unstable regime.

The example of an azimuthal cross-correlation function is shown in Fig. 4; it indicates that an $m = 1$ mode is excited. The experimental data also indicate the presence of higher harmonics in the azimuthal structure. The total power of oscillations with $m = 0.1$, measured by the windings and the Rogowski loop, is usually less than the power of the oscillations received by the magnetic probe. The radial dependences of the mean amplitude obtained using the movable probe are indicated by this. For the $m = 1$ mode the magnetic perturbation field should decrease according to a quadratic law: $\tilde{H}(r) = \tilde{H}_0(r_0/r)^{m+1}$; in most regimes we observe a stronger dependence. The presence of higher harmonics can be due to strong nonlinear distortions of the $m = 1$ structure although the theory does not exclude the possibility of excitation of different branches of short-wave instabilities.[2] It is impossible to investigate the spatial structure more thoroughly in our experiments because the probes are located at a considerable distance from the plasma surface and experience a strong shielding effect due to the conducting chamber. Thus, the magnetic field of the short-wave perturbations is weakened considerably and the accuracy of the correlation analysis is poor.

If we assume that the current density is perturbed by surfaces localized at a radius $r \approx r_0$, then the value of the perturbed currents J_{pert} calculated from the measured values of $\tilde{H}$ reaches $J_{\text{pert}} \approx 0.05$ J. Oscillations of the total current J usually exhibit a considerably lower level.

The experimental data do not allow us to verify that the observed hydrodynamic perturbations are the cause of the macroscopic instability. The perturbations are not large enough for them to be considered as the direct mechanism for the increased loss of plasma. The sharp transition of the discharge to an unstable regime is not accompanied by any special features in the magnetic-probe signals. It is possible that the helical instability is the initial phase and causes some complicated instability. In particular, it is entirely probable that the transition to the unstable regime in our case is similar to the disruptive instability in tokamaks.[3] The following result favors this interpretation. An important feature of the disruptive instability is the contraction of the current channel, which precedes it. In these experiments we observe a rapid increase in the major radius,[1] which can also be explained by a contraction of the current channel.

In conclusion we note interesting results obtained by measurements of the function $H_{\varphi}(r)$ with a movable probe. The corresponding current-density profiles, constructed assuming axial symmetry, have negative values near the pinch boundary (Fig. 5). According to these measurements, a reverse current is excited in the unstable regime and can be a considerable fraction of the total current. Since the use of probes for measuring the current density introduces uncertainties, we also check all the other measurable parameters of the discharge. There is no noticeable effect, even when the probe is inserted at the radius r = 5 cm. This gives us a basis for assuming that the data on the excitation of negative currents are reliable. The possibility of the appearance of such a current is indicated, in particular, by the nonlinear theory of the helical instability given by Kadomtsev and Pogutse.[5] This effect can also be explained by the formation of a longitudinal electric field owing to the anomalously rapid expansion of the plasma pinch across the azimuthal component of the helical field and current field.

The authors thank V. A. Suprunenko for helpful remarks.

Equations and boundary conditions for a three-dimensional quasistationary field

V. I. Yurchenko

Institute of Nuclear Physics, Siberian Branch,
Academy of Sciences of the USSR

(Submitted November 22, 1973)
Zh. Tekh. Fiz., 44, 1799-1802 (August 1974)

The problem of determining a quasistationary three-dimensional field is formulated. The source is described in the equations by means of an auxiliary vector $\mathbf{E}^a$ on which are imposed certain simple limitations. It is shown that the magnetic field is then uniquely defined by the magnitude of the emf of the source and does not depend on the form of $\mathbf{E}^a$. Sets of equations and boundary conditions for the electromagnetic potentials **A** and φ and the electromagnetic fields are given. The electric field vector is represented as a sum of a solenoidal vector $\mathbf{E}^r$ and a gradient vector $\mathbf{E}^g$. It is possible to eliminate either the vector $\mathbf{E}^r$ or **B** from the equations, and to set down two different sets of equations. The latter are not as tractable as the equations for **A** and φ. It is noted that violation of charge conservation is permissible in the quasistationary approximation. As a result, unless special conditions are invoked the equations of the quasistationary field do not have a unique solution.

In the analysis of a magnetic field allowing for the skin effect there are many applications in which one requires a matched solution in a mixed conductor–vacuum region or in which the current in a circuit has to be matched to the characteristics of the voltage source. The complexity of such problems is such that exact solutions can be obtained only in certain cases which reduce, in the long run, to the one-dimensional case.[1,2] In two-dimensional problems, if the accuracy of estimates is insufficient, one is obliged to seek a solution by numerical methods. Some contemporary examples of such calculations are found in refs. 3-8.

The transition to three measurements requires special consideration. This is due both to the increase in the number of measurements and also to the need to introduce into the field equations certain quantities characterizing the voltage source. In the strict formulation, the field must be uniquely determined by these quantities. This requires that the formulation of the problem be given special consideration, and it is with this problem that the present paper is concerned. For simplicity the relative dielectric and magnetic permitivities of the medium are set equal to unity, $\varepsilon = \mu = 1$, while the conductivity σ is taken to be a function which has a constant value in the domain of a conductor and which equals zero in vacuum.

1. The source is most easily introduced into the equations by means of the generalized Ohm's law

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{E}^a), \tag{1}$$

the vector $\mathbf{E}^a$ in the conductor being regarded as a given function of the coordinates and time (see Fig. 1). The initial set of equations, obtained by combining (1) with Maxwells equations, is written in the form (the displacement current is neglected)

$$\operatorname{curl} \mathbf{B} = \mu_0 \mathbf{j}, \tag{2}$$

$$\operatorname{div} \mathbf{B} = 0, \tag{3}$$

$$\operatorname{curl} \mathbf{E}^r = -\frac{\partial \mathbf{B}}{\partial t}, \tag{4}$$

$$\operatorname{div} \mathbf{E}^r = 0, \tag{5}$$

$$\operatorname{curl} \mathbf{E}^g = 0 \tag{6}$$

$$\operatorname{div} \mathbf{E}^g = \frac{\rho}{\varepsilon_0}, \tag{7}$$

$$j = \sigma(\mathbf{E}^r + \mathbf{E}^g + \mathbf{E}^a). \tag{8}$$

Here we have represented the vector electric field **E** as the sum of a solenoidal vector $\mathbf{E}^r$ and a gradient vector $\mathbf{E}^g$, i.e., we have split it up into two simpler vectors that are different in mathematical (and physical) respects. This sort of decomposition is utilized in the determination of vector fields[9] and simplifies the formulation of the problem. From (2) div $\mathbf{j} = 0$ everywhere, and consequently $\mathbf{j}_\perp = 0$ (otherwise div **j** becomes infinite on the surface of the conductor). This is the only boundary condition needed to solve the problem, and it follows directly from the equations. In Eqs. (2)-(8) the vector $\mathbf{E}^a$ is prescribed; the quantities **B**, $\mathbf{E}^r$, $\mathbf{E}^g$, **j**, ρ are to be determined.

2. We now write equations for **A** and φ. We take div **A** = 0. The vector potential then only describes solenoidal fields:1) $\mathbf{B} = \operatorname{curl} \mathbf{A}$, $\mathbf{E}^r = -\partial \mathbf{A}/\partial t$, $\mathbf{E}^r = -\nabla\varphi$, and from (2)-(8)

$$\Delta \mathbf{A} = -\mu_0 \mathbf{j},$$

$$\Delta\varphi = -\frac{\rho}{\varepsilon_0},$$

$$\mathbf{j} = \sigma\left(-\frac{\partial \mathbf{A}}{\partial t} + \mathbf{E}^g + \mathbf{E}^a\right).$$

By eliminating ρ and **j** from these equations (to eliminate ρ it is necessary to use div $\mathbf{j} = 0$, div $\mathbf{A} = 0$) we obtain the equations

$$\gamma \frac{\partial \mathbf{A}}{\partial t} = \Delta \mathbf{A} + \gamma(\mathbf{E}^g + \mathbf{E}^a), \tag{9}$$

$$\Delta\varphi = \operatorname{div} \mathbf{E}^a, \tag{10}$$

where $\gamma = \sigma\mu_0$, with the boundary condition

$$E^g_{\perp i} = -E^a_{\perp i} + \frac{\partial A_{\perp i}}{\partial t} \quad (j_\perp = 0). \tag{11}$$

Here and below the index i indicates that a quantity is taken at the interior side of the conductor surface and e that it is taken at the exterior side, $\perp$ indicates the projection of the vector on the interior normal **n**.

Equation (10) holds only within the conductor: It does not allow for surface charges ρ_S or for charges in vacuum. However, the value of $\mathbf{E}^g$ in vacuum has no effect on **A** and does not enter into boundary condition (11). It is therefore sufficient to know it only in the conductors. For this we have the problem (10)-(11). The distribution of $\mathbf{E}^g$ in vacuum can be found by solving the external boundary problem for $\Delta\varphi = -\rho/\varepsilon_0$ with the boundary value of the potential obtained from (10)-(11).

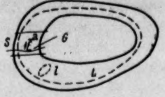

Fig. 1

It is important to note that the potential in (10)-(11) is determined to within an arbitrary constant and that this is a consequence of the approximation under consideration. Because of the absence of displacement current in (2)-(8) it is possible for charge conservation to be violated. To $\mathbf{E}^g$ one can add the electric field of charges arbitrarily dependent on time, and to ρ one can add their density, provided the charges are distributed in vacuum and on the surfaces of the conductors in such a manner that the boundaries of the conductors coincide with equipotentials of their electric field. This does not affect the remaining quantities. If the charges are assumed to be independent of time then this can also be done in the general case in which the displacement current is incorporated in the equations. Here, however, the lack of uniqueness is removed by prescribing the initial value of $\mathbf{E}^g$ in vacuum. This is not possible in the quasistationary approximation. In this case it is necessary to fix the value of ρ outside the conductors (below we assume that $\rho = 0$ there) when the lack of uniqueness in a problem like (10)-(11) can be removed by prescribing either the total charge on the conductor[10] or the value of the potential at any point of the conductor.

We note that Eq. (9) for $\mathbf{A}$ is formally like an inhomogeneous equation for thermal conductivity in which the coefficient γ depends on the coordinates. By writing it in the conductors in the form $\mathbf{E}^g + \mathbf{E}^a = -1/\gamma\ \Delta\mathbf{A} - \mathbf{E}^r$ we see that $(-1/\gamma)\Delta\mathbf{A}$ corresponds to the ohmic voltage drop per unit length, $\mathbf{E}^r$ corresponds to the induced emf per unit length, and $\mathbf{E}^g + \mathbf{E}^a$ corresponds to the total voltage drop per unit length. In the language of electrical engineering Eq. (9) can be regarded as the voltage law in a circuit consisting of a source and a resistor and inductor in series. It is necessary to prescribe the initial value $\mathbf{A}(\mathbf{r}, 0) = \mathbf{f}(\mathbf{r})$ for $\mathbf{A}$ in (9) subject to the condition $\operatorname{div}\mathbf{f} = 0$.

3. Let us manipulate (2)-(8), eliminating certain of the dependent quantities. As above, we can eliminate ρ and $\mathbf{j}$. Then, from (4)-(5), we obtain

$$\mathbf{E}^r = -\operatorname{curl}\iiint\limits_V \frac{\partial\mathbf{B}(\mathbf{r}', t)}{\partial t}\frac{d^3r'}{4\pi|\mathbf{r}-\mathbf{r}'|},$$

where the integration is extended over all space; we thus eliminate $\mathbf{E}^r$ from the remaining equations. Taking the curl of (2) and utilizing (3), we obtain an equation for $\mathbf{B}$

$$\gamma\frac{\partial\mathbf{B}}{\partial t} = \Delta\mathbf{B} + \gamma\operatorname{curl}\mathbf{E}^a + \mathbf{q}, \tag{12}$$

where $\mathbf{q}$ is the surface source due to the jump of σ at the boundary of the conductor. The surface density is

$$\gamma_i\left[\mathbf{n}\times\left(-\operatorname{curl}_i\iiint\limits_V \frac{\partial\mathbf{B}(\mathbf{r}', t)}{\partial t}\frac{d^3r'}{4\pi|\mathbf{r}-\mathbf{r}'|} + \mathbf{E}_i^g + \mathbf{E}_i^a\right)\right].$$

We write (12) inside and outside the conductor; then, in addition to taking

$$E^g_{\perp i} = \operatorname{curl}_{\perp i}\iiint\limits_V \frac{\partial\mathbf{B}(\mathbf{r}', t)}{\partial t}\frac{d^3r'}{4\pi|\mathbf{r}-\mathbf{r}'|} - E^a_{\perp i} \tag{13}$$

($j_\perp = 0$) it is necessary to prescribe the condition of continuity

$$\mathbf{B}_i = \mathbf{B}_e \tag{14}$$

and the condition on the jump of $\partial\mathbf{B}/\partial n$ allowing for $\mathbf{q}$. As in the case of the normal derivative of the potential of a simple layer in passing through a surface containing charges, we obtain

$$\left.\frac{\partial\mathbf{B}}{\partial n}\right|_e - \left.\frac{\partial\mathbf{B}}{\partial n}\right|_i = \gamma_i\left[\mathbf{n}\times\left(-\operatorname{curl}_i\iiint\limits_V \frac{\partial\mathbf{B}(\mathbf{r}', t)}{\partial t}\frac{d^3r'}{4\pi|\mathbf{r}-\mathbf{r}'|} + \mathbf{E}_i^g + \mathbf{E}_i^a\right)\right] \tag{15}$$

Thus (2)-(8) can be replaced by:

$$\left.\begin{array}{l}\left.\begin{array}{c}\gamma\dfrac{\partial\mathbf{B}}{\partial t} = \Delta\mathbf{B} + \gamma\operatorname{curl}\mathbf{E}^a\\ \Delta\varphi = \operatorname{div}\mathbf{E}^a\end{array}\right\}\text{in the conductor}\\ \quad\Delta\mathbf{B} = 0 \quad \text{in vacuo}\end{array}\right\} \tag{16}$$

with boundary conditions (13)-(15). Similarly, by eliminating $\mathbf{B}$ from (2)-(8) we obtain the following set of equations for $\mathbf{E}^g$ and $\mathbf{E}^r$:

$$\left.\begin{array}{c}\gamma\dfrac{\partial\mathbf{E}^r}{\partial t} = \Delta\mathbf{E}^r - \gamma\dfrac{\partial}{\partial t}(\mathbf{E}^g + \mathbf{E}^a),\\ \Delta\varphi = \operatorname{div}\mathbf{E}^a,\\ E^g_{\perp i} = -(E^a_{\perp i} + E^r_{\perp i}),\end{array}\right\} \tag{17}$$

which is simpler than (13)-(16).

We make two remarks. The representation $\mathbf{E} = \mathbf{E}^r + \mathbf{E}^g$ enables us to obtain equations and boundary conditions that do not contain ρ_S. If this representation is not used and if one prescribes $\Delta\mathbf{E} = 0$ in vacuum, $\gamma(\partial\mathbf{E}/\partial t) = \Delta\mathbf{E}\,(\mathbf{E}^a = 0)$ in the conductor, and $E_{\parallel i} = E_{\parallel e}$ and $E_{\perp i} - E_{\perp e} = \rho/\varepsilon_0$ on the boundary, then an incomplete set is obtained since ρ_S, like $\mathbf{E}$, is unknown; in this scheme the second boundary condition is nothing more than a renaming of the variables. The formulation of the problem for the vector $\mathbf{E}$ that does not involve splitting the latter into a solenoidal and a gradient part thus seems to us to be difficult.

It is easy to eliminate $\mathbf{E}^r$ or $\mathbf{B}$ from (2)-(8), but not $\mathbf{E}^g$. If the surface charges are taken into account in the right side of $\Delta\varphi = \operatorname{div}\mathbf{E}^a$, the solution is written in free space, and after this $\mathbf{E}^g = -\nabla\varphi$ is substituted into the equations and boundary conditions, we eliminate $\mathbf{E}^g$, but in place of $\mathbf{E}^g$ in the equations there appears another unknown quantity, ρ_S.

We note that the set of equations given in the present section, (13)-(16) and (17), are less convenient for obtaining solutions than (9)-(11) as they contain equations of higher order either in the space variables or in time.

4. In Maxwell's equations the arbitrarily prescribed vector $\mathbf{E}^a$ is an external quantity. Restrictions corresponding to the conditions of the problem must be imposed upon it.

The circulation of $\mathbf{E}^a$ around any contour of type L (see Fig. 1) must always have the same value, equal to the emf of the voltage generator. This requires that the circulation around any contour of type l must equal zero. Whence follows the first restriction, curl $\mathbf{E}^a = 0$. (The condition $\mathbf{E}^a = 0$ does not imply that $\mathbf{E}^a$ is a gradient vector. For this the circulation of $\mathbf{E}^a$ around contour L must equal zero[11].) For a given emf, the vector $\mathbf{E}^a$ with this restriction can be specified in an infinite number of ways, although the vector **A** does not depend on the form of $\mathbf{E}^a$. Let us consider the stationary case in which $\partial\mathbf{A} \cdot (\partial t)^{-1} = 0$ in (9)-(11). Suppose for different $\mathbf{E}_1^a$, $\mathbf{E}_2^a$ corresponding to the same value of the emf we find respectively $\mathbf{E}_1^g$, $\mathbf{E}_2^g$ and $\mathbf{j}_1 = \sigma(\mathbf{E}_1^g + \mathbf{E}_1^a)$, $\mathbf{j}_2 = \sigma(\mathbf{E}_2^g + \mathbf{E}_2^a)$. Evidently, the circulation of $\mathbf{j}_2 - \mathbf{j}_1$ around any contour in the conductor is equal to zero; accordingly $\mathbf{j}_2 - \mathbf{j}_1 = \Delta\psi$. For ψ we obtain $\nabla\psi = 0$, $d\psi/dn|_1 = 0$. The solution of this problem is an arbitrary constant, so that $\mathbf{j}_1 = \mathbf{j}_2$. Having made the substitution $\mathbf{E}^a - \Delta\varphi_0 \to \mathbf{E}^a$, $\varphi - \varphi_0 \to \varphi$ is the potential determined from (10)-(11) for $\partial\mathbf{A}/\partial t = 0$ in (9)-(11) we obtain equations for **A** that are independent of the initial form of $\mathbf{E}^a$. Thus, to determine $\mathbf{j}$, $\mathbf{E}^r$, **B** (the quantities most frequently encountered in practical applications), any convenient form of $\mathbf{E}^a$ may be chosen, not necessarily localized in the region of the generator G. The latter feature is significant for the determination of φ.

Assume that Eqs. (9)-(11) are solved for a prescribed $\mathbf{E}^a$. Assume that the conductor is bounded by a surface S (see Fig. 1) such that the region occupied by the conductor is singly connected (any contour in this region is a contour of type l); let us redefine the potential by $\varphi = C(t) - \int_{\mathbf{r}_0}^{\mathbf{r}} (\mathbf{E}^g + \mathbf{E}^a) \cdot d\mathbf{r}$ where $\mathbf{r}_0$ is a point taken on either side of S and C(t) is an arbitrary function of time (the ambiguity of the potential is discussed in Sec. 2 above). Let the integration be taken within the conductor without intersecting S. With this definition of the potential the region of the generator reduces to an infinitesimally thin layer on the surface S, and the value of the potential is independent of the form of the vector $\mathbf{E}^a$ chosen for the calculations.

I thank B. V. Chirikov for useful discussion.

[1)] This is also valid for $\partial/\partial t$ div $\mathbf{A} = 0$. For any other gauge the vector potential also describes a part of the gradient field.

Steady-state operation of a surface-ionization thermionic converter

N. V. Volkov, Yu. K. Gus'kov, Yu. I. Kostikov, and V. P. Pashchenko

(Submitted August 7, 1973; resubmitted January 2, 1974)
Zh. Tekh. Fiz., 44, 1802-1804 (August 1974)

The transient waveform obtained by switching a thermionic converter from open-circuit to short-circuit conditions is studied. The analysis centers on processes with characteristic time much greater than the diffusion time. It is shown that these slow processes are a feature of underneutralized operation, and are absent in overneutralized regimes. The cathode temperature is varied in the range 1000-1500°K and the cesium vapor pressure in the range 10^{-3} 0.3 torr.

It has been noted in a previous paper[1] that two time constants are associated with the establishment of steady-state conditions in a converter subsequent to a stepwise switching operation. The shorter, τ_1, is determined by the diffusion time. The character of the processes responsible for the longer time constant, τ_2, was tentatively ascribed to the effect of "well filling" by thermally emitted ions.

In the present paper we present the results of transient-recovery measurements for times much greater than the diffusion time. An experiment has shown that edge effects have a strong influence on the time dependence of the current; accordingly the device is placed in an axial magnetic field of 400 Oe. The electrodes of the device, with an area 1 cm^2, are made from molybdenum. The cathode is indirectly heated. Temperatures are measured by thermocouples. The cesium vapor pressure in the device varies from 10^{-3}–3.10^{-1} torr; the variation of the cathode temperature lies in the range 1000–1500°K.

Figure 1 shows typical transient current and voltage waveforms obtained when the converter is switched (in a time of order 0.2 μsec) from open-circuit to short-circuit conditions. In the time interval (0, τ_1) the recovery is determined by the diffusion time and τ_1 coincides with the ambipolar diffusion time.[1] It is also evident from Fig. 1 that in the absence of an axial magnetic field the current variation in the interval $\tau > \tau_1$ is very weak; when an axial field is applied and edge effects thereby eliminated, the current can vary by a factor of 1.5–2. The time required to establish the voltage does not exceed the switching time (0.2 μsec). The quantity τ_2 is determined from the experimental curves as the time required for the current to reach 95% of its steady-state value, as the precise time at which the latter value is achieved cannot be determined accurately.

Slow variations of current (in a time $\tau > \tau_1$) are observed only in the underneutralized regime (defiency of ions); when short-circuiting occurs an ion trap is formed in the interelectrode gap (which can freely pass to the anode when the diode is open-circuited). Figure 2 shows the volt–ampere characteristic and the current recovery times for switching of the converter from open circuit to a given point on the volt–ampere characteristic. As the amplitude of the voltage pulse increases the recovery time first increases; then, reaching a maximum value in the current saturation region it decreases. The quantity τ_2 falls sharply when an arc discharge is established.

The calculated time to reach steady-state conditions is shown in Fig. 2. In the current saturation region this time is defined as the time required to establish an equilibrium density for the Saha–Langmuir current:

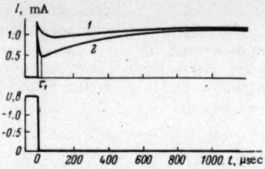

Fig. 1. Oscillograms of current and voltage transient behavior. Pressure p = 0.12 torr, T = 1200 °K. Axial magnetic field H (Oe): 1) 0; 2) 400.

$$\tau_2 = \frac{n_0}{I_c} L,$$

where n_0 is the equilibrium density of the plasma, J_C is the Saha–Langmuir current, L = L – Δ is the effective interelectrode gap, L_0 = 0.2 cm is the geometric gap, and Δ is the reduction of the region occupied by the plasma due to penetration of the electric field when a positive potential is applied to the converter anode; Δ is determined through the equations of refs. 2 and 3. In the above expression the product n_0L determines the total number of cesium ions in the interelectrode gap for an electrode area of 1 cm^2. In the calculation of J_C we use the data of Aamodt et al.[4] on the work function of molybdenum in cesium vapor.

As can be seen from Fig. 2, the experimental and calculated times agree in the current saturation region. On the tail of the volt–ampere characteristic the plasma density is below equilibrium,[5] and the time required to establish the steady state is correspondingly small. At the point on the volt–ampere characteristic at which the near-anode potential jump is approximately zero, the well-filling time is 250 μsec and exceeds the calculated time (200 μsec) for L = L_0. This probably occurs because the

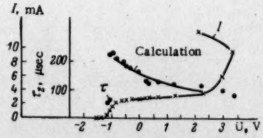

Fig. 2. Dependence of transient duration on anode voltage. p = $2.2 \cdot 10^{-2}$ torr; T = 1250°K; H = 400 Oe.

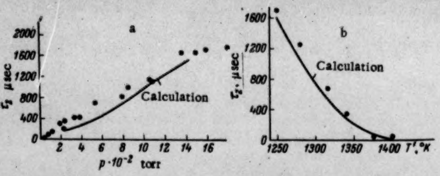

Fig. 3. Dependence of τ_2 on cesium vapor pressure (a): T = 1250°K, U = 0, H = 400 Oe; and on cathode temperature (b): p = 0.16 torr, U = 0, H = 400 Oe.

confinement of the ions in the interelectrode gap is not efficient at small positive potential jumps. The quantity τ_2 begins to fall strongly for U > 3 V on account of ions generated in the near-anode region. In this case a glow can be visually observed in the anode region and the current increases sharply.

Figure 3 shows the experimental and calculated variation of the duration of the transient with cesium vapor pressure (Fig. 3a) and cathode temperature (Fig. 3b). Evidently τ_2 decreases with increasing cathode temperature and increases with increasing cesium vapor pressure because of the increase in the cathode work function and the associated increase in the ion flux from the emitter.

The experimental and calculated curves are in good agreement; accordingly the time τ_2 can be used to estimate the cathode work function in the underneutralized regime.

In conclusion we thank R. Ya. Kucherov for useful discussion.

Transient thermionic-field emission from a point cathode

E. A. Litvinov and A. F. Shubin

Institute of Atmosphere Optics, Tomsk

(Submitted June 8, 1973; resubmitted January 30, 1974)
Zh. Tekh. Fiz., 44, 1804-1806 (August 1974)

The variation of the electron and phonon temperatures of the cathode material under condition of intense thermionic-field emission is investigated. A numerical calculation shows that the electron temperature can exceed the lattice temperature. This feature introduces certain changes in the time criteria for the onset of vacuum breakdown and opens the possibility of obtaining short-duration pulses of emission current with density 10^{10}-10^{11} A/cm^2.

It has been shown by Kartsev et al.[1] that the prebreakdown emission current density j and the delay t_d in vacuum breakdown (with respect to the application of the voltage pulse) are related by $j^2 t_d \simeq 4.5 \cdot 10^9$ A^2·sec/cm^4 (for tungsten). Calculations performed in a previous paper[2] for a cylindrical point emitting under thermionic-field conditions show that the field-emission current density j_0 and t_d are related by $j_0^2 t_d \simeq 2.2\,\rho C/\varkappa_0$, where ρ is the density of the cathode material and C is its specific heat, $\varkappa_0$ is the temperature coefficient of the resistivity, i.e., $\varkappa = \varkappa_0 T$ (T is temperature in degrees K). Numerical estimates of t_d via the equation of ref. 2 are in good agreement with the experimental results of ref. 1.

In the present paper a more detailed analysis is given of the processes at the cathode accompanying intense thermionic-field emission. A more realistic emitter geometry is used: an emitter in the form of a truncated cone with emitting tip radius r_{em}, base radius r_0, and apex angle 2θ. When a high-density emission current is drawn the temperature of the electrons in the metal T_e increases by Joule heating and the Nottingham effect.[3] The latter is due to the fact that the mean energy carried by conduction electrons to the emitting metal–vacuum boundary differs from the mean energy that is removed by the emitted electrons. The lattice temperature of the cathode metal, T_{ph}, increases as a result of electron–phonon interaction.

The following two-temperature model can be used to describe the situation:

$$\left.\begin{aligned}
&C_e\frac{\partial T_e}{\partial t}=\lambda_e\left(\frac{\partial^2 T_e}{\partial r^2}+\frac{2}{r}\frac{\partial T_e}{\partial r}\right)\\
&\quad+\frac{jC_e}{en_e}\left(\frac{r_{em}}{r}\right)^2\frac{\partial T_e}{\partial r}+j^2\left(\frac{r_{em}}{r}\right)^4\varkappa_0 T_{ph}-\dot{\varepsilon},\\
&C_{ph}\frac{\partial T_{ph}}{\partial t}=\dot{\varepsilon};\quad T_e=T_{ph}\big|_{t=0}=T_0;\quad T_e=T_{ph}\big|_{r=r_0}=T_0;\\
&\lambda_e\frac{\partial T_e}{\partial r}\bigg|_{r=r_{em}}=-\frac{2kT_u j}{e}\left[\frac{\pi^2 kT_e^2}{4\mu T_u}+\frac{\pi T_e}{2T_u}\operatorname{ctg}\frac{\pi T_e}{2T_u}\right],\\
&j=\frac{j_0\dfrac{\pi T_e}{2T_u}}{\sin\dfrac{\pi T_e}{2T_u}};\quad T_u\,[^\circ\mathrm{K}]=\frac{5.67\cdot 10^{-5}E}{\sqrt{\varphi}},
\end{aligned}\right\}\qquad(1)$$

$$r_0=\frac{r_{em}}{\sin\theta};\quad r_{em}=\frac{r_{em}}{\sin\theta}.$$

Here, $C_{ph} = \rho C$ is the phonon specific heat, C_e is the electronic specific heat, λ_e is the electronic thermal conductivity, n_e is the density of conduction electrons, e is the electron charge, μ is the Fermi level, φ (eV) is the work function, E (V/cm) is the electric field at the cathode, and k is Boltzmann's constant. The emission characteristics of the cathode are written for strong electric fields and relatively low temperatures ($\pi T_e/2T_u \le 2$) (see ref. 5).

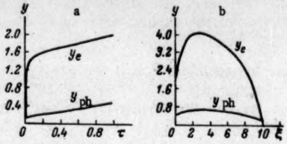

Fig. 1. Dimensionless temperature $y = \pi T_e/2T_u$ versus: a) a time $\tau = (j_0^2\varkappa_0/c\,C_{ph})t$ (for $\xi = 0$) and b) distance from emitter tip $\xi = (j_0^2\varkappa_0/\lambda_e)^{1/2}(r - r_{em})$ (for $\tau = 1$). $E = 1.2\cdot 10^8$ V/cm, $j_0 = 1.25\cdot 10^9$ A/cm^2, $r - r_{em} = 4\cdot 10^{-6}\,\xi$ cm, $t = 1.3\cdot 10^{-11}\,\tau$ sec, $T = 2\cdot 10^3\,y$ °K.

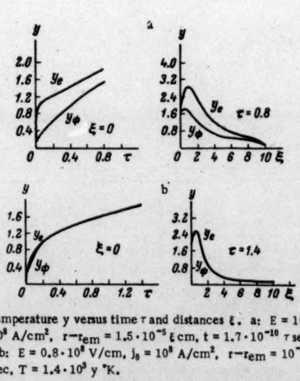
The quantity $\dot{\varepsilon}$ characterizes the rate of transfer of energy from the electronic subsystem to the lattice. This process has been examined in detail[4] and the following equation obtains:

$$\dot{\varepsilon}=AT_D\left[\left(\frac{T_e}{T_D}\right)^5\int_0^{T_D/T_e}\frac{x^4dx}{e^x-1}-\left(\frac{T_{ph}}{T_D}\right)^5\int_0^{T_D/T_{ph}}\frac{x^4dx}{e^x-1}\right],\qquad(2)$$

where T_D is the Debye temperature. Estimates in ref. 6 indicate that the coefficient $A \simeq 2\cdot 10^{11}$ J/cm^3·sec·deg.

The problem has been solved numerically for the case of tungsten ($C_{ph} = 2.73$ J/cm^3·sec·deg, $\lambda_e = 1.68$ J/cm·sec·deg, $\mu = 1.12\cdot 10^{-18}$ J, $\varkappa_0 = 3\cdot 10^{-8}$ Ω·cm/deg, $\varphi = 4.52$ eV, $n_e = 10^{23}$ cm^{-3}, $T_0 = 300$°K, $T_D = 350$°K, $r_{em} = 3\cdot 10^{-5}$ cm, $\theta = 5°$). The results of the calculations are presented in Figs. 1 and 2.



ig. 2. Temperature y versus time τ and distances ξ. a: $E = 10^8$ V/cm, $j_0 = 6.8\cdot 10^8$ A/cm^2, $r - r_{em} = 1.5\cdot 10^{-5}\,\xi$ cm, $t = 1.7\cdot 10^{-10}\,\tau$ sec, $T = 1.7\cdot 10^3\,y$ °K. b: $E = 0.8\cdot 10^8$ V/cm, $j_0 = 10^8$ A/cm^2, $r - r_{em} = 10^{-4}\,\xi$ cm, $t = 8\cdot 10^{-9}\,\tau$ sec, $T = 1.4\cdot 10^3\,y$ °K.

It follows from the curves that the basic features established in ref. 2 apply for cathode fields $E \leq 0.8 \cdot 10^8$ V/cm. At fields $E \geq 10^8$ V/cm new and interesting effects appear. The electron temperature T_e can exceed the lattice temperature T_{ph}. The value of t_d is not determined by the current density j_0 but more by the rate of transfer of energy from the electrons to the lattice. For example, Fig. 1 shows that in fields $E = 1.2 \cdot 10^8$ V/cm the electron temperature rises in a characteristic time of 10^{-12} sec on account of the Nottingham effect. The lattice temperature T_{ph} approaches the melting point of the cathode material ($T_{ph} \simeq 1500$°K, $T_{melt} = 3600$°K) in a characteristic time of $1.3 \cdot 10^{-11}$ sec. It follows from ref. 7 that the minimum value of the experimental t_d is close to this value, $1.3 \cdot 10^{-11}$ sec.

We note in conclusion that it is probably possible to obtain short-duration [$\tau \simeq 4C_{ph}/A \simeq (10^{-11}-10^{-10})$ sec] pulses of emission current with density $j \simeq (10^{10}-10^{12})$ A/cm^2. A value $j = 10^{12}$ A/cm^2 means that the current removes all conduction electrons ($j = en_e v_F = 10^{-19} \cdot 10^{23} \cdot 10^8 = 10^{12}$ A/cm^2).

Recent developments in surface ionization (review)*

É. Ya. Zandberg

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted February 1, 1974)
Zh. Tekh. Fiz., 44, 1809-1828 (September 1974)

Recent work on surface ionization, carried out primarily over the period 1970-1973, is reviewed. General questions related to surface ionization, the surface ionization of organic compounds in weak electric fields, and applications of surface ionization in electronics and physical-chemistry research are discussed.

I. CERTAIN GENERAL QUESTIONS OF SURFACE IONIZATION

Since surface ionization was discovered 50 years ago by Langmuir and Kingdon,[1] we have acquired a clear overall picture of this phenomenon, although a detailed quantum-mechanical theory has not yet been worked out. Equations for the ion currents for the ionization of atomic and molecular fluxes involving the production of positive and negative ions at homogeneous and polycrystalline emitters have been derived and, in general, experimentally verified with weak and strong electric fields at the emitter surface. These questions are treated in ref. 2. Over the time period reviewed here, some of these questions have been refined and developed further. In this review we discuss only those aspects of the recent work which are most interesting.

1. Ion Emission by Film Systems Involving a First-Order Phase Transition in a Chemisorbed Film

Until recently there had been essentially no investigations of the surface ionization of particles on emitters consisting of synthesized film systems. The search for efficient thermionic emitters has spurred interest in film systems, and research in this field by various methods is increasing in intensity.

Film emitters can be efficient emitters of positive ions as well as of thermionic electrons. Furthermore, even the earliest studies of ionization with the film system Ir (III) − C showed that the surface ionization of elements which are not readily ionized is, when combined with thermionic emission, a very useful tool for studying several properties of film systems, since first-order phase transitions in the films can be easily detected.[3]

The study of ion emission in film systems undergoing first-order phase transitions is a new field in emission electronics and an important one, since features observed in ion emission are also manifested in the electron emission of such systems.

We now know that first-order phase transitions occur in many two-dimensional films over the temperature range which can be studied experimentally. For example, such transitions occur in a system consisting of a platinum-group metal and carbon;[3-4] in sodium films on the tungsten (100) face;[5] in barium films on many metal substrates;[6] in zirconium, hafnium,[7-11] and platinum[12] films on refractory metals; and, apparently, in gold and copper films on graphite[13] and in other film systems. First-order phase transitions, including transitions of the condensation type, can occur even in two-dimensional films of electropositive atoms, despite the large effective charge of the adsorbed atoms and the repulsive nature of the interaction between them. This possibility has been pointed out in theoretical papers[14,15] on the properties of adsorbed films of alkali metals on refractory-metal substrates. The phase transitions in these systems arise in contraction of the film, which reduces the effective charge of the adsorbed atoms.

Systems with homogeneous metal substrates become inhomogeneous with respect to emission as a result of first-order phase transitions, in particular, transitions of the condensation type. Accordingly, phase transitions can be detected if the experimental method is sensitive to inhomogeneity in emission, and we can expect that as such methods are developed a large number of systems in which phase transitions occur in a film will be discovered. Among such methods are field microscopy, low-energy electron diffraction, and a method combining thermionic emission and surface ionization of elements which are not readily ionized.[2,3] The latter method is particularly good for film systems which are studied at high temperatures; with this method the work function of each phase of the film coating can be found directly at these temperatures and the critical coverage ĉan be determined.

Figure 1 (from ref. 3) shows the behavior of the thermionic-emission current and the current of positive In^+ ions during a change in the average carbon coverage of the (111) Ir face. Figure 2 (also from ref. 3) shows the behavior of the work function of the Ir (111) − C film system. We see that the emitter initially remains homogeneous and its work function increases with increasing coverage; then a phase transition occurs, causing the system to become inhomogeneous with respect to emission. The emission becomes homogeneous again at a coverage $\Theta = 1$. We see from Fig. 2 that the work function of the (111) Ir face is ~ 5.8 V, that of the adsorbed gaseous carbon phase on this face is ~ 6 V, and that of the condensed carbon phase is ~ 4.8 V.

A general approach to the description of the emission of systems in which a first-order phase transition of the

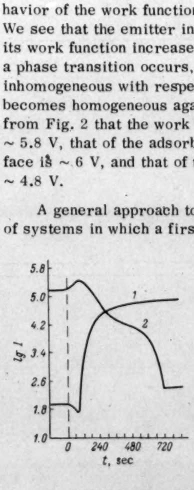

Fig. 1. Thermionic current (1) and current of In^+ ions (2) in carbon deposition on the (111) Ir face; the atomic flux is constant in time. The iridium temperature is T= 1685°K.

condensation type occurs has now been worked out. The occurrence of a transition at a given temperature in a given system (if possible) requires that the surface coverage Θ reach a certain (critical) value Θ_{cr}. At $\Theta < \Theta_{cr}$ the film consists of simply a two-dimensional adsorbed gaseous phase and is homogeneous if the substrate is homogeneous. A subsequent increase in the number of particles in the film leads to the condensation of the excess particles in islands, and the system becomes a two-phase system with a coverage Θ_{cr} in the adsorbed gaseous phase and $\Theta \approx 1$ in the adsorbed condensed phase. A further increase in the number of particles in the film leads to an increase in the area of the condensed phase through a contraction of the area of the gaseous phase; the system again becomes a single-phase system at a monolayer coverage, at which only the condensed phase remains. The example of the Ir (111)−C system shows that the gaseous and condensed phases can differ significantly in characteristics other than the work function: the heat of vaporization, the sticking probability, the particle-reflection coefficient, the catalytic activity, etc.[3,16,17]

The emission properties of these systems, which become inhomogeneous as a result of phase transitions, differ significantly from those of inhomogeneous polycrystalline emitters, for which the behavior has been studied thoroughly. It is shown in refs. 3, 17–19 that, for film systems in which a first-order phase transition of the condensation type occurs in a film, the emission features are governed by the following properties of these systems:

1. The areas occupied by the phases are functions of the average coverage at a constant temperature or of the temperature at a constant average coverage. This latter functional dependence results from the temperature dependence of the critical coverage Θ_{cr}, at which the phase transition occurs.

2. Changes in the substrate temperature can affect the work function of the gaseous phase but have little effect on the work function of the condensed phase.

3. The redistribution of phase areas which occurs upon changes in the degree of coverage or the temperature leads to a change in the effect on the emission of the contact fields of the spots at a constant external electric field. When the average coverage is higher than the critical coverage, but only slightly so, it is essentially impossible to produce an external field sufficient to balance the contact spot fields above regions of condensed phase, and as $\bar{\Theta}$ approaches $\Theta = 1$ it is essentially impossible to produce fields sufficient to balance the contact spot fields above the remaining areas of a two-dimensional gaseous phase.

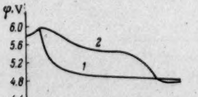

Fig. 2. Work function calculated from the total thermionic current (1) and from the total current of In^+ ions (2) in the Ir (111)−C system during carbon deposition on the (111) Ir face. T = 1685°K. The changes in φ correspond to the changes in the currents in Fig. 1.

A method has been worked out[17] for finding a quantitative description of the thermionic emission of electrons and ions by film emitters in which there is a two-dimensional condensation of particles in a film. This method takes into account the continuously changing degree of compensation of the contact spot fields with increasing amounts of adsorbate, and it permits the relative areas occupied by each coverage phase on the emitter surface to be determined from the electron and ion currents at all coverages $\bar{\Theta} > \Theta_{cr}$.

It has been pointed out that because of these features of film systems characterized by first-order phase transitions the methods for determining various physicochemical characteristics on the basis of temperature changes cannot be used. Among these methods are the widely used nonisothermal methods for determining the heat of vaporization and the heat of desorption for atoms and ions, methods in which the work function is determined from the temperature dependences of the ion and electron currents, etc.[18,19] It has been shown that the large temperature coefficient of the work function in such a system is not a consequence of the functional dependence of the Fermi level on the temperature; instead it is due to a redistribution of the areas of the phases due to a change in the temperature. It has also been pointed out that there may be errors in the functional dependence of the work function on the concentration, $\varphi(\Theta)$ obtained at a constant temperature by the contact-potential difference methods worked out for obtaining the functional dependence $\varphi(\Theta)$ for homogeneous systems. This question is studied in ref. 20, where a study is made of the displacement of the retardation curves for the positive ions produced by surface ionization and for thermionic electrons corresponding to changes in the average coverage in a film system with two-dimensional condensation. Analytic equations are derived for the retardation curves for the cases of balanced and unbalanced contact spot fields (the electrodes are assumed to be in a planar arrangement, the spots are assumed to be sharply defined, and the "normal energy" approximation is used). It follows from this analysis[20] that under the conditions corresponding to two-dimensional adsorbate condensation the method based on the displacement of the retardation curves upon changes in the average coverage does not unambiguously give the changes in work function. This situation is illustrated by Fig. 3 (from ref. 20).

Finally, we emphasize that the question of phase transition in films at the pertinent operating temperatures of

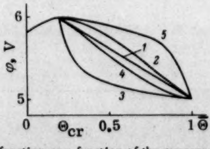

Fig. 3. The work function as a function of the average coverage, $\varphi(\bar{\Theta})$, of the (111) Ir face by carbon. 1) The function $\bar{\varphi} = f(\bar{\Theta})$ determined by the vibrating-capacitor method; 2–5) the same, obtained from the displacement of the linear regions of the retardation curves for thermionic electrons and ions of readily ionizable elements [2) from the displacement of the retardation curves for thermionic electrons in an unbalanced spot field; 3) in a balanced spot field; 4) from the displacement of the ion retardation curves in an unbalanced spot field; 5) in a balanced spot field].

film emitters should be studied further; it is necessary to determine the work function and heat of vaporization of particles from the film as functions of the concentration and to determine other characteristics of these systems and of their interactions with foreign particles adsorbed on them, by the methods developed for homogeneous systems. The possibility of phase transitions in films has frequently been neglected.

2. Ion Emission from Inhomogeneous Emitters When the Contact Spot Field Is Not Balanced

This case occurs in thermionic converters and film systems with phase transitions at average coverages for which the emitting spots are very small. It was assumed previously that the ions from spots with a work function larger than the average value move in the retarding field of the spots and must overcome an additional potential barrier,[2] but reflection of the desorbed ions from a barrier was neglected. As a result, the particle flux of homogeneous density directed toward the emitters converted into an inhomogeneous flux within the effective range of the contact fields (Fig. 4). Taking account of this feature in ref. 21 leads to a change in the expression for the ion current taken from an exposed surface in the ionization of a flux of neutral particles of a specified density ν_0 far from the emitter. This equation is now written

$$I = \nu_0 S_0 A e \left[\sum_k \frac{s_k}{A + \exp \frac{e}{kT}(V - \varphi_k)} + \sum_i \frac{s_i}{A + \exp \frac{e}{kT}(V - \varphi)} \right], \quad (1)$$

where S_0 is the total area of the emitting surface, A is the ratio of the statistical sum for the ion states to that for the states of the neutral, ionizable particles, s_k and s_i are the relative areas of spots having work functions $\varphi_k < \bar{\varphi}$; (the average over the surface $\varphi_i > \bar{\varphi}$, V is the ionization potential of the particles being ionized, and e, k, and T have their usual meanings. The first term in brackets gives the current from spots with $\varphi_k < \bar{\varphi}$, while the second gives that from spots with $\varphi_i > \bar{\varphi}$. As in ref. 2, the equation for the current is derived under the assumption that the spots have sharp boundaries, in the normal-energy approximation; the spot dimensions are assumed to be small in comparison with the dimension of the total emitting surface area and in comparison with the distance between the emitter and collector; migration and the space-charge field are neglected.

Equation (1) shows that during the ionization of readily ionizable elements [for which the condition $e(\varphi_{\min} - V) \gg kT$ is satisfied], i.e., under the condition $V \ll \bar{\varphi}$, there is complete ionization of the incident particle flux, since $I = e\nu_0 S_0$. The current cannot be a function of the external electric field, so that there can be neither a normal nor anomalous Schottky effect. Accordingly, the effect of the external field on the surface-ionization current of readily ionizable elements differs markedly from the effect on the thermionic-emission current: In the ionization of Cs atoms ($V \simeq 3.9$ V) on the two-phase surface of the film system Ir(111)–C with $\varphi \sim 6$ V for the gaseous phase of carbon and ~ 4.8 V for the condensed phase, an anomalous electronic Schottky effect is observed, but the anomalous ion Schottky effect is not observed at any coverage.

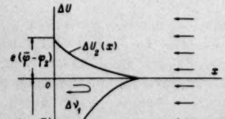

Fig. 4. Changes in the ion potential energy ΔU above spots having φ_1 and φ_2 ($\varphi_1 > \varphi_2$). Some of the ions produced at spots having φ_1 are reflected from the spot field barrier.

3. Surface Ionization of Molecules

In surface ionization of molecules it is not only the molecules which can undergo ionization, but also the products of all reactions which the molecules and the particles which they form undergo in the adsorbed film on the emitter. In fact, it is usually the products of reactions (primarily, dissociation reactions) which are ionized, since their ionization potentials are generally lower than those of the corresponding molecules.

Calculation of the ion currents of various chemical compositions requires a determination of the concentration of the particles of each species formed on the emitter. This problem is simpler to deal with if a state near chemical equilibrium is established in the adsorbed film; then the equilibrium constants for the reactions can be used to determine the numbers of particles of the various species.[22] This case apparently arises over a broad temperature range in the ionization of alkali halide molecules on metals.[23] A special experimental study is required in each particular case in order to determine the chemical equilibrium in the adsorbed particle film. It has been recently demonstrated that an equilibrium cannot occur in an adsorbed film in the case of adsorption of the vapor of metallic bismuth, which has a complex composition, on the (100) face of tungsten.[24]

A more general approach to the problem would be to analyze the conditions for a steady state, giving the conservation law for the particles of each chemical species; the case of the chemical equilibrium of particles in an adsorbed film is a particular case. This approach, proposed in ref. 25, has been used in the surface ionization of MX molecules of alkali halide salts.[25,26]

A chemical equilibrium between the particles in an adsorbed film is possible when $(\nu_0 - \nu_{MX})/\nu_d \ll 1$, where ν_0 is the molecular flux to the emitter, ν_{MX} is the inverse flux of molecules evaporated from the emitter, and ν_d is the effective particle flux to the surface (taking dissociation into account). Lacking information on the heats of vaporization of molecules from emitters of various materials and lacking information on the dissociation energies of molecules on various materials, we cannot predict in which metal–molecule systems and at what temperatures

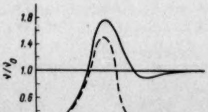

Fig. 5. Dissociation rate (solid curve) and association rate (dashed curve) as functions of the temperature for the ionization of LiCl molecules on Re.

this chemical-equilibrium condition can be satisfied. For a given system a chemical equilibrium can be approached very closely in an adsorbed film at a low temperature, at which the rate of particle desorption from the surface is low; at a high temperature, because of the rapid disruption of reaction products, the predominant reaction is molecular dissociation, whose rate is comparable to the rate at which particles reach the surface, so that the chemical equilibrium is disrupted. This situation is illustrated in Fig. 5 (from ref. 26), which shows the calculated rates for the forward and reverse reactions $MX \rightleftharpoons M + X$ for ionization of LiCl on Re in the case in which the rate constants for particle desorption are higher than the rate constants for particle dissociation on the emitter surface.

Coverage of metals by foreign particles can affect the ratio of dissociation and evaporation rates. If the work function does not change, or if it changes in a controllable manner, the ion current gives information about the changes in the degree of molecular dissociation in the adsorbed film. It follows that surface ionization can be used to study the effects of various adsorbates on the course of heterogeneous catalytic reactions which involve a dissociation step. This method has been used to determine the mechanism for the poisoning effect of carbon on molecular-dissociation reactions on metals of the platinum group.[16]

4. Transient Behavior of the Ion Current After a Change in Emitter Temperature

The functional dependences of the currents on the temperature yield several important characteristics, e.g., the work function, the ionization potential, the electron affinity, and the heat of vaporization of ions. Accordingly, it is important to record these functional dependences in undistorted form. However, the literature reveals that in certain cases the establishment of a steady-state current after a change in the emitter temperatures takes a long time – a time much longer than that required for the establishment of a steady-state emitter temperature. The time required to establish a steady-state current is particularly long if the temperatures involved are low.[2] The reasons for the transient behavior of the currents have not been studied; the experimentalist usually records the transient currents corresponding to an arbitrarily chosen delay time.

The temporal behavior of the currents has been studied recently in an ionization experiment in which the particle flux to the emitter is held constant in time.[27,28] It is shown that a neglect of the temporal changes leads, in certain cases, to serious distortions of the functional dependences on the temperature, e.g., false thresholds can appear, as are observed in the ionization of barium atoms on the (111) Ir face (Fig. 6, from ref. 28).

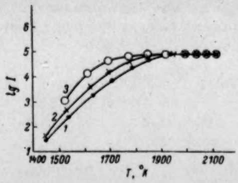

Fig. 6. Current of Ba⁺ ions as a function of the temperature for the ionization of Ba atoms on the (111) Ir face. The delay times for the current measurements are: 1) 30, 2) 240, 3) 600 sec.

Transient currents occur after a change in the emitter temperature T because when T is changed rapidly from T_1 to T_2 the equilibrium coverage N_1 of the emitter by ionizable particles at T_1 becomes a nonequilibrium coverage at T_2 and approaches the equilibrium coverage N_2 at the new temperature only after a finite time. Using the familiar equation

$$\frac{dN}{dt} + W(T_2)N = \nu_0,$$

where $W(T_2)$ is the probability for particle evaporation in the form of ions and neutrals from the emitter surface at temperature T_2, and ν_0 is the flux of particles incident on the emitter, and assuming that the heats of vaporization of the ions, l_+, and the neutrals, l_0, are independent of the degree of coverage over the possible range of this coverage, we find

$$t^* = \frac{\ln\left[\frac{1}{1-\gamma}\left(1 - \frac{W(T_2)}{W(T_1)}\right)\right]}{W(T_2)}, \tag{2}$$

where t^* is the time required to obtain at T_2 a coverage $N = \gamma N_2$ $(\gamma \leq 1)$; $W(T) = C \exp(-l_+/kT) + D \exp(-l_0/kT)$.

It follows from Eq. (2) that in the ionization of specified particles and with a selected value of γ the time t^* is a strong function of T_2 and the difference $T_1 - T_2$: The larger the heats of desorption of the atoms and ions (l_0 and l_+), the longer the time required to establish a steady-state current. To illustrate this point, in Fig. 7 we show the $t^*(l_+)$ functional dependences calculated from Eq. (2) in ref. 28 for the ionization of readily ionizable particles for the case $\gamma = 0.9$, $T_1 - T_2 = 100°$, and various temperatures. We see that at large l_+ and low T the attainment of a coverage with $\gamma = 0.9$ requires long delay times (the dashed line in Fig. 7 corresponds to 100 sec). The larger l_+, the higher the temperatures at which significantly time-dependent currents are observed. It is for this reason that time-dependent currents are only observed at low threshold temperatures in the ionization of alkali metal atoms ($l_+ \approx 2$ eV), while such currents are observed in the ionization of Ba on the (111) Ir face also at extremely high temperatures ($l_+ \simeq 5$ eV).

It follows from Eq. (2) and from the equation for W(T) that the desorbed fluxes of neutral particles should also be functions of the time, especially if the corresponding heats of desorption are large. This circumstance must be kept in mind in determining the heats of desorption of neutral particles by any nonisothermal method.

5. Aspects of Ionization in Strong Electric Fields

Opinion is divided on the mechanism for ionization in strong electric fields produced at the surface of a point emitter in field-ion microscopes and field-ion sources. In the literature from outside the Soviet Union the ionization of atoms having high ionization potentials is frequently attributed to field ionization, regardless of whether the atoms involved pass through an adsorption step. The ionization of atoms of the point material (field evaporation) and of adsorbed atoms (field desorption), on the other hand, are treated as the evaporation of ions under conditions such that the field lowers the potential barrier at the surface.[29,30]

An approach like that used for surface ionization in strong electric fields[2,31-33] has been proposed for dealing with all ionization phenomena in strong fields in which the particles being ionized pass through a step in which they are on the emitter. This approach has led to explanations for many of the features observed experimentally for each of these processes, and a study has been made of the energy distribution of the ions produced by surface ionization in strong electric fields.[2,33] (An error has been made here in taking into account the effect of the surface potential at the collector on the ions; it is corrected in ref. 34.)

The motion of ions from an emitter to a collector through an accelerating grid is studied in ref. 34 for external electric fields weaker than those required to balance the surface field; stronger fields are also studied. The ions are assumed to have an initial Maxwellian velocity distribution (characteristic of surface ionization), and the emitter and collector are assumed to be homogeneous with respect to work function (in this case the ion retardation curves consist of two linear regions; Fig. 8). The following equation has been derived for the potential U_0 at which these linear regions intersect:

$$eU_0 = e(V - \varphi') + kT \ln \frac{\alpha}{A}, \tag{3}$$

where V is the ionization potential of the atoms being ionized, φ' is the work function of the ion collector, A is the ratio of the statistical sums for the states of the ions and atoms, and α is the degree of ionization of particles at the emitter in the applied field.

Retardation curves for the ions produced at the emitters in strong electric fields can be determined experimentally only if the currents are large, i.e., if the degree of ionization is not too small. By appropriately choosing the field, the condition $\alpha \approx A$ can be arranged. Under this condition, when elements have different values of V are undergoing ionization, the retardation curves should be displaced (Fig. 8) according to

$$e(U_{01} - U_{02}) \approx e(V_1 - V_2). \tag{4}$$

If the ionization potential is not known for one of the particles, it can be found with respect to that of a reference particle from the displacement of the retardation curves. In the case of complex particles, e.g., molecules and radicals of organic compounds, the ratios of statistical sums are approximately equal to unity. If the ionization of two substances occurs at approximately equal pressures of these substances and leads to approximately equal currents at various field intensities, we would have $\alpha_1 \approx \alpha_2$; here the absolute values of the difference $kT(\ln \alpha_1/A_1 - \ln \alpha_2/A_2)$ are small, and we can assume that Eq. (4) holds. For organic compounds, for which the ionization potentials are not known for many molecules and, especially radicals, a determination of the ionization potentials on the basis of the displacement of the retardation curves could be very useful.

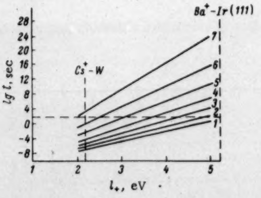

Fig. 7. Delay time required to obtain $\theta = 0.9$ of the equilibrium value as a function of the heat of vaporization of ions in the ionization of readily ionizable elements. The changes in T (°K) are as follows: 1) 2000 → 1900; 3) 1600 → 1500; 5) 1200 → 1100; 7) 800 → 700.

The retardation-potential method has recently been used independently to measure the energy distributions of polyatomic ions produced in the ionization of organic compounds of various classes in strong electric fields produced at the surfaces of sharp points.[35] Here the concept of surface ionization is not used in analyzing the experimental results, and the displacement of the energy distributions as a function of the ionization potentials of the ionizing particles is explained on the basis of the energy balance for the ions produced in the strong field, at a critical distance from the surface. The equation obtained in this manner for the displacement of the initial ion currents in the ionization of particles with different values of V is essentially the same as Eq. (4), differing only in small correction terms, which are not used in analyzing the experimental results. As measurements of the ionization potentials for many compounds with known values of V have shown, the error in the determination of the ionization potential does not exceed 0.1 V; the previously unknown values of V for several compounds of various classes have been determined within this error.

The results of the experiments which have been reported are consistent with the concept that ionization in a strong field is a surface-ionization process. The curves of the molecular ion distributions should be parallel, and if the small correction terms in the equations for determining V from the displacement of the ion energy distributions are neglected, it does not matter how V is determined – from the intersection of the linear parts of the charging curve or from the intercept at the retarding-potential axis.

Several schemes for energy analyzers in mass spectrometers involving particle ionization in a strong field are analyzed in ref. 36, where it is shown that the ion energy distributions are distorted least if the energy analyzer is placed directly behind the ion source, rather than near the ion collector.

II. SURFACE IONIZATION OF ORGANIC COMPOUNDS IN WEAK ELECTRIC FIELDS

1. Positive Ions

In recent experimental work on the surface ionization of organic compounds leading to the formation of positive ions an attempt has been made to determine the behavior of the ionization of complex particles, to search for compounds capable of being ionized efficiently, and to make practical use of the ionization of compounds of this type.

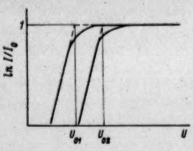

Fig. 8. Displacement of the ion retardation curves for ionization in a strong electric field of particles having ionization potentials V_1 and V_2.

Studies have been made of the composition of the ions produced, the ionization coefficients of particles of various chemical composition, the absolute current densities, the functional dependences of the currents on the temperature, reactions at the emitter surfaces, and monomolecular decay of the ions during their free motion. Surface-ionization methods have been used to determine or estimate the ionization potentials of many radicals.[37]

It has been found that certain compounds are ionized particularly efficiently: compounds of nitrogen, including alkyl-substituted amines[38] and hydrazines,[39] and many cyclic compounds, including alkaloids[40] (the amines are compounds of the type  $R_1-\underset{\underset{R_3}{|}}{N}-R_2$, e.g.,  $C_2H_5-\underset{\underset{H}{|}}{N}-C_2H_5$

while the hydrazines are of the type  , e.g., ).

On the basis of evidence acquired recently we can draw several conclusions.[40] It has been shown that the mass spectra for the surface ionization of compounds of nitrogen contain fewer lines than those corresponding to ionization by electrons, consisting of a set of characteristic lines corresponding to the following species: M^+ (molecular ions); $(M + H)^+$, associative ions (with an attached hydrogen atom); $(M - R_i)^+$, ionized products of the dissociation on the emitter of molecules from which radicals R_i are detached; and $(M - nH)^+$ ions, where n is an odd number.

In an explanation of the mass spectra of the compounds of nitrogen the ion charge can be assumed to be localized at the nitrogen atom; the nitrogen ion is tetravalent because of orbital hybridization; the ions which are formed are primarily those in which the valence bonds of the nitrogen ion are saturated. The bond saturation also determines the course of the particle dissociation at the emitter, and the chemical composition of the product ions can be explained on this basis. The relatively few lines in the mass spectra result from the selectivity of the surface-ionization process, itself a result of the strong functional dependence of the degree of ionization on the ionization potentials of the particles being ionized. Rules are given in ref. 40 for the formation of ions in the surface ionization of organic compounds containing nitrogen; these rules can be used to predict the ion composition in the mass spectra of the surface ionization of these substances. This capability is of practical value in solving several analytic problems.

A study has been made of the surface ionization of the new classes of heteroorganic compounds containing phosphorus and arsenic heteroatoms.[41] It has been shown that the alkyl-substituted phosphines  $\left(R_1-\underset{\underset{R_3}{|}}{P}-R_2\right)$ and arsines  $\left(R_1-\underset{\underset{R_3}{|}}{As}-R_2\right)$ ionize, forming ions of the same type as the amines, but at a vastly lower efficiency, and it has been shown that the intensity distribution among the lines in the mass spectra of these compounds is different than that in the case of the amines. These ionization features are attributed to differences in the orbitals of unshared pairs of nitrogen, phosphorus, and arsenic heteroatoms in the molecules and to the circumstance that phosphorus and arsenic have incomplete d orbitals at relatively low energies, so that they are capable of inversely accepting electrons.

There has been further study of monomolecular decay of ions of complex composition produced in surface ionization as they move freely after desorption from the emitter. The decay results from a statistical redistribution in the freely moving ions of the vibrational energy accumulated over the time they spend at the emitter; it leads to the formation of simpler charged particles and neutral fragments. In contrast with decays of impact ionization by electrons or photons, the decay schemes for polyatomic ions in the case of surface ionization can be mapped out well. It has been shown for the amines that the course of the monomolecular decay of the ions is the same in surface ionization as in impact ionization.[42] Accordingly, a study of the decay of ions formed in surface ionization can facilitate identification of the multistage decay which occurs within ion sources in which ionization is achieved with electrons. Serious experimental difficulties are involved in determining the path of ion decay in ionization chambers. The decay path must be known in order to derive a theory for the impact-ionization mass spectra of polyatomic molecules.

The circumstance that the vibrational-excitation states in equilibrium surface-ionization processes are the same as in nonequilibrium impact-ionization processes implies that the ion decay path is governed by the properties of the ion and is relatively independent of the ionization mechanism. This circumstance was also noted in a comparison of field and impact ionization.

The monomolecular decay of freely moving ions of complex composition obtained by surface ionization can be described by means of the statistical theory of mass spectra.[43-45] Since the ions have a Boltzmann distribution of

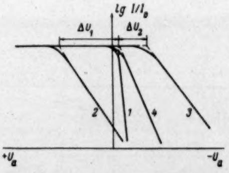

Fig. 9. Retardation curves for the negative ions produced in various processes. 1) Surface ionization; 2) dissociative resonant capture of electrons; 3) conversion of positive ions to negative ions on the emitter; 4) secondary ion–ion emission from the emitter and resonant capture of electrons having a very low energy.

TABLE 1

Substance	Emitters	Primary ions	Secondary ions
Carbon tetrachloride, CCl_4	W	Cl^-	CCl^-, CCl_2^-, C_2^-, CH^-, C_2H^-, etc.
	C	Cl^-	C_n^-, C_nCl^-, C_nH^-, Cl_2^-
Benzene, C_6H_6	W	—	C_2^-, C_2H^-
	C	—	C^-, C_2^-, C_3^- etc.
Acetone, $CO(CH_3)_2$	W	—	C_2^-, C_2H^-
	LaB_6	—	CN^-, C_2^-, C_2H^- background
Silicon tetrachloride, $SiCl_4$	Ta	Cl^-, $SiCl_3^-$, Si^-	$SiCl^-$, Cl_2^-, $SiCl_2^-$
Aniline, $C_6H_5NH_2$	W	CN^-	C_2^-, C_2H^-
	C	CN^-	C_n^-, $C_{(n-1)}N^-$
Bromoform, $HCBr_3$	W	Br^-	C_2^-, C_2H^-, Br_2^-
Chlorobenzene, C_6H_5Cl	W	Cl^-	C_2^-, C_2H^-, Cl_2^-

Thiophene, C_4SH_4	Ta	S^-	C_2^-, C_2H^-
Diethylamine, $C_4H_{11}N$	W	CN^-	C_2^-

initial energies in this case, there is more justification for using the statistical theory to describe the decay than in the case in which the ions are produced as a result of impact ionization. A method for determining the activation energy for the ion decay from the experimental functional dependences of the decay rate on the temperature is proposed in ref. 43 for the simple case of monomolecular decay not involving a change in the particle structure, and a method is proposed in ref. 45 for decay which does involve a change in the ion structure.

2. Negative Ions

According to data in the literature, many organic compounds form molecular and radical negative ions of complex composition through surface ionization. The magnetron surface ionization method has even been used to determine the electron affinities of many molecules and radicals.[46] It turns out that these determinations are erroneous[47] and that negative ions of complex composition generally are not produced in surface ionization. This circumstance can be explained on the basis of the inadequate thermal excitation of electronic states at small values of the electron affinity and on the basis of effective dissociation of the compounds on emitters at the high temperatures required for ionization in the case.

Negative ions are produced in thermionic emission sources in secondary processes not related to surface ionization. These secondary processes begin with the accompanying thermionic emission of electrons by the emitter: in resonant capture of thermionic electrons by free molecules, through conversion at the emitters of the positive ions produced in ionization by electrons, and in secondary emission under the influence of these positive ions.[47] Table 1, from ref. 47, illustrates the situation for several compounds. An explanation of the "origin" of negative ions in surface-ionization experiments requires a special study of the functional dependences of the ion currents and, especially, of the ion energy distributions on the temperature. Figure 9, also from ref. 47, shows the retardation curves for the ions produced in the various processes; we see that the curves corresponding to the different processes are quite different.

Although they do not form ions in surface ionization, many complex organic compounds yield rich mass spectra of negative ions in the bombardment of adsorbed films by positive ions. Apparently, something like a gas-discharge plasma is produced near the impact point in the adsorbed film, since the ion composition of the mass spectra are similar to those of gas-discharge spectra, and the ion energy distributions are not homogeneous and are governed by the complexity of the chemical composition.[48]

Figure 10 shows a negative-ion source, in which the efficiency of the surface ionization of the vapor of a compound can be compared with the efficiencies of ion bombardment and ionization by electrons.[49] The positive ions used for the bombardment are produced in the source through ionization of the vapor of the working material by electrons when the auxiliary cathode is activated. Like an ion-bombardment source, it operates stably over time due to continuous regeneration of the vapor film at the target, held at room temperature, and its service life is governed by the useful lifetime of only a single element – the thermionic cathode. Comparison of the three types of ionization under comparable conditions reveals that the mass spectra of the surface ionization of organic compounds are extremely poor in comparison with those of other types of ionization and that the line intensity in the ion-bombardment case is greater than in the case in which the negative ions are produced through ionization of vapor by electrons.

Finally, we should point out that secondary processes leading to the formation of negative ions also occur in the ionization of atomic fluxes; these processes introduce errors into the determination of the atomic affinities by sur-

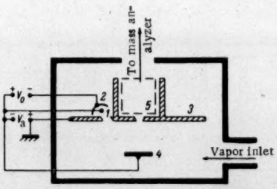

Fig. 10. Ion source designed for comparing the efficiencies at which negative ions are produced in various processes. 1, 2) Thermionic electron source for producing positive ions near electrodes 3 and 4 (4 is a thermionic emitter for producing ions through surface ionization and target for secondary ion emission); 5) Nier source for producing negative ions in resonant electron capture.

face-ionization methods, particularly when the affinities are low. This question is examined in detail in ref. 50.

III. APPLICATIONS OF SURFACE IONIZATION

The traditional applications of surface ionization have been in the production of charged particles, the detection of neutral particles, and in various physicochemical studies.[2] Over the time period with which we are concerned here, each of these fields has expanded significantly.

1. Ion Production

Surface ionization is used to produce atomic ions in order to form plasma, to provide a jet thrust in low-thrust engines, to neutralize electronic space charge (e.g., in thermionic converters), for alloying materials, for isotopic and chemical analysis, to study the elementary interactions between particles and between particles and solid surfaces, and for many other purposes. The variety of applications has lead to a wide variety of ion sources. Recently developed positive-ion sources are distinguished by the use of refractory metals with high work functions (rhenium and iridium) as the emitter material. The (111) Ir face has the highest work function known for a metal, $\varphi \approx 5.8$ V, so that emitters having a (111) working surface are the most efficient emitters for producing positive ions, especially of elements which are not easily ionized. When iridium emitters are used, however, it must be kept in mind that the adsorption of carbon to a surface coverage $\Theta > \Theta_{cr}$ significantly reduces the work function so that such emitters should be used only in evacuated devices not containing traces of hydrocarbon vapor.[51] A source having an iridium emitter has been described for producing ions on elements having ionization potentials Al^+, Ga^+, In^+, Tl^+, and Ba^+ ions at a current density of $j \approx 10 \mu A \cdot cm^{-2}$ (ref. 52). A source of Ba^+ ions having the same current density and using a rhenium emitter has also been reported.[53]

It is now possible to produce Na^+ and Li^+ ions at current densities of up to tens[54] and even hundreds[55] of microamperes per square centimeter.

The most efficient use of material is also achieved in sources of the capillary type, in which the substance to be ionized is passed through narrow channels in the emitter.[56-58] The best examples of this design are sources in which the material to be ionized reaches the emitter surface by diffusion through pores in the emitter.[2,59] Ionization on porous emitters is used in low-thrust ion rockets used to correct the trajectories of space vehicles outside the earth's atmosphere.[2] An effort is still being made to improve the efficiency of ion sources used in low-thrust ion rockets (see, e.g., ref. 60).

Surface ionization in weak and strong electric fields is used to produce polyatomic ions of organic compounds. In the case of weak fields, selective ion sources are used for certain compounds having comparatively low ionization potentials. In the ionization of certain compounds on the oxides of transition metals an ion current density can be reached which is comparable to the current density of the ions of alkali metals in the case of their ionization on tungsten wires.[61] Sources having a strong electric field — "field sources" — are very versatile and are widely used in the mass spectrometry of organic compounds in analytic chemistry. In these sources the emitters are needles, fine wires, knife edges, or arrays of needles of various metals. The applications of field mass spectrometry in analytic chemistry have been discussed most thoroughly in ref. 62.

2. Detection of Neutral Particles

Surface ionization is used to detect atomic fluxes in vacuum in a variety of applications: in determining the thickness of a deposited alkali-metal film, in the development of ion sources for low-thrust rockets for space vehicles having a minimal emission of neutral particles, in the detection atomic and molecular fluxes, in studies of chemical reactions in molecular beams, etc.

The production and use of ultrapure materials requires detection of traces of various elements in the air. There has been a report of the analysis of microimpurities of elements with ionization potentials up to 8 V (there are 56 such elements) in air by means of a mass spectrometer with a surface-ionization ion source, in which the emitter is a rhenium tape.[63]

Important practical problems are the detection of microimpurities in chromatographic analysis of substances and the detection of traces of certain organic compounds in the atmosphere during the production and storage of these substances.

Evacuated surface-ionization detectors can detect fluxes of molecules of many amines and hydrazines at partial pressures of 10^{-13}–10^{-14} torr (ref. 61). The theoretical threshold sensitivity for the detection of these compounds with these detectors is several orders of magnitude better than that of the most sensitive selective detectors.

Further improvements in the sensitivity of detectors intended for detecting traces of compounds in the atmosphere and efforts to simplify the operation of these detectors require that the detector operate, not in vacuum, but directly at atmospheric pressure. Emitters of oxidized tungsten are not suitable for such purposes, so a search has been carried out for materials capable of efficient ionization of organic compounds and suitable for use at atmospheric pressure.[64] The best material found so far is oxidized molybdenum, even though its emission properties gradually become degraded (the emitter becomes "poisoned"). The degradation occurs because the products resulting from the decomposition on the emitter of organic compounds are reduced and a carbon coating is therefore formed. The poisoning of oxidized molybdenum occurs more slowly in air than in vacuum. The poisoning

TABLE 2

Element	s, V	
	SI	PD
Si	1.24±0.02 [67,50]	
Ge	1.14±0.08 [67,50]	
Sn	1.16±0.06 [66,50]	
Pb	1.05±0.08 [66,50]	
Sb	0.90±0.07 [65,50]	
Bi	1.16±0.06 [65,50]	
Cu	1.18±0.06 [66,50]	1.226 ±0.010 [68]
Ag	1.38±0.10 [50]	1.303 ±0.010 [68]
Au	2.34±0.10 [50]	2.3086±0.0007 [69]

can be either reversible or irreversible, depending on the total number of particles supplied to the emitter surface in the detection of compounds having a specified chemical composition. Where the poisoning is reversible, a brief heating of the emitter to a temperature above the working temperature restores the emitter properties; oxygen diffuses from the interior of the oxide to the emitter surface and converts carbon into carbon dioxide, which evaporates from the surface, leaving the surface film oxidized to the original degree.

3. Surface Ionization as a Tool of Physicochemical Research

a) Determination of ionization potentials. We have already mentioned the use of surface ionization in weak and strong electric fields for estimates and precise determinations of the ionization potentials of molecules and radicals of organic compounds. The first experiments on the determination of the ionization potentials for molecules of complex organic compounds through a comparison of the distributions of ions formed on emitters in strong electric fields demonstrated the usefulness of this method. This method, based on a displacement of the energy distributions during surface ionization in strong fields, will probably find a wide variety of future applications. It has already been used for compounds of various classes. Another virtue of this method is that it does not require a complicated procedure, and the results obtained with it are extremely simple to interpret.

b) Determination of the electron affinities of atoms. Determination of the electron affinities of atoms through surface ionization has been extended to atoms with relatively low affinities.[50,65–67] This method has been used as both an absolute method[2] and as a comparison method,[65] in which the reference element is silver. Table 2 illustrates the results. Shown for comparison here are the affinities determined very recently for copper, silver, and gold by photodissociation methods employing laser light sources.[68,69] These methods are highly accurate. We see that the differences in the values of the affinities are of the order of a hundredth of a volt. Although surface-ionization methods are not as accurate as optical methods for determining affinities, their relative simplicity makes them convenient for primarily experimental estimates. They are used where the affinity is $S \geq 1$ V.

c) Studies of particle desorption from solid surfaces. In recent work, desorption characteristics have been determined for various particle–solid combinations by surface-ionization methods or in experiments in which surface ionization is used to detect the desorbed particles.

TABLE 3

Adsorbate	Substrate	Ref.
Cs, K, Na, Li	Mo	[70]
Cs	W (110), (100)	[71]
Cs, K, Na, Li	Si (111)	[72]
F, Cl, Br	Mo	[73]
U	W	[74]
Th, Nb	W	[75]
U	Re	[76]
Ba	Ir (111)	[28]
K, Na, Li	W + O_2	[77]
Ca, Sr, Ba	W + O_2	[78]
CsI	W	[79]

Most of the determinations have been carried out by the modulated-flux method.[28,70–79] Table 3 shows the absorbate–substrate systems which have been studied. We see that the method has been used to study the adsorption of atoms of many metals on the various faces of metal and semiconducting single crystals as well as on metal surfaces covered by films of different particles. It is the first method which has been used to study the desorption characteristics of molecules. The possibilities of this method have by no means been exhausted; in fact they are being realized at an increasing rate.

In a few experiments the desorption kinetics of atoms and ions of alkali metals has been studied by the flash method with the temperature changing as a linear function of the time.[80,81]

A new method which has been proposed for determining desorption characteristics is the constant-coverage method[27] or the "temperature-modulation method." In this method, with a constant particle flux to the emitter, the emitter temperature is changed from T_1 to T_2 so rapidly that the equilibrium surface coverage at T_1 does not manage to change as fast as the temperature. The coverage gradually changes, approaching the equilibrium coverage at T_2, as is observed in the subsequent time dependence of the flux of desorbed particles. If the particle flux ν_1 desorbed at T_1 (these particles are atoms or positive or negative ions) is given by $\nu_1 = N_1 C \exp(-l/kT_1)$, then the flux initially desorbed after an abrupt change from T_1 to T_2 is, by virtue of the conservation of the original surface coverage N_1, $\nu_2 = N_1 C \exp(-l/kT_2)$. It follows from the equations for ν_1 and ν_2 that

$$l = \frac{\ln \frac{\nu_1}{\nu_2}}{\left(\frac{1}{kT_2} - \frac{1}{kT_1}\right)}. \tag{5}$$

In a determination of the heat of vaporization for positive or negative ions the ratio of particle fluxes is replaced by the ratio of the corresponding currents. Tontegode and Yusifov[27] have analyzed the range of applicability of this method (assuming conservation of the coverage at the initial instant following the temperature change) and have shown how to use the method to determine the average time spent by particles on the emitter surface. The isothermal heats of vaporization and average "lifetimes" have been determined experimentally for the adsorption systems Ir (111)–In (ref. 27) and Ir (111)–Ba (ref. 28). This method has the advantages of versatility (it can be used with particles having any charge) and simplicity in the procedure for experimentally determining the desorption characteristics.

Ionov et al.[82] analyzed the method further, showing how it could be used if the initial coverage manages to change during the temperature change. The kinetic characteristics have been determined for the desorption of atoms and ions for 13 lanthanides from tungsten surfaces.[82,83] The heats of vaporization for the lanthaide atoms display a periodic dependence on the atomic number;[83] a study of the reasons for this periodicity would be interesting.

A method based on an analysis of the threshold regions in the functional dependences of the currents on the temperature for various flux densities of the particles being ionized was extended to the determination of the heats of desorption for negative ions.[84] It should be noted that the methods for determining desorption characteristics on the basis of surface ionization are finding increasing use.

d) Study of the emission homogeneity of thermionic emitters. In studies of the emission properties of various faces of single crystals, in studies of the processes occurring on such surfaces, and in many other cases it is important to know the inhomogeneity of the surface with respect to emission. This information is difficult to obtain by thermionic-emission methods alone, especially when the emitter has a high work function. In this latter case a contamination of the surface by foreign particles tends to reduce the value of φ. Under these circumstances, it is being found increasingly useful to combine the surface ionization of elements not readily ionized with a thermionic-emission method to determine the emission inhomogeneity: The emitter is judged homogeneous if the values of φ found by the two emission methods are the same. The reader is referred to refs. 3 and 85-89 for recent examples of the use of surface ionization. This double method is particularly useful in studying the properties of film systems: As mentioned previously, this method easily detects first-order phase transitions in films if these transitions occur at emission temperatures; it reveals the critical coverages and their functional dependence on the substrate temperature, and it reveals the work functions of different phases and the areas which they occupy. This method has been used to study phase transitions in systems formed by carbon on metals of the platinum group.[3,4] Its use to study film systems is just beginning.

e) Study of certain problems of catalysis. We already pointed out that study of the dissociation of molecules on the surface of an emitter covered by foreign particles is one problem in catalysis.

The surface ionization of alkali halide molecules has been used successfully to determine the mechanism for carbon poisoning of platinum-group metals in heterogeneous dissociation reactions. Alkali halide molecules have been selected for study because of the convenience of detecting the alkali metal atoms formed on the emitter surface in the dissociation reactions, through surface ionization. The efficiency with which the molecules dissociate on graphite and on the various carbon phases jointly present on a platinum-group metal after a first-order phase transition in a carbon film has been determined. It has been found that the efficiency of the dissociation on monolithic graphite is lower by a factor of 10 than that of dissociation on metals, that the phase of a two-dimensional adsorbed carbon gas has essentially no effect on the dissociation, and that a condensed carbon phase reduces the dissociation by a factor of 10^3-10^4, depending on the temperature of the substrate metal. The results are illustrated in Figs. 11-13 (from refs. 16, 90). Since the states of the carbon atoms on the surface differ in the degree of saturation of the valence bonds in these cases, it is concluded from the results that the effects of poisons in heterogeneous dissociation reactions on metal catalysis are governed by the type of structure formed on the surface as well as by the chemical composition of the poisons: Only those adsorbates which form structures having a high degree of valence saturation become poisons.[16]

f) Study of carbon diffusion in metals. An interesting application of surface ionization of alkali halide molecules has been in the study of carbon diffusion across the boundary between metal crystals not forming bulk carbides.[91] There have been few experimental studies of particle diffusion across metal boundaries because sensitive methods have not been available for detecting particles on the surface and in the surface layer. The diffusion of carbon is particularly interesting, since carbon is one of the principal impurities in metals. The sensitive detection of carbon on the surfaces of these metals is made possible by a change in the efficiency of the surface ionization of alkali halide molecules on two-dimensional carbon films having the graphite structure.[16] The use of this method for detecting carbon on surfaces has revealed the general features of the "diffusive penetration" of atoms across a metal—gas interface. These features were explained in ref. 92.

g) Temperature measurements by means of retardation curves for the positive ions produced in surface ionization. According to the theory for the retardation curves of ions produced in surface ionization, the slope of the linear region in the range of potentials retarding ions is related to the emitter temperature by $d\ln I/dU = -e/kT$, for ionization on both

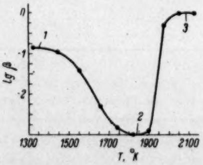

Fig. 11. Changes in the ionization coefficient for CsCl molecules as a dense carbon film deposited beforehand from a carbon filament is evaporated from iridium. 1) Graphite film on iridium; 2) monolayer coverage; 3) Ir surface cleansed of carbon.

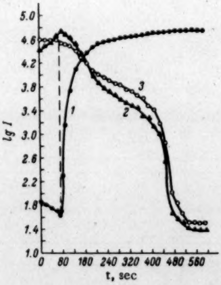

Fig. 12. Changes in the currents during carbon deposition on the (111) Ir face. T = 1685°K. 1) Thermionic electrons; 2) In^+ ions; 3) Cs^+ ions formed during the ionization of CsCl molecules. We see that this current begins to change only after the phase transition occurs in the carbon film.

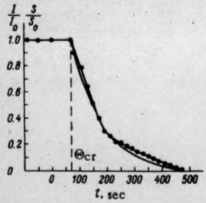

Fig. 13. Changes in the relative areas of the condensed carbon phase on the (111) Ir face during a change in the carbon coverage as a function of the deposition time, calculated from the data in Fig. 12; relative current of Cs^+ ions during ionization of CsCl molecules on this emitter.

homogeneous and inhomogeneous emitters. The ion retardation curves can thus be used to determine emitter temperatures.[2]

The integrated values of the emissivity, ε, and the monochromatic values, ε_λ, are known for many metals and semiconductors, so that there is no particular difficulty in determining their temperatures, but the emissivities for most binary and more complicated systems and the functional dependences of these emissivities on the composition are not known.

Tontegode and Yusifov[93] found that, as carbon diffuses from the surface into the interior of rhodium, bulk phase transitions occur in a surface layer at certain temperatures and lead to a spatial redistribution of the carbon atoms and to the precipitation or dissolution in this layer of microscopic carbon grains. The process is accompanied by changes in ε_λ and ε. Determining T from the retardation curves for Cs^+ ions, Tontegode and Yusifov followed the changes in ε_λ accompanying the phase transition and showed that large changes in ε_λ correspond to relatively low concentrations of carbon dissolved in the surface layer and to a small amount of carbon in the microscopic grains which form. It follows from these experiments that the retardation-curve method can be used successfully to determine the actual temperature of binary and more complicated systems in an effort to determine the spectral characteristics of their emission.

CONCLUSION

The recent papers show that all the traditional fields in surface-ionization research have continued to develop. New results have been obtained in studies of the surface ionization of simple and complicated molecules. The research has led to the development of new applications of the phenomenon of surface ionization.

Modern vacuum techniques, techniques for obtaining perfect single crystals and pure materials, and, especially, the development of new methods for studying the state of surface layers in solids (see, e.g., ref. 94) lay the groundwork for several new studies of fundamental importance. One such study is the determination of the absolute ionization coefficients of atoms, a study which is particularly interesting in the cases of the ionization of atoms having complicated electronic shells and of the ionization of atoms on semiconducting crystals in weak and strong electric fields. The results of this research cannot be predicted; fine details of the phenomena may be revealed, and information may be obtained on the reflection coefficients of particles at the potential barrier near a surface and on the shape of this barrier.

Further study of the surface ionization of molecules of various compositions in weak and strong electric fields would be interesting. We can expect that such research will broaden our understanding of the ionization and adsorption of complex particles and will yield much information about many physicochemical properties of molecules and radicals, about their state in adsorbed films, and about the catalytic properties of various solids with respect to many heterogeneous reactions.

Finally, there is interest in a further development of research in the field of the surface ionization of atoms and molecules on film systems – new emitters for surface ionization. On the basis of the first results in this field we can assume that this research will lead to an understanding of the features of ionization on such emitters and that experiments of this type, combined with other methods for studying surfaces, will yield information on the adsorption of simple and complex particles on film systems. We will also gain more information on the properties of film systems, especially on first-order phase transitions in films.

Plasma

Transverse-current plasma instability

D. G. Lominadze and V. L. Sizonenko

(Submitted November 22, 1973)
Zh. Tekh. Fiz., 44, 1829-1838 (September 1974)

The stability of a low-β plasma with a current perpendicular to the magnetic field is analyzed. Ion-acoustic waves that propagate across the magnetic field have a high excitation threshold and are not excited if the magnetic field is large when the directed velocity u is lower than the electron thermal velocity v_{Te}. Electron cyclotron waves for $u \sim v_{Te}$ and the Buneman instability $u \gg v_{Te}$ are analyzed.

INTRODUCTION

Instabilities and turbulence in a plasma with an electric current perpendicular to the magnetic field play an important role in many plasma experiments (in θ pinches, in the propagation of large-amplitude waves in a plasma, in plasma formations interacting with magnetic field, in plasma guns, etc.) and in plasmas of astrophysical interest. Many theoretical and experimental papers have appeared on these topics in recent years (see refs. 1, 2 and the cited literature).

In this paper we are concerned with instabilities of this type for the case of a low-β plasma in which the waves propagate across the magnetic field. We find that ion-acoustic waves have a high excitation threshold in this case and that they are not excited in a strong magnetic field provided that the relative velocity of the electrons and ions **u** is lower than the electron thermal velocity v_{Te}. We analyze the excitation of electron cyclotron waves when $u \sim v_{Te}$ and the Buneman instability when $u \gg v_{Te}$. In addition to the hydrodynamic Buneman instability there are kinetic instabilities with the same growth rate as the hydrodynamic instability.

1. DISPERSION RELATION

In this section we derive the dispersion relation for a plasma with a transverse current for extraordinary electromagnetic waves that propagate across the magnetic field. Taking account of the small inhomogeneities in the temperature, density, and equilibrium magnetic field, and adopting the local approximation, we write this relation as[3]

$$\varepsilon_{00}\left(\varepsilon_{22}-\frac{k^2c^2}{\omega^2}\right)+\varepsilon_{02}^2=0. \qquad (1.1)$$

In this case, in which the growth rate is much larger than the ion gyrofrequency and the wavelength is much smaller than the ion Larmor radius, we can assume the ions to be unmagnetized. Then the ions contribute to the longitudinal dielectric constant only

$$\varepsilon_{00}=\varepsilon_{00}^{(i)}+\varepsilon_{00}^{(e)}+1, \qquad (1.2)$$

where

$$\varepsilon_{00}^{(i)}=\frac{\omega_{pi}^2}{k^2v_{Ti}^2}\left[1+i\sqrt{\pi}z_iW(z_i)\right],$$

and

$$\omega_{pi}=\left(\frac{4\pi n_0e^2}{m_i}\right)^{1/2}, \quad v_{Ti}=\left(\frac{T_i}{m_i}\right)^{1/2},$$

$$W(z)=e^{-z^2}\left(1+\frac{2i}{\sqrt{\pi}}\int_0^z e^{t^2}dt\right), \quad z_i=\frac{\omega-\mathbf{ku}}{\sqrt{2}kv_{Ti}}.$$

The other components of the tensor ε_{ij} are given by Mikhailovskii:[3]

$$\left.\begin{aligned}\varepsilon_{00}^{(e)}&=\frac{\omega_{pe}^2}{k^2v_{Te}^2}\left[1-\frac{\omega}{n_0}\hat{l}\sum_{n=-\infty}^{\infty}\int d\mathbf{v}f_eJ_n^2(a)\zeta_n\right],\\ \varepsilon_{22}&=1-\frac{\omega_{pe}^2}{n_0\omega v_{Te}^2}\hat{l}\sum_{n=-\infty}^{\infty}\int d\mathbf{v}v_\perp^2f_e[J_n'(a)]^2\zeta_n,\\ \varepsilon_{02}&=-i\frac{\omega_{pe}^2}{n_0kv_{Te}^2}\hat{l}\sum_{n=-\infty}^{\infty}\int d\mathbf{v}v_\perp f_eJ_n(a)J_n'(a)\zeta_n,\end{aligned}\right\} \qquad (1.3)$$

where

$$\hat{l}=1+\frac{k_xv_{Te}^2}{\omega\omega_{He}}\left(\frac{\partial n_0}{\partial y}\frac{\partial}{\partial n_0}+\frac{\partial T_e}{\partial y}\frac{\partial}{\partial T_e}\right),$$

$$a=\frac{kv_\perp}{\omega_{He}}, \quad \zeta_n=\left(\omega-n\omega_{He}+\frac{k_x\varkappa_Hv_\perp^2}{2\omega_{He}}\right)^{-1}, \quad \varkappa_H=\frac{1}{H_0}\frac{\partial H_0}{\partial y},$$

$$\omega_{pe}^2=\left(\frac{4\pi n_0e^2}{m_e}\right), \quad \omega_{He}=\frac{eH_0}{m_ec}, \quad v_{Te}=\left(\frac{T_e}{m_e}\right)^{1/2}.$$

Here ω and **k** are the frequency and wave vector, n_0 is the plasma density, J_n is the Bessel function, and **u** is the directed velocity along the x axis. In the absence of a current the equilibrium distribution functions of the plasma ions and electrons are assumed to be Maxwellian distributions, and the density, temperature, and magnetic field are assumed to be slowly varying functions of the y coordinate. The magnetic field is parallel to the axis.

Writing (1.3) in terms of single integrals, we find sums of the type

$$Q_1\equiv\sum_{n=-\infty}^{\infty}\int d\mathbf{v}f_eJ_n^2(a)\zeta_n.$$

Using

$$\frac{1}{\omega-n\omega_{He}+bv_\perp^2}\equiv-i\int_0^\infty d\xi\exp\left[i\xi(\omega-n\omega_{He}+bv_\perp^2)\right], \qquad (1.4)$$

where $b\equiv k_x\varkappa_H/2\omega_{He}$, and where convergence of the integral as $\xi\to\infty$ is ensured by Im $\omega > 0$, we find

$$Q_1=-i\sum_{n=-\infty}^{\infty}\int_0^\infty d\xi e^{i(\omega-n\omega_{He})\xi}\frac{n_0}{v_{Te}^2}\int_0^\infty dv_\perp v_\perp J_n^2(a)e^{-\frac{v_\perp^2}{2v_{Te}^2}+ib\xi v_{Te}^2}$$

$$=-in_0\sum_{n=-\infty}^{\infty}\int_0^\infty d\xi e^{i(\omega-n\omega_{He})\xi}Ae^{-\mu A}I_n(\mu A),$$

where $A\equiv(1-2ib\xi v_{Te}^2)^{-1}$, $\mu\equiv(kv_{Te}/\omega_{He})^2$, and I_n is the modified Bessel function. Then, using

$$\sum_{n=-\infty}^{\infty}e^{-in\omega_{He}\xi}I_n(z)=e^{z\cos(\omega_{He}\xi)},$$

we write Q_1 as

$$Q_1 = -\frac{in_0}{|\omega_{He}|}\int\limits_0^\infty d\varphi e^{i\frac{\omega}{|\omega_{He}|}\varphi + \frac{\mu(\cos\varphi - 1)}{(1-i\rho\varphi)}} \frac{1}{1-i\rho\varphi}, \qquad (1.5)$$

where $\rho = k_x \varkappa_H v_{Te}^2 / |\omega_{He}| \omega_{He}$. We now introduce the function

$$R(p) = \int\limits_0^\infty d\varphi e^{i\frac{\omega}{|\omega_{He}|}\varphi - \frac{\mu(1-\cos\varphi)}{1-i\rho\varphi}} \frac{1}{p - i\rho\varphi} \qquad (1.6)$$

and its derivatives at p = 1:

$$R_n = \frac{d^n R(p)}{dp^n}\bigg|_{p=1} \quad (n = 0,\ 1,\ 2,\ \ldots). \qquad (1.7)$$

We then find

$$Q_1 = -\frac{in_0}{|\omega_{He}|} R_0. \qquad (1.8)$$

Using (1.4) in

$$Q_2 \equiv \sum_{n=-\infty}^{\infty} \int d\mathbf{v} v_\perp^2 f_e [J_n'(a)]^2 \zeta_n$$

and integrating over $v_\perp$ as above, we find

$$Q_2 = \frac{in_0|\omega_{He}|}{k^2}\left\{ i\frac{\omega}{|\omega_{He}|} - \left(\frac{\omega}{\omega_{He}}\right)^2 R_0 + 2i\mu^2\frac{dR_1}{d\mu} + \rho\left[i(1-2\mu) + 2\frac{\omega}{|\omega_{He}|}R_1 + \frac{\omega}{|\omega_{He}|}\mu R_2\right] - \rho^2\left[R_2 + \frac{2}{3}\mu R_3 + \frac{1}{24}\mu^2 R_4\right]\right\}. \qquad (1.9)$$

Similarly, for

$$Q_3 \equiv \sum_{n=-\infty}^{\infty} \int d\mathbf{v} v_\perp f_e J_n(a) J_n'(a) \zeta_n$$

we find

$$Q_3 = \frac{in_0}{k}\mu\frac{dR_0}{d\mu}. \qquad (1.10)$$

Now substituting (1.8)-(1.10) into the components of the tensor ε_{ij}, and neglecting unity in comparison with k^2c^2/ω^2, we rewrite dispersion relation (1.1) as

$$\left[1 + k^2\lambda_D^2 + \frac{T_e}{T_i}(1 + i\sqrt{\pi}z_i W(z_i)) + i\frac{\omega}{n_0|\omega_{He}|}\hat{l}n_0R_0\right] \times \left[\frac{|\omega_{He}|}{\omega}\frac{1}{n_0}\hat{l}n_0 S + \frac{\omega_{He}^2}{\omega^2}\frac{\mu^2}{\beta_e}\right] = \left(\frac{1}{n_0}\hat{l}n_0\mu\frac{dR_0}{d\mu}\right)^2, \qquad (1.11)$$

where

$$S \equiv -2\mu^2\frac{dR_1}{d\mu} - \frac{\omega}{|\omega_{He}|} - i\left(\frac{\omega}{\omega_{He}}\right)^2 R_0 + \rho\left(2\mu - 1 + 2i\frac{\omega}{|\omega_{He}|}R_1 + i\frac{\omega}{|\omega_{He}|}R_2\mu\right) - i\rho^2\left(R_2 + \frac{2}{3}\mu R_3 + \frac{1}{24}\mu^2 R_4\right),$$

where $\lambda_D = (v_{Te}/\omega_{pe})$ and $\beta_e = 4\pi n_0 T_e/H_0^2$.

Using

$$\varkappa_n = \frac{4\pi e n_0 u}{cH_0}, \qquad (1.12)$$

which follows from the Maxwell equation curl H = 4π/cj, we see that in a plasma with a low electron pressure ($\mu^2/\beta_e \gg 1$) the principal contribution to Eq. (1.11) comes from the terms due to the electrostatic part of the electric field of the waves. In this case Eq. (1.12) becomes $\varepsilon_{00} = 0$ or

$$1 + k^2\lambda_D^2 + \frac{T_e}{T_i}(1 + i\sqrt{\pi}z_i W(z_i)) + i\frac{\omega}{n_0|\omega_{He}|}\hat{l}n_0R_0 = 0. \qquad (1.13)$$

This equation is analyzed in refs. 5 and 6 in a study of the excitation of electron cyclotron waves.

In the case of a high directed velocity ($u \sim v_{Te}$) and finite electron pressure ($\beta_e \sim 1$), Eq. (1.13) cannot be used to describe the excitation of these waves; instead we must use Eq. (1.11), in which the nonelectrostatic terms play an important role.

2. ION-ACOUSTIC INSTABILITIES IN A LOW-β PLASMA

In a low-β plasma ($\beta_e \ll 1$) with cold ions and hot electrons ($T_e \gg T_i$), electron cyclotron and ion-acoustic waves are known to be excited when $u \ll v_{Te}$. Although such instabilities have received considerable attention,[1,2,7] the effect of magnetization of the electrons on the growth of ion-acoustic waves propagating across the magnetic field has not been fully resolved. We show below that the ion-acoustic instability occurs when $u < v_{Te}$ only at sufficiently high directed velocities, $u > u_{cr} \sim v_{Te}\omega_{He}/\omega_{pi}$. Accordingly, in a plasma in a strong magnetic field, in which $\omega_{He} > \omega_{pi}$ at $u < v_{Te}$, the ion-acoustic instability does not occur. The characteristic wavelength of the ion-acoustic waves is known to be of the order of λ_D ($k\lambda_D \sim 1$); hence, when $\omega_{pe} \gg \omega_{He}$ we have $kv_{Te} \sim \omega_{pe} \gg \omega_{He}$. Since the growth rate of the ion-acoustic instability γ is of order $\gamma \sim \omega_{pi}(u/v_{Te})$ (ref. 1), the condition $\gamma \gg \omega_{He}$ may not hold, so that the effect of a magnetic field on the instability should be taken into account. If the wave vector has a nonvanishing component along the magnetic field ($k_z \neq 0$), the function R_0 (for $\beta_e \sim \rho \to 0$), would be

$$R_0 = \int\limits_0^\infty d\varphi e^{i\frac{\omega}{|\omega_{He}|}\varphi - \frac{k_\perp^2 v_{Te}^2}{\omega_{He}^2}(1-\cos\varphi) - \frac{k_z^2 v_{Te}^2}{2\omega_{He}^2}\varphi^2}. \qquad (2.1)$$

In this case, with $k_z \gtrsim \omega_{He}/v_{Te}$, the integral converges as $\varphi \to \infty$ because of the terms containing k_z. Furthermore, in the integration over φ by the method of steepest descent (since $k^2v_{Te}^2/\omega_{He}^2 \gg 1$), account need be taken of only the contribution of the region $\varphi \lesssim \omega_{He}/k_\perp v_{Te} \ll 1$, since the integrals near other points $\varphi \simeq 2n\pi$ are exponentially small. In this case we have

$$R_0 \doteq \sqrt{\frac{\pi}{2}}\frac{|\omega_{He}|}{k_\perp v_{Te}} W(z_e), \quad z_e = \frac{\omega}{\sqrt{2}kv_{Te}}$$

and the electrons are unmagnetized. Accordingly, the magnetic field only affects waves with $k_z \ll \omega_{He}/v_{Te}$. Then, neglecting terms containing k_z, we can convert the function R(p) (for $\beta_e \sim \rho \to 0$) to the form[8]

$$R(p) = \left(\frac{\pi}{2}\right)^{1/2}\frac{1}{p}\frac{|\omega_{He}|}{k_\perp v_{Te}}\left[\frac{\xi+1}{\xi-1}e^{-z_e^2} + \frac{2i}{\sqrt{\pi}}e^{-z_e^2}\int\limits_0^{z_e} e^{t^2}dt\right], \qquad (2.2)$$

where $\xi = \exp(-2\pi i\omega/|\omega_{He}|)$.

Below we call those waves for which ω is not approximately equal to $n\omega_{He}$ "ion-acoustic," and we call those for which we have $\omega \approx n\omega_{He}$ "electron cyclotron." Assuming $\mathrm{Re}\,\omega \sim \omega_{pi} > |\omega_{He}|$ and using the condition $z_e \sim u/v_{Te} \ll 1$ for ion sound, we find

$$R(p) = \frac{1}{p}\sqrt{\frac{\pi}{2}}\frac{|\omega_{He}|}{kv_{Te}}\frac{\eta^2 - 1 + 2i\eta\sin\psi}{\eta^2 + 1 - 2\eta\cos\psi}, \qquad (2.3)$$

where

$$\eta \equiv \exp\left(2\pi\frac{\gamma}{|\omega_{He}|}\right), \quad \psi \equiv 2\pi\frac{\mathrm{Re}\,\omega}{|\omega_{He}|} \geqslant 2\pi.$$

Now substituting (2.3) into (1.13) and neglecting (for simplicity) the inhomogeneity of the density and temperature, we find the following dispersion relation for the ion-acoustic waves:

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}+\frac{\omega_{pe}^2}{k^2v_{Te}^2}\left(1+i\sqrt{\pi}z_e\frac{\eta^2-1}{\eta^2+1-2\eta\cos\psi}\right)=0. \quad (2.4)$$

From (2.4) we find the wave frequency,

$$\operatorname{Re}\omega=\mathbf{ku}+\omega_s,\quad \omega_s=\frac{kv_s}{\sqrt{1+k^2\lambda_D^2}},$$

and an equation for the growth rate,

$$F(b)\equiv b\frac{e^{2b}+1-2e^b\cos\psi}{e^{2b}-1}=-\sqrt{\frac{\pi^3}{2}\frac{m_e}{m_i}}\frac{(\mathbf{ku}+\omega_s)}{|\omega_{He}|(1+k^2\lambda_D^2)^{3/2}}, \quad (2.5)$$

where $b \equiv 2\pi(\gamma/|\omega_{He}|)$.

The function F(b) is given in the asymptotic limit $|b| \gg 1$ by $F(b) \approx |b|$; it reaches a minimum at $b = 0$, and near the origin it is given approximately by

$$F(b)\approx 1-\cos\psi+\frac{b^2}{3}\left(1+\frac{\cos\psi}{2}\right).$$

Accordingly, when

$$-\sqrt{\frac{\pi^3}{2}\frac{m_e}{m_i}}\frac{(\mathbf{ku}+\omega_s)}{|\omega_{He}|(1+k^2\lambda_D^2)^{3/2}}\gg 1$$

the growth rate becomes the same as in an unmagnetized plasma, and when

$$-\sqrt{\frac{\pi^3}{2}\frac{m_e}{m_i}}\frac{(\mathbf{ku}+\omega_s)}{|\omega_{He}|(1+k^2\lambda_D^2)^{3/2}}\leqslant 1-\cos\psi \quad (2.6)$$

the unstable solutions vanish.

Accordingly, when $k_z \ll |\omega_{He}|/v_{Te}$ the ion-acoustic instability exists only when $u > u_{cr}$. The threshold current velocity u_{cr} can be evaluated for the case $u_{cr} \gg v_s$ in the following manner: Setting $\mathbf{ku} = -ku$ and requiring that the equation in (2.6) hold,

$$\sqrt{\frac{\pi^3}{3}\frac{m_e}{m_i}}\frac{u}{v_{Te}}\frac{\omega_{pe}}{|\omega_{He}|}\frac{k\lambda_D}{(1+k^2\lambda_D^2)^{3/2}}=1-\cos\psi, \quad (2.7)$$

using $1-\cos\psi \sim 1$, and choosing the maximum value of the quantity $k\lambda_D(1+k^2\lambda_D^2)^{-3/2}=2/3\sqrt{3}$, we find that u_{cr} is of order

$$u_{cr}\simeq v_{Te}\frac{|\omega_{He}|}{\omega_{pi}}<v_{Te}. \quad (2.8)$$

In a stronger magnetic field, with $\omega_{pi} \ll |\omega_{He}|$, we have $2\pi\omega/|\omega_{He}| \ll 1$ and $R(p) \simeq i\omega_{He}^2/\sqrt{2\pi}pkv_{Te}\omega$, so that Eq. (1.13) becomes

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}+\frac{\omega_{pe}^2}{k^2v_{Te}^2}\left\{1-\frac{|\omega_{He}|}{\sqrt{2\pi}kv_{Te}}\right\}=0,$$

and there is no instability.

Accordingly, in a plasma with $\omega_{pi} < |\omega_{He}|$ the ion-acoustic waves are stable, and only electron cyclotron waves can be excited.

3. EXCITATION OF ELECTRON CYCLOTRON WAVES IN THE CASE $\mathbf{u} \sim v_{Te}$ AND $\beta_e \ll 1$

We turn now to the excitation of electron cyclotron waves in a low-β plasma in which the current velocity is the order of the electron thermal velocity. Using the condition $\omega \sim ku \sim \omega_{He}$ we find that the wavelength of these waves is of the order of the electron Larmor radius $k\rho_e \sim 1$. Over the wavelength range $k \sim (\omega_{He}/v_{Te})$ the natural frequencies of the waves in this case are not close to $n\omega_{He}$ (where n is an integer) (see e.g., ref. 9). In a plasma without a current the ion terms are unimportant because of the inequalities

$$z_i\sim\frac{\omega_{He}}{kv_{Ti}}\sim\frac{v_{Te}}{v_{Ti}}\gg 1,\quad \frac{\omega_{pi}^2}{\omega^2}\sim\frac{\omega_{pi}^2}{\omega_{He}^2}\ll\frac{\omega_{pe}^2}{k^2v_{Te}^2}.$$

When there is a current the ion terms are important when the natural frequency of the electron cyclotron waves, $\omega = \omega(k)$, intersects the beam branch $\omega = \mathbf{ku}$. Since the ion terms appear only in ε_{00}, dispersion relation (1.1) should be written

$$\frac{\omega_{pi}^2}{k^2v_{Ti}^2}[1+i\sqrt{\pi}z_iW(z_i)]=\frac{\varepsilon_{02}^2}{\left(\frac{kc}{\omega}\right)^2-\varepsilon_{22}}-\varepsilon_{00}^{(e)}-1. \quad (3.1)$$

Equating to zero the right-hand side of Eq. (3.1), and neglecting terms containing $\varkappa_n$, $\varkappa_T$, and $\varkappa_H$, we find the dispersion relation studied previously (see ref. 9 and the literature cited there). Neglecting the nonelectrostatic terms, other workers have studied Eq. (3.1) in detail for the case $u \ll v_{Te}$ (see, e.g., ref. 7 and the literature cited there). The growth rate is found in ref. 10 for the case $u \sim v_{Te}$ in certain limiting approximations.

Now assuming that the wave frequency is approximately equal to $\omega(k)$ when the ion terms are taken into account, and expanding the right-hand side of (3.1) in the small parameter $\omega-\omega(k)$, we can replace (3.1) by the dispersion relation

$$D(\omega-\omega(k))+\frac{\omega_{pi}^2}{k^2v_{Ti}^2}[1+i\sqrt{\pi}z_iW(z_i)]=0, \quad (3.2)$$

where

$$D\equiv\frac{\partial}{\partial\omega}\left\{1+\varepsilon_{00}^{(e)}-\frac{\varepsilon_{02}^2}{(kc/\omega)^2-\varepsilon_{22}}\right\}\Big|_{\omega=\omega(k)}.$$

It follows from Eq. (1.11) that with $\beta_e \ll 1$, $\mu \sim 1$, and $\omega \sim \omega_{He}$ the nonelectrostatic terms are smaller than the electrostatic terms by a factor of $1/\beta_e$. Also noting that $k_\perp v_{Te}^2\varkappa_{n, T}/\omega\omega_{He} \sim \varkappa_{n, T}v_{Te}/\omega_{He} \ll 1$ and $k_\perp v_{Te}^2\varkappa_H \cdot (\omega\omega_{He})^{-1} \sim \beta_e \ll 1$, we find that we can in fact neglect in the ε_{ij} components those terms having $\varkappa_n$, $\varkappa_T$, and $\varkappa_H$, and we can set $\hat{I} = 1$. It is not difficult to see that in this case

$$D\approx\frac{\omega_{pe}^2}{k^2v_{Te}^2|\omega_{He}|}D_0,$$

where

$$D_0\equiv i\left\{\frac{\partial}{\partial\omega}\omega R_0(\omega)\right\}_{\omega=\omega(k)}\sim 1.$$

Equation (3.2) can now be rewritten as

$$z_i-z_0+\eta[1+i\sqrt{\pi}z_iW(z_i)]=0, \quad (3.3)$$

where

$$z_0\equiv\frac{\omega(k)-\mathbf{ku}}{\sqrt{2}kv_{Ti}},\quad \eta\equiv\frac{T_e}{T_i}\frac{|\omega_{He}|}{\sqrt{2}kv_{Ti}D_0}.$$

With $z_0 = 0$, Eq. (3.3) is the same as the equation given in ref. 11. With $\eta = 1$ and $z_0 = 0$ we have $z_i = -0.46 + i0.36$; with $|\eta| \leq 1$ and $|z_0| \leq 1$ Eq. (3.3) has an unstable solution with $\operatorname{Re} z_i \sim \operatorname{Im} z_i \sim 1$.

In the case $T_e/T_i \lesssim (m_e/m_i)^{1/3}$, $|z_0| \lesssim 1$, the electron cyclotron waves thus interact resonantly with the ions and the growth rate is given in order of magnitude by

$$\gamma \sim \left(\frac{T_i}{T_e}\omega_{He}\omega_{Hi}\right)^{1/2}. \tag{3.4}$$

We note that in a plasma having $T_i \gg T_e$ growth rate (3.4) can be much larger than $(\omega_{He}\,\omega_{Hi})^{1/2}$, so that these instabilities can play an important role in energy dissipation at the front of a collisionless shock wave.

In the case $(T_e/T_i) \gg (m_e/m_i)^{1/3}$ we find $|\eta| \gg 1$, so that Eq. (3.3) is satisfied only for $|z_i| \gg 1$. Then at $z_0 = 0$ we find the cubic equation $z_i^3 = (\eta/2)$, from which we can easily find the growth rate for the waves:

$$\gamma = \left(\frac{3}{2}\right)^{1/2}\left(\frac{\eta}{2}\right)^{1/3} kv_{Ti} \sim |D_0|^{-1/3}\left(\frac{m_e}{m_i}\right)^{1/3}|\omega_{He}|. \tag{3.5}$$

If the growth rates in (3.4) and (3.5) are smaller than the corresponding growth rates for electron cyclotron waves found in the case $u \ll v_{Te}$ (ref. 7), then with a large current velocity, $v \sim v_{Te}$, it is primarily waves whose wave vector $\mathbf{k}$ is nearly perpendicular to current velocity $\mathbf{u}$ which should be excited. Setting $\mathbf{ku} = k_x u = ku_{\text{eff}}$ ($u_{\text{eff}} \ll u_{Te}$), we can make u_{eff} quite small and convert to the case of the excitation of electron cyclotron waves, which have the largest growth rate.

If, on the other hand, the growth rates in (3.4) and (3.5) are larger than the corresponding growth rates for electron cyclotron waves, it would be primarily waves propagating along the current which are excited, at a wavelength on the order of the electron Larmor radius. We note that the excitation of electron cyclotron waves by an ion beam moving across a magnetic field in a plasma has been detected experimentally.[12]

4. BUNEMAN INSTABILITY IN A LOW-β PLASMA

We turn now to the excitation of waves in the case $u \gg v_{Te}$ and $\beta \ll 1$. The instability of the Buneman type was analyzed in refs. 13-16, where account is taken of the inhomogeneity of the plasma density in the presence of a longitudinal current, as in this section; for the case of magnetized electrons ($\omega \ll \omega_{He}$, $kv_{Te} \ll \omega_{He}$) with a transverse current it is analyzed in ref. 17 (see also ref. 18). The Buneman instability occurs when $|\mathbf{ku}| \lesssim \omega_{pe}$; in order-of-magnitude terms

$$\rho = \beta_e \ll 1,\ \mu \sim \frac{v_{Te}^2}{\omega_{He}^2}\frac{\omega_{pe}^2}{u^2}\left(\frac{k_\perp}{k_x}\right)^2,$$

$$\frac{k_x v_{Te}^2 \varkappa_{n,T}}{\omega|\omega_{He}|} \sim \frac{v_{Te}}{u}\frac{\varkappa_{n,T}v_{Te}}{|\omega_{He}|} \ll 1,\quad \hat{l} \approx 1.$$

Now assuming μ^2/β to be large enough to satisfy Eq. (1.13) for electrostatic waves, and writing R(p) as in (2.2) (for the case $\mu \gg 1$, $\beta_e \ll 1$), we find the following dispersion relation for the unstable waves:

$$1 + k^2\lambda_D^2 + \frac{T_e}{T_i}[1 + i\sqrt{\pi}\,z_iW(z_i)] + i\frac{\sqrt{\pi}}{n_0}\hat{l}n_0 z_e \times \left[\frac{\xi+1}{\xi-1}e^{-z_e^2} + \frac{2i}{\sqrt{\pi}}e^{-z_e^2}\int_0^{z_e} e^{t^2}dt\right] = 0. \tag{4.1}$$

For waves with $|z_e| \gg 1$ we then find

$$k^2\lambda_D^2 + \frac{T_e}{T_i}[1 + i\sqrt{\pi}z_iW(z_i)] - \frac{1}{n_0}\hat{l}n_0\left[\frac{1}{2z_e^2} - i\sqrt{\pi}\frac{\xi+1}{\xi-1}z_e e^{-z_e^2}\right] - \frac{k_x v_{Te}^2\varkappa_n}{\omega\omega_{He}} = 0. \tag{4.2}$$

If $\omega \neq n\omega_{He}$ and $|\mathbf{ku}| \neq \omega_{pe}$, we can neglect the terms preceded by minus signs in (4.2) and set $\hat{l} = 1$; we then find

$$1 - \frac{\omega_{pe}^2}{\omega^2} + \frac{\omega_{pi}^2}{k^2v_{Ti}^2}[1 + i\sqrt{\pi}z_iW(z_i)] - \frac{k_x\varkappa_n\omega_{pe}^2}{k^2\omega\omega_{He}} = 0. \tag{4.3}$$

When the last term in Eq. (4.3) is dropped, this equation becomes the familiar dispersion relation for the Buneman instability.[1]

We now set $\omega \approx k_x u$ in (4.3) and assume $|z_i| \gg 1$, finding

$$1 - \frac{\varkappa_n\omega_{pe}^2}{k^2\omega_{He}u} - \frac{\omega_{pe}^2}{\omega^2} - \frac{\omega_{pi}^2}{(\omega - k_xu)^2} = 0. \tag{4.4}$$

When $k_xu \neq \omega_{pe}$ Eq. (4.4) has the solution

$$\omega = k_xu \pm \frac{i\omega_{pi}}{\left(\frac{\omega_{pe}^2}{k_x^2u^2} + \frac{\varkappa_n\omega_{pe}^2}{k^2\omega_{He}u} - 1\right)^{1/2}}. \tag{4.5}$$

It follows that with $|\varkappa_n u/\omega_{He}|(k_x/k)^2 \gtrsim 1$ the contribution from the density inhomogeneity is important. Under the resonance condition $\omega_{pe}^2/k_x^2u^2 = 1 - \varkappa_n\omega_{pe}^2/k^2\omega_{He}u$ the growth rate increases and is given by

$$\gamma = \frac{\sqrt{3}}{2^{4/3}}\omega_{pe}\left(\frac{m_e}{m_i}\right)^{1/3}\left(1 + \frac{k_x^2}{k^2}\frac{\varkappa_nu}{\omega_{He}}\right)^{1/3}\left(1 + \frac{\varkappa_nu}{2\omega_{He}}\frac{k_x^2}{k^2}\right)^{-1/3}. \tag{4.6}$$

Hydrodynamic equations (4.4)-(4.6) can be used in the case $\gamma \gg kv_{Ti}$, i.e., in the case

$$\left(1 + \frac{k_x^2}{k^2}\frac{\varkappa_nu}{\omega_{He}}\right)^{2/3}\frac{T_i}{T_e} \ll \left(\frac{k_x}{k}\right)^2\left(\frac{u}{v_{Te}}\right)^2\left(\frac{m_i}{m_e}\right)^{1/3}.$$

If this inequality does not hold, we must take the thermal motion of the ions into account in determining the growth rate. In this case Eq. (4.3) reduces to an equation like (3.3), in which

$$\left.\begin{aligned} \eta &= \frac{m_e}{m_i}\left(\frac{k_xu}{\sqrt{2}\,kv_{Ti}}\right)^3\left(1 + \frac{k_x^2}{2k^2}\frac{\varkappa_nu}{\omega_{He}}\right)^{-1}, \\ z_0 &= \frac{k_xu}{2\sqrt{2}\,kv_{Ti}}\left(1 + \frac{k_x^2}{k^2}\frac{\varkappa_nu}{\omega_{He}} - \frac{k_x^2u^2}{\omega_{pe}^2}\right)\left(1 + \frac{k_x^2}{2k^2}\frac{\varkappa_nu}{\omega_{He}}\right)^{-1}. \end{aligned}\right\} \tag{4.7}$$

With $\eta \sim 1$ and $|z_0| \lesssim 1$ we find from (3.3) that the growth rate is given in order of magnitude by (4.6).

Thermal motion of the electrons can be neglected ($|z_e| \gg 1$) for solutions (4.4)-(4.6) in all cases except that in which the waves are propagating nearly perpendicular to the beam ($k_k \ll k$). In this case, instead of (2.4) we find from (4.1) the following equation, which holds for cold ions:

$$1 + k^2\lambda_D^2 - \frac{k^2v_e^2}{(\omega - k_xu)^2} - \sqrt{\pi}z_e e^{-z_e^2}\operatorname{ctg}\pi\frac{\omega}{|\omega_{He}|} - 2z_e e^{-z_e^2}\int_0^{z_e} e^{t^2}dt = 0. \tag{4.8}$$

Setting $\omega = k_xu + i\gamma$ ($\gamma \ll k_xu$) we find

$$\gamma = kv_e|f(z_e)|^{-1/2}, \tag{4.9}$$

where

$$f(z_e) = \left[\sqrt{\pi}z_e e^{-z_e^2}\operatorname{ctg}\pi\frac{k_xu}{|\omega_{He}|} + 2z_e e^{-z_e^2}\int_0^{z_e} e^{t^2}dt - 1 - k^2\lambda_D^2\right], \tag{4.10}$$

and $z_e = k_x u/\sqrt{2}kv_{Te}$. If $k_x/k \sim v_{Te}/u \ll 1$, then $z_e \sim 1$ and $\gamma \sim kv_s$. With $z_e \gg 1$ we find from (4.9) an equation for Im ω, which follows from (4.5) if terms $\sim \varkappa_n$ are neglected there.

At resonance, with $f(z_e = 0)$, (4.9) is replaced by the following growth rate:

$$\gamma = \frac{\sqrt{6}}{2^{4/3}}\left(\frac{m_e}{m_i\,|f'(z_e)|}\right)^{1/3} kv_{Te}. \tag{4.11}$$

If $k\lambda_D \sim 1$ and $z_e \sim 1$, then it follows from (4.11) that $\gamma \sim \omega_{pe}(m_e/m_i)^{1/3}$. We note that the growth rate is even larger at a double resonance with $f(z_e) = 0$ and $f'(z_e) = 0$. In this case, setting $\omega = k_x u + \Delta\omega$, we find

$$(\Delta\omega)^4 = \frac{4k^4 v_s^2 v_{Te}^2}{f''(z_0)}. \tag{4.12}$$

Hence the growth rate for $k\lambda_D \sim 1$ is

$$\gamma \sim \omega_{pe}(m_e/m_i)^{1/4}. \tag{4.13}$$

At the intersection of the "beam" frequency $\omega = k_x u$ with the gyrofrequencies ($k_x u \approx n|\omega_{He}|$) the growth rate for this instability is lower than in (4.11)-(4.13).

In conclusion the authors thank K. N. Stepanov for useful discussion.

Plasma instability due to an anisotropic electron distribution

D. G. Lominadze and V. L. Sizonenko

(Submitted November 22, 1973)
Zh. Tekh. Fiz., 44, 1839-1845 (September 1974)

The stability of a uniform plasma with a nonmonotonic electron velocity distribution in a plane perpendicular to the magnetic field is studied with a transverse current. It is shown that ion plasma instabilities due to a loss cone in the electron distribution in the presence of a transverse current occur even when the loss cone is almost filled. In turn, the appearance of the loss cone leads to an increase in the growth rate for electron cyclotron oscillations; these are unstable because of the transverse current.

The nonmonotonic form of the electron velocity distribution and the presence of relative electron and ion motion perpendicular to the magnetic field are the reasons for the numerous anisotropic and beam-type instabilities in a plasma.[1] In particular, a current can drive electrostatic electron cyclotron instabilities; the radiation due to these has recently received considerable attention.[2-28] In practical situations electrons often have a nonmonotonic velocity distribution in the plane perpendicular to the magnetic field (for example, due to the particles drifting out of adiabatic traps).

1. In this paper we investigate the effect of a nonmonotonic particle velocity distribution on the development of an instability at the electron cyclotron frequency in the presence of a transverse current; it is shown that the growth rate of these instabilities in the presence of a loss cone increases considerably. In addition, in a weak magnetic field the presence of a loss cone leads to the appearance of a distinctive conical instability in the ion plasma oscillation, which also develops when there is no transverse current (in the presence of a transverse current the electron cone instability can also develop in the case when the loss cone is almost filled).

2. We assume that the frequency ω and the growth rate are much greater than the ion cyclotron frequency, and that the wavelength is much smaller than the ion Larmor radius so that the ions can be assumed to be unmagnetized. If the ions are cold ($\gamma \gg kv_{Ti}$, $v_{Ti} = \sqrt{2T_i/m_i}$) the dispersion equation transverse to the magnetic field is[1]

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}+2\pi F(0)\frac{\omega_{pe}^2}{k^2}$$

$$+\frac{\omega_{pe}^2}{k^2}\sum_{n=-\infty}^{\infty}\frac{\omega}{\omega-n\omega_{He}}2\pi\int_0^\infty dv_\perp J_n^2\left(\frac{kv_\perp}{\omega_{He}}\right)\frac{\partial F(v_\perp)}{\partial v_\perp}=0, \tag{1}$$

where $F(v_\perp)=\int_{-\infty}^{\infty} dv_\parallel f(v_\perp, v_\parallel)$; $\omega_{p\alpha}=(4\pi n_0e^2/m_\alpha)^{1/2}$; $f(v_\parallel, v_\perp)$ is the equilibrium electron velocity distribution function, normalized to unity, J_n is the Bessel function, and $\mathbf{u}$ is the directed velocity.

We assume that the electron distribution function has the form[1]

$$F(v_\perp)=\frac{1}{\pi v_0^2}\left[q+(1-q)\frac{1}{j!}\left(\frac{v_\perp}{v_0}\right)^{2j}\right]e^{-\left(\frac{v_\perp}{v_0}\right)^2}\quad (j=1,\ 2,\ 3,\ \ldots). \tag{2}$$

The distribution function (2) when $q = 1$ is a Maxwellian velocity distribution, in which v_0 means the thermal velocity; when $q = 0$ the function $F(v_\perp)$ describes the characteristic electron distribution when there is a loss cone. Hence, by changing q from zero to unity we can investigate the change in the nature of the instability as the loss cone becomes filled.

For the distribution function given by Eq. (2), Eq. (1) takes the form

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}+2\frac{\omega_{pe}^2}{k^2v_0^2}\left[q-\sum_{n=-\infty}^{\infty}\frac{\omega}{\omega-n\omega_{He}}Q_n(q)\right]=0, \tag{3}$$

where

$$Q_n(q)=\hat{S}(q)\exp\left(-\frac{\mu}{\rho}\right)\frac{1}{\rho}I_n\left(\frac{\mu}{\rho}\right)\Big|_{\rho=1}, \tag{4}$$

$$\hat{S}(q)=\left[q+(-1)^j\frac{(1-q)}{j!}\frac{\partial^j}{\partial\rho_j}+(-1)^j\frac{(1-q)}{(j-1)!}\frac{\partial^{(j-1)}}{\partial\rho_{j-1}}\right],$$

$$\mu=\frac{1}{2}\left(\frac{k^2v_0^2}{\omega_{He}^2}\right). \tag{5}$$

Below we will investigate shortwave oscillations with wavelength which is considerably smaller than the electron Larmor radius. Using the asymptotic expression[29] for the sum

$$i\sum\frac{\omega_{He}e^{-x}J_n(x)}{\omega-n\omega_{He}}=\int_0^\infty d\varphi e^{x(\cos\varphi-1)+\frac{\omega}{\omega_{He}}\varphi}$$

$$=\sqrt{\frac{\pi}{2}x}\,e^{-z^2}\left(1+\frac{2i}{\sqrt{\pi}}\int_0^z e^{t^2}dt\right)+\sqrt{\frac{2\pi}{x}}\,e^{-z^2}\frac{1}{e^{-\xi}-1},$$

where $z = (\omega/\omega_{He})\sqrt{1/2x}$, $\xi = 2\pi i\omega/\omega_{He}$ holds for $x \gg 1$, we can reduce Eq. (3) to the following form:

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}$$

$$+2\frac{\omega_{pe}^2}{k^2v_0^2}\left\{q+i\sqrt{\pi}\,z_0\hat{S}(q)\frac{e^{-z_0^2}}{\sqrt{\rho}}\rho\left[\frac{2i}{\sqrt{\pi}}\int_0^{z_0\sqrt{\rho}}e^{t^2}dt+\frac{e^{-\xi}+1}{e^{-\xi}-1}\right]\right\}_{\rho=1}=0, \tag{6}$$

where $z_0 = \omega/kv_0$.

We confine ourselves to the case $z_0 \ll 1$, in which case Eq. (6) becomes

$$1-\frac{\omega_{pi}^2}{(\omega-\mathbf{ku})^2}+2\frac{\omega_{pe}^2}{k^2v_0^2}\left[q+i\sqrt{\pi}z_0S_j\frac{e^{-\xi}+1}{e^{-\xi}-1}\right]=0; \tag{7}$$

here $S_j = -A_j\,(1-q/q_j)$, $q_j = A_j/(1+A_j)$, $A_j = (2j-3)!!/2^jj!$ $(j \geq 2)$, $A_1 = 1/2$, $q_1 = 1/3$.

3. We first investigate all the instabilities in the plasma with no current ($\mathbf{u} = 0$). We assume that the condition $2\pi\gamma/\omega_{He} \gg 1$ is satisfied for unstable modes so that $|e^{-\xi}| \gg 1$. In this case the effect of the magnetic field on the electrons can be neglected, and Eq. (7) takes the form

$$1-\frac{\omega_{pi}^2}{\omega^2}+2\frac{\omega_{pe}^2}{k^2v_0^2}\left[q+i\sqrt{\pi}\frac{\omega}{kv_0}S_j\right]=0. \tag{8}$$

Introducing the dimensionless variables

$$y \equiv \frac{\omega}{\omega_{pi}}, \quad a \equiv 1 + 2q\frac{\omega_{pe}^2}{k^2 v_0^2}, \quad b \equiv 2\sqrt{\pi}\frac{\omega_{pe}^2 \omega_{pi}}{k^3 v_0^3} S_j,$$

we can write Eq. (8) in the form

$$iby^3 + ay^2 - 1 = 0. \tag{9}$$

In the region of fairly small wavelengths where $2q\omega_{pe}^2/k^2v_0^2 \ll 1$ and $a \approx 1$, Eq. (9) has the following solutions:

$$y_{1,2} = \pm 1 - i\frac{b}{2}, \; y_3 = i\frac{1}{b} \; (b \ll 1), \tag{10}$$

$$y_{1,2} = -\frac{(i \pm \sqrt{3})}{2b^{1/3}}, \; y_3 = i\frac{1}{b^{1/3}} \; (b \gg 1). \tag{11}$$

If $q < q_j$, $S_j < 0$ $(b < 0)$, the solution $y_{1,2}$ is unstable and the growth rate is

$$\gamma = \omega_{pi}(|b|/2) \; (|b| \ll 1), \tag{12}$$

$$\gamma = \omega_{pi}\left(\frac{1}{2|b|^{1/3}}\right) \; (|b| \gg 1). \tag{13}$$

It follows that the growth rate reaches a maximum value when $|b| \sim 1$; this value is of order

$$\gamma \sim \omega_{pi} \quad \left(k \approx \frac{\omega_{pe}}{v_0}\left(\frac{m_e}{m_i}\right)^{1/6}(2\sqrt{\pi}|S_j|)^{1/3}\right). \tag{14}$$

The condition $2q\omega_{pe}^2/k^2v_0^2 \ll 1$ for the solution (14) is satisfied when $q \ll (m_e/m_i)^{1/3}(2\sqrt{\pi}|S_j|)^{2/3}$. The solution y_3 when $q < q_j$ is a damped solution, and when $q > q_j$ is a growing solution, but is inapplicable since it does not satisfy the condition $z_0 \ll 1$.

It is easy to show that Eq. (9) also has unstable solutions when $q \gtrsim (m_e/m_i)^{1/3}(2\sqrt{\pi}|S_j|)^{2/3}$ (but $q < q_j$). Assuming, for example, that $a \gg 1$, we obtain the following unstable solution of Eq. (9) for $|b| \ll 2a^{3/2}$:

$$y_{1,2} = \pm\frac{1}{a^{1/2}} - i\frac{b}{2a^2}. \tag{15}$$

The growth rate is

$$\gamma = -\omega_{pi}\frac{|b|}{2a^2} = -\frac{\sqrt{\pi}}{4}S_j\frac{\omega_{pi}^2}{\omega_{pe}^2}\frac{kv_0}{q^2}. \tag{16}$$

Expression (16) increases with k, and the growth rate reaches a maximum value given by Eq. (14) when $a \sim 1$.

This instability is due to the nonmonotonic behavior[30] of the electron distribution function $F(v_\perp)$ and can be called by analogy with the instability described,[1] which is due to the nonmonotonic behavior of the ion distribution function, the electron loss-cone instability. The above consideration shows that this instability occurs everywhere in the region $q < q_j$, and in this case for $0 < q \lesssim (m_e/m_i)^{1/3} \cdot (2\sqrt{\pi}|S_j|)^{2/3}$ the growth rate is of the order of the ion plasma frequency, and decreases monotonically to zero in the region $(m_e/m_i)^{1/3}(2\sqrt{\pi}|S_j|)^{2/3} \lesssim q \lesssim q_j$.

If the filling of the loss cone is fairly large $(q > q_j)$, the quantity S_j changes sign, and the increase in the oscillations changes to attenuation, so that in this region there is no electron cone instability.

4. For the growth rate (14) the condition that the electrons should be unmagnetized $2\pi\gamma/\omega_{He} \sim 2\pi\omega_{pi}/\omega_{He} \gg 1$ is only satisfied when the magnetic field is fairly weak. We now investigate the electron loss-cone instability with no current; the plasma is strong in a magnetic field $2\pi\gamma/\omega_{He} \ll 1$, and we assume that this instability does not develop even when $q = 0$.

For convenience we introduce the phase ψ according to the relation $\psi = 2\pi \operatorname{Re} \omega/\omega_{He}$; then for ψ not close to $2n\pi(|1 - \cos\psi| \gg 2\pi\gamma/\omega_{He})$, Eq. (7) takes the form

$$\left(\frac{\omega}{\omega_{pi}}\right)^2 - 1 - 2\sqrt{\pi}\left(\frac{\omega_{pe}}{kv_0}\right)^3 S_j\left(\frac{m_e}{m_i}\right)^{1/2}\left(\frac{\omega}{\omega_{pi}}\right)^2\frac{\sin\psi}{1-\cos\psi} = 0 \quad (\gamma \ll \operatorname{Re}\omega). \tag{17}$$

Assuming that $\omega_{He}^2/4\pi^2 \gg \omega_{pi}^2$ when $\psi \sim 1$ Eq. (17) reduces to the form

$$\frac{\psi}{2}\operatorname{ctg}\frac{\psi}{2} = \frac{\sqrt{\pi}}{2S_j}\left(\frac{m_i}{m_e}\right)^{1/2}\frac{\omega_{pi}}{\omega_{He}}\left(\frac{kv_0}{\omega_{pe}}\right)^3. \tag{18}$$

It is easy to show graphically that this equation has a purely real solution.

For $\psi \approx 2n\pi$ $(\omega \approx n\omega_{He})$, we obtain from Eq. (7)

$$1 - \frac{\omega_{pi}^2}{\omega^2} - \frac{2}{\sqrt{\pi}}\frac{\omega_{pe}^2 n\omega_{He}^2 S_j}{k^3v_0^3(\omega - n\omega_{He})} = 0. \tag{19}$$

Assuming that $(\omega_{pi}/\omega)^2 \approx (\omega_{pi}/n\omega_{He})^2 \ll 1$, we find

$$\omega \approx n\omega_{He} + \frac{2}{\sqrt{\pi}}\frac{n\omega_{He}^2\omega_{pe}^2}{k^3v_0^3}S_j. \tag{20}$$

It is easy to show that there is also no instability in the frequency range $\omega \ll \omega_{He}$.

Hence, for fairly high magnetic fields $2\pi\omega_{pi}/\omega_{He} \ll 1$ there is no electron loss-cone instability with zero current. Consequently, the instabilities considered above would only be expected when the following inequality is satisfied:

$$2\pi\frac{\omega_{pi}}{\omega_{He}} \geqslant 1. \tag{21}$$

5. When a transverse current is present it is necessary to use Eq. (7) to describe the loss-cone instability; this equation reduces to the form (9) in the case of magnetized electrons $(2\pi\gamma/\omega_{He} \gg 1)$. In this case, the coefficient b in Eq. (9) remains as before, whereas the coefficient a must be changed to the following:

$$a = 1 + 2q\frac{\omega_{pe}^2}{k^2v_0^2} + 2i\sqrt{\pi}\frac{u}{v_0}\frac{\omega_{pe}^2}{k^2v_0^2}S_j.$$

Investigation of the solutions of Eq. (9) in this case shows that when $q \lesssim q^* \equiv (m_e/m_i)^{1/3}(2\sqrt{\pi}|S_j|)^{2/3}(1 + u/u_0)$ the maximum growth rate, as before, is determined by the estimate (14), while the wave vector k in the presence of a current is changed, being of order

$$k \sim \frac{\omega_{pe}}{v_0}(2\sqrt{\pi}|S_j|)^{1/3}\left(\frac{m_e}{m_i}\right)^{1/6}\sqrt{1 + \frac{u}{u_0}}, \tag{22}$$

where

$$u_0 \equiv \frac{v_0}{(2\sqrt{\pi}|S_j|)^{1/3}}\left(\frac{m_e}{m_i}\right)^{1/2}.$$

When q increases in the region $q > (m_e/m_i)^{1/3} \cdot (2\sqrt{\pi}|S_j|)^{1/3}$ the growth rate decreases, and remains positive even when $q > q_j$.

It is easy to show that when $q > q_j$ and $u \gg v_0(m_e/m_i)^{1/2}$.

$q^{-1/2}$, growth rate γ has the form

$$\gamma=\left(\frac{\pi}{2}\frac{m_e}{m_i}\right)^{1/2}ku\,|S_j|\left(2q+\frac{k^2v_0^2}{\omega_{pe}^2}\right)^{-3/2}. \tag{23}$$

When q = 1 Eq. (23) is identical with the well-known expression for the growth rate of ion-acoustic oscillations in the limiting case when $u \gg v_s = (T_e/m_i)^{1/2}$. As can be easily shown, the growth rate (23) reaches a maximum when $k = (\omega_{pe}/v_0)q^{1/2}$, given by

$$\gamma_{\max}=\frac{1}{3}\omega_{pi}\left(\frac{\pi}{6}\right)^{1/2}\frac{|S_j|}{q}\frac{u}{v_0}. \tag{24}$$

Hence, the growth rate in a plasma with a current decreases monotonically as q increases; when q = 1 it is identical with the well-known expression for the growth rate of ion-acoustic oscillations.

The behavior of the growth rate as a function of q is shown schematically in Fig. 1. As the figure shows, in the region $0 < q \leqslant q^*$ there is a loss-cone instability ($\gamma \sim \omega \sim \omega_{pi}$), and its growth rate decreases monotonically as q increases. When there is no current, the instability ceases when $q = q_j$; when there is a current present it also exists in the region $q > q_j$, and when q = 1 it changes into the usual ion-acoustic instability.

6. We will now consider the effect of the loss cone on the excitation of electron cyclotron waves (the Bernstein mode) in a plasma with a transverse current, assuming that $(2\pi\gamma/\omega_{He}) \ll 1$. Taking the condition $|\omega - n\omega_{He}| \ll \omega_{He}$ into account, Eq. (7) can be simplified and reduced to the form

$$ay^3+(Aa-B)y^2-y-A=0, \tag{25}$$

where

$$a=1+2q\frac{\omega_{pe}^2}{k^2v_0^2},\quad A=\frac{ku-n\omega_{He}}{\omega_{pi}},$$
$$B=\frac{2n\omega_{pe}^2\omega_{He}^2}{\sqrt{\pi}\,\omega_{pi}k^3v_0^3}S_j,\quad y=\frac{\omega-\mathbf{ku}}{\omega_{pi}}.$$

We will investigate the solution of dispersion equation (25) in a number of special cases.

If $Aa = B$ and $|y| \ll A$, Eq. (25) takes the form $y^3a = A$, and its solution gives the following growth rate:

$$\gamma=\sqrt{3}\left(\frac{1}{16\sqrt{\pi}}\frac{m_e}{m_i}\frac{v_0}{u}\right)^{1/3}\left(\frac{n^2|S_j|}{(q+k^2\lambda_{De}^2)^2}\right)^{1/3}\omega_{He},\quad \lambda_{De}=(v_{Te}/\sqrt{2}\omega_{pe}). \tag{26}$$

The condition $|y| \ll A$ is satisfied in this case if

$$\left(\frac{u}{v_0}\right)^2 \gg n\left(\frac{\pi}{2}\right)^{1/2}\frac{(q+k^2\lambda_{De}^2)^{1/2}}{S_j}\left(\frac{m_e}{m_i}\right)^{1/2}. \tag{27}$$

When q = 1 the growth rate (26) is identical with the growth rate of electron cyclotron frequencies in the region where the cyclotron and bunch branches of the oscillations intersect.[2,28] In this case the condition $aA = B$ represents exactly the condition for the branches of the oscillations to intersect.

We will now consider the case when $aA^2 = 1$. Assuming $y = -A + \Delta y$, where $|\Delta y| \ll A$, we obtain from Eq. (25) the equation

$$\Delta y = \pm i\,(B/2a^{3/2})^{1/2}. \tag{28}$$

From expression (28) we obtain the growth rate

$$\gamma=\left(\frac{1}{8\pi}\frac{m_e}{m_i}\right)^{1/4}\frac{n^{1/2}\omega_{He}|S_j|^{1/2}}{(q+k^2\lambda_{De}^2)^{3/4}}. \tag{29}$$

The condition $|\Delta y| \ll A$ is satisfied if

$$\left(\frac{u}{v_0}\right)^2 \ll n\left(\frac{\pi}{2}\right)^{1/2}\left(\frac{m_e}{m_i}\right)^{1/2}\frac{(q+k^2\lambda_{De}^2)^{1/2}}{S_j}. \tag{30}$$

When q = 1, the growth rate given by Eq. (29) is identical with the well-known expression (see, for example, refs. 2, 3, 7–9, 17–20, 28) for the growth rate of ion-acoustic oscillations, when their frequency is close to $n\omega_{He}$. The equation $aA^2 = 1$ also represents the condition for the frequency of ion sound and the electron cyclotron harmonic to intersect.

Note that condition (30), which is the criterion for the solution (29) to be applicable, is an inequality which is the opposite of the inequality (27). Hence, the solutions (26) and (29) can be regarded as solutions of Eq. (25), obtained in two opposite limiting cases, which can be obtained by changing the parameter q for a fixed value of $k = n\omega_{He}/u$.

The characteristic relationship $\gamma = \gamma(q)$ obtained on the basis of the solutions (26) and (29), is shown schematically in Fig. 2. When q = 0 the growth rate is

$$\gamma=\sqrt{3}\left(\frac{1}{4\sqrt{\pi}}\frac{m_e}{m_i}\frac{\omega_{pe}}{n^2\omega_{He}}S_j\right)^{1/3}\omega_{pe}\frac{u}{v_0},\quad \text{if}\quad \frac{u}{v_0}>\left\{\frac{n^2}{2}\sqrt{\pi\frac{m_e}{m_i}}\frac{\omega_{He}}{\omega_{pe}S_j}\right\}^{1/3}, \tag{31}$$

$$\gamma=\left(\frac{1}{8\pi}\frac{m_e}{m_i}\right)^{1/4}\left(\frac{u}{v_0}\right)^3\frac{\omega_{pe}^3}{\omega_{He}^2}\frac{2^{3/2}S_j^{1/2}}{n^3},\quad \text{if}\quad \frac{u}{v_0}<\left\{\frac{n^2}{2}\sqrt{\pi\frac{m_e}{m_i}}\frac{\omega_{He}}{\omega_{pe}}\frac{1}{S_j}\right\}^{1/3}. \tag{32}$$

When $q = q_j$, as follows from Eq. (29), the growth rate becomes zero. When $q = q_m$ the growth rate reaches a maximum, and is given by the following expression if inequality (27) holds:

$$\gamma=\gamma_m=\sqrt{3}\left(\frac{1}{16\sqrt{\pi}}\frac{m_e}{m_i}\frac{v_0}{u}\right)^{1/3}\left[\frac{n^2(1+A_j)}{4(q_j+k^2\lambda_{De}^2)}\right]^{1/3}\omega_{He},\quad q_m=2q_j+k^2\lambda_{De}^2. \tag{33}$$

When the inequality opposite to (27) holds, the maximum growth rate is

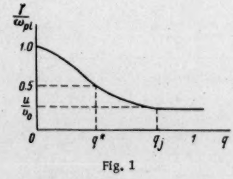

Fig. 1

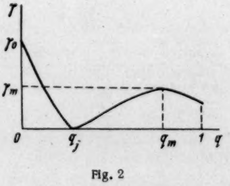

Fig. 2

$$\gamma_m=\left(\frac{1}{8\pi}\frac{m_e}{m_i}\right)^{1/3}\left[\frac{2n(1+A_j)}{3\sqrt{3}\,(q_j+k^2\lambda_{De}^2)^{1/2}}\right]^{1/2}\omega_{He}, \qquad (34)$$

where $q_m = 3q_j + 2k^2\lambda_{De}^2$.

It should be noted that the point $q = q_m$ can be both to the left and to the right of the point $q = 1$. The case when $k^2\lambda_{De}^2 \ll 1$ is particularly interesting. In this case the point q_m is to the left of the point $q=1$, and $\gamma \gg \gamma_m$. Hence, when $k^2\lambda_{De}^2 \ll 1$ the growth rate of electron cyclotron oscillations when there is a conical distribution is much greater than the growth rate obtained in the case of a Maxwellian distribution.

We wish to thank K. N. Stepanov for discussion.

Stochastic acceleration of electrons in nanosecond discharges

L. P. Babich

(Submitted June 19, 1973; resubmitted October 15, 1973)
Zh. Tekh. Fiz., 44, 1846-1851 (September 1974)

Stochastic acceleration is possible for some electrons in field-emission beams in the cathode plasma of nanosecond discharges in air at atmospheric pressure. Equations are derived which relate the energy of the stochastically accelerated electrons to the density and energy of the beam, the density and temperature of the plasma electrons, and the beam dimensions.

In refs. 1 and 2 it is reported that in nanosecond vacuum and gas discharges with average fields $E_0 \sim 10^5\ \mathrm{V\cdot cm^{-1}}$ electrons are detected with ε greater than the applied voltage U_0. It is known at the present time that fast electrons and ions are observed frequently in nature and in laboratory experiments involving discharges and plasmas over a wide range of conditions (see, for example, refs. 3-12); as a rule, the acceleration effects are correlated with intense oscillations in the plasma[13,14] (stochastic acceleration). In a nanosecond discharge a field-emission beam–plasma system is produced in the region of micrononuniformities on the surface of the cathode; this plasma can be unstable with respect to the generation of plasma oscillations.[15] Hence, there is a probable stochastic mechanism for the acceleration of that part of the electrons of the field-emission beams, for which the derivative of the distribution function $\partial f_a/\partial \mathbf{v} < 0$.

To obtain appropriate estimates it is necessary to know the plasma density n_0, the degree of ionization $i = n_0/N$, the electron temperature T_e, and the density n_1 and the energy of the electrons ε_1 in the beams. Under the conditions described in refs. 1 and 2 these characteristics are unknown. However, the quantities n_0, n_1, and ε_1 in nanosecond discharges in air at atmospheric pressure can be estimated using certain indirect data. On photographs of the external form of nanosecond discharges in air at atmospheric pressure, given in ref. 2 under conditions for which electrons with $\varepsilon > eU_0$ are generated, one can see plasmoids in the region of the cathode; these have dimensions $h_0 \sim 0.1$ cm, and are formed near microprojections which initiate the discharge. Weak diffuse fluorescence which propagates to the anode is also observed. In ref. 16, in diffuse channels (the channel diameter approximately 0.2 cm and the length approximately 0.6 cm) of nanosecond discharges in air at atmospheric pressure values of $i \sim 10^{-2}$ are recorded, and the possibility of a local excess of i above the value obtained is noted. In ref. 2 the slope of the leading edge of the voltage pulse dU/dt and its amplitude exceed the values of these characteristics in ref. 16 and the voltage pulse length is very much shorter than in ref. 16; thus, the energy of the emission beam in ref. 2 is used to generate a plasma and to heat it more effectively than in ref. 16. This is confirmed by the external form of the discharges.[2] It can be assumed that in ref. 2 (at least in the denser parts of the plasma in the region of the microprojections,) values of $i \sim 1$ ($n_0 \sim 10^{20}\ \mathrm{cm^{-3}}$) are reached exactly as in the cathode bursts of nanosecond vacuum discharges.[17]

We estimate the characteristics of the beam n_1 and ε_1 starting from the fact that in nanosecond gas discharges at high overvoltages explosion of microprojections on the cathode surface is possible.[18] A relation is proposed in ref. 19 between the density of the emission current j_e, which ensures explosion of a tungsten point, and the delay time of the explosion

$$j_e^2 t_d \simeq 4\cdot 10^9\ \mathrm{A^2\cdot cm^{-1}\cdot sec}.$$

Assuming $t_d \sim 10^{-9}$ sec, we obtain $j_e \simeq 2\cdot 10^9\ \mathrm{A\cdot cm^{-2}}$, for which the field intensity in the region of the micropoint[20] should be $E \simeq 10^8\ \mathrm{V\cdot cm^{-1}}$. A field with this intensity can be obtained by amplification of the external field at the microprojections and by amplification due to the space-charge field.[21]

The cathode potential drop, which occurs as a result of polarization in the external field E_0 of a plasma layer of thickness h_0, is $\Delta\varphi \simeq (1/2)E_0h_0 \simeq 5$ kV. If we assume that the plasma is uniform[16] and $i = 10^{-2}$, the field in the region of the cathode drop[21] $E_k = (1/2)\,(eiNE_0h_0/6)^{1/2} \simeq 4\cdot 10^6\ \mathrm{V\cdot cm^{-1}}$. Projections which amplify this field by a factor of 25 must explode. The observed gains of the external field in the region of the microprojections lie[18] in the range 10–300.

In fields of approximately $10^6\ \mathrm{V\cdot cm^{-1}}$ the energy losses of the electrons are small,[22] and $\varepsilon_1 \simeq e\Delta\varphi = 5$ keV, $n_1 \simeq j_e/ev_1 = 10^{18}\ \mathrm{cm^{-3}}$.

The energy spread of the electrons emitted from a single point of the surface of a microprojection[20] $\Delta\varepsilon \ll \varepsilon_1$. It can be shown that for a semiellipsoidal isolated projection[23] the spread of the electron velocity component along the external field

$$\frac{\Delta v_z}{v_z} = \frac{\sin^2\theta}{(\cos\theta)^2} \simeq \frac{4\theta\sin^2\theta}{2\theta + \sin 2\theta}, \tag{1}$$

where θ is the angle of divergence of the electron beam. Assuming[23] $\theta = 20°$, we obtain $\Delta v_z/v_z \simeq 0.12 < (n_1/n_0)^{1/3} \simeq 0.22$. In fact, the angular divergence of the beam is somewhat smaller because of the focusing effect of the fields of a plane cathode and the neighboring microprojections. Hence, initially the instability of the beam in the densest part of the plasma is hydrodynamic with a growth rate[5]

$$\gamma_h = \sqrt{3}\left(\frac{n_1}{16 n_0}\right)^{1/3}\omega_{p0} \simeq 10^{14}\ \mathrm{sec^{-1}}, \tag{2}$$

where $\omega_{p0} = \sqrt{4\pi n_0 e^2/m_e}$ is the plasma frequency.

The hydrodynamic instability along the path $\sim v_1\gamma_h^{-1} \simeq 4\cdot 10^{-5}$ cm increases the velocity spread up to $(n_1/n_0)^{1/3}$, and further relaxation of the beam is determined by the quasilinear stage. The characteristic relaxation time[24] to $v_{\min}$ is

$$t_q = \left(\frac{v_1}{v_{\min}} - 1 + \ln\frac{v_{\min}}{v_1}\right)\frac{\Lambda}{\pi}\,\frac{n_0}{n_1}\,\omega_{p0}^{-1}, \tag{3}$$

where Λ is the Coulomb logarithm

$$v^{\min} = v_{Te}\left[2\ln\left(\frac{n_0 v_1}{n_1 v_{Te}}\right)\right]^{1/2},$$

and $v_{Te} = (T_e/m_e)^{1/2}$ is the thermal velocity of the plasma electrons.

The energy density of the plasma oscillations excited in the beam instability is[13,14]

$$\dot{W} = \left[2 - \frac{v_{\min}}{v_1} - \left(\frac{v_{\min}}{v_1}\right)^2\right]\frac{n_1\varepsilon_1}{3} \simeq \frac{2}{3}n_1\varepsilon_1, \tag{4}$$

and the spectral density is[14,25]

$$W_k = \frac{n_1 m_e \omega_{p0}^3}{v_1 k^4}. \tag{5}$$

In order to ensure the resonance condition of the accelerated particles with a large number of oscillations it is necessary to take account of the spectral transfer of turbulent energy from the generation region $k \geq \omega_{p0}/v_1$ to the acceleration region $k \leq \omega_{p0}/v_1$.

In the cathode plasma of nanosecond gas discharges one might expect a considerable difference between the electron temperature T_e and the ion temperature T_i. In a strongly nonisothermal plasma ($T_e \gg T_i$) the following interactions are available to increase the length of the plasma waves: decay of the plasma wave into an ion-acoustic wave and a plasma wave with a longer wavelength:[13,14]

$$l \rightarrow S + l' \tag{6}$$

and scattering of the plasma waves by thermal ions

$$l + i \rightarrow l' + i' \tag{7}$$

and by plasma electrons

$$l + e \rightarrow l' + e. \tag{8}$$

We neglect slow ion-acoustic oscillations in the transfer processes because of the extremely small lifetime of the plasma investigated in ref. 2.

The efficiency of the stochastic acceleration of particles in a turbulent plasma is determined by the spectral distribution of the turbulent pulses which build up in the transfer process. In a hot isothermal plasma in which nonlinear scattering of plasmons by ions is the main process by which turbulent energy is saturated at high phase velocities v_p, the spectrum which is established is not suitable for particle acceleration.[13] However, in a nonisothermal plasma with heavy ions the range of values of v_p for which the spectrum of plasma turbulence is determined by electron scattering is broadened.

The plasma rapidly becomes isotropic when spectral transfer of the oscillations takes place.[14,25] Hence, the turbulence is assumed to be isotropic below.

The change in the spectral energy density W_k of isotropic turbulent pulses due to scattering on electrons and damping in binary electron collisions is

$$\frac{\partial W_k}{\partial t} = (\gamma_e^l - 2\nu_e)W_k, \tag{9}$$

where the rate of scattering of plasmons[14] by electrons γ_e^l is

$$\gamma_e^l = \frac{6v_{Te}\sqrt{2\pi}}{4m_e n_0 \omega_{p0}^2}\left\{\int_k^\infty dk_1 W_{k_1}\frac{k^2}{k_1^3}(k_1^2 - k^2)\right.$$
$$\left.\times\left(\frac{1}{3}k_1^2 + \frac{4}{7}k^2\right) - \int_0^k dk_1 W_{k_1}\frac{k_1^2}{k^3}(k^2 - k_1^2)\left(\frac{1}{3}k^2 + \frac{4}{7}k_1^2\right)\right\}. \tag{10}$$

Assuming $W_k = T(t)K_k(k)$, Eq. (9) reduces to the following equations:

$$\dot{T} + 2\nu_e T = \mathrm{const}\, T^2, \tag{11}$$

$$\int_k^\infty K_{k_1}dk_1\frac{k^2}{k_1^3}(k_1^2 - k^2)\left(\frac{1}{3}k_1^2 + \frac{4}{7}k^2\right) - \int_0^k K_{k_1}dk_1\frac{k_1^2}{k^3}(k^2 - k_1^2)$$
$$\times\left(\frac{1}{3}k^2 + \frac{4}{7}k_1^2\right) = \mathrm{const}. \tag{12}$$

The solution of Eq. (12) which satisfies the condition that the transfer of energy along the spectrum is local, has[14] the form $K_k \sim k^{-5/2}$, in which case const $= 0$. Then $T \sim \exp(-2\nu_e t)$, and

$$W_k = Ak^{-5/2}\exp(-2\nu_e t). \tag{13}$$

The constant A is found by matching Eq. (13) with Eq. (5) at $t = 0$ at the point $k = \omega_{p0}/v_1$. Finally we obtain

$$W_k = \frac{n_1 m_e v_1^3}{\omega_{p0}}\left(\frac{\omega_{p0}}{v_1 k}\right)^{5/2}\exp(-2\nu_e t). \tag{14}$$

We find the mean energy acquired by electrons of the beam accelerated stochastically by turbulent pulses of this spectrum in a plasma layer of thickness h. In the nonrelativistic approximation the rate of acceleration is determined solely by the spectrum[14,25]

$$\dot{\varepsilon} = \frac{\pi}{2}\frac{\omega_{p0}^2 m_e}{n_0\sqrt{2m_e\varepsilon}}W_k\bigg|_{k=\omega_{p0}\sqrt{\frac{m_e}{2\varepsilon}}}. \tag{15}$$

The solution of Eq. (15) with W_k defined by Eq. (14), and with the initial condition $\varepsilon(t = 0) = \varepsilon_1 \ll \varepsilon$ has the following form:

$$\varepsilon = \varepsilon_\infty(1 - e^{-2\nu_e t})^4, \tag{16}$$

where

$$\varepsilon_\infty = \left[3\left(\frac{\pi}{2}\right)^2\sqrt{2\pi}\frac{n_1 d_{p0}^3}{\Lambda}\right]^4\varepsilon_1, \tag{17}$$

$d_{p0} = v_{Te}/\omega_{p0}$ is the Debye radius of the plasma. Assuming that $h = \int_0^{t(\varepsilon)} v(t')dt'$, where $t(\varepsilon)$ is determined from Eq. (16), we find the relation between the mean energy of the accelerated electrons ε and the dimensions of the plasma h:

$$h = -\frac{1}{2\nu_e}\sqrt{\frac{2\varepsilon_\infty}{m_e}}\left\{\ln\left[1 - \left(\frac{\varepsilon}{\varepsilon_\infty}\right)^{1/4}\right] + \left(\frac{\varepsilon}{\varepsilon_\infty}\right)^{1/4} + \frac{1}{2}\left(\frac{\varepsilon}{\varepsilon_\infty}\right)^{1/2}\right\}. \tag{18}$$

We do not know the electron temperature in the plasma in ref. 2. Hence, taking as the base of the acceleration h the dimension of the densest part of the plasma, which in ref. 2 is approximately 10^{-2} cm, we find from Eq. (18) that for stochastic acceleration of the electrons in a completely ionized plasma with $n_0 \sim 10^{20}$ cm^{-3} up to an energy[2] $\varepsilon \simeq 300$ keV we require $T_e \sim 200$ eV.

In such a plasma the quasilinear relaxation time $t_q \simeq 10^{-13}$ sec. Since the Landau damping $\gamma_L(v^{\min}) \simeq 5 \cdot 10^{12}$ sec^{-1}, and the frequency of binary electron collisions $\nu_e \simeq 0.7 \cdot 10^{12}$ sec^{-1}, relaxation of the beam takes place completely without dissipative processes. The characteristic scale of the plasma nonuniformities, capable of stabilizing the instability,[25] is

$$L \leqslant v_g t_q \simeq 3 \frac{v_{T_e}^2}{v_p} t_q \simeq (2 \div 5) \cdot 10^{-5} \text{ cm}.$$

where v_g is the group velocity of the plasma waves. It can be assumed that the characteristic scale of the nonuniformities of the densest part of the plasma in ref. 2 is not smaller than the dimensions of the microprojections [$\sim 10^{-4}$ cm (ref. 26)], and that there is no stabilization of the instability by the nonuniformities.

Comparing the characteristic rate of scattering of plasma oscillations by electrons for $v_p/v_{Te} \ll (3m_i/m_e)^{1/3}$

$$\gamma_e = 3\sqrt{\frac{\pi}{2}}\, \omega_{p0} \frac{W}{n_0 T_e} \left(\frac{v_{T_e}}{v_p}\right)^3 \simeq 2.8 \cdot 10^{12} \text{ sec}^{-1}$$

with the rate of differential transfer to ions[14] ($v_p/v_{Te} \ll 3v_{Te}/v_{Ti}$)

$$\gamma_i = \frac{\pi}{27} \omega_{p0} \frac{W}{n_0 T_e} \left(\frac{v_p}{v_{T_e}}\right)^2 \left(1 + \frac{T_e}{T_i}\right)^{-2},$$

we obtain the region v_p where scattering by electrons predominates over scattering by ions:

$$\left(\frac{v_p}{v_{T_e}}\right)^5 \ll \frac{9 \cdot 2^{1/2}}{\pi^{5/2}} \frac{m_i}{m_e} \left(1 + \frac{T_e}{T_i}\right)^2. \tag{19}$$

In our case the time taken to transfer energy from electrons to ions considerably exceeds the lifetime of the plasma ($t_{ei} \sim 10^{-7}$ sec) and T_i is not greater than the mean electron energy in single avalanches, which for $E \sim 10^5$ V · cm^{-1} and p = 760 torr in air and Eq. (19) is satisfied over the whole region of acceleration. The anisotropic nature of the overshoot of the fast electrons observed in ref. 2 can obviously be explained by the fact that the oscillations are not completely isotropic.

The phenomenon of stochastic acceleration of electrons is connected with the excitation in the plasma of high-frequency slow waves with phase velocities smaller than the velocity of light. Besides oscillations of the electrostatic type with frequencies of the order of ω_{p0}, these include electromagnetic waves with frequencies below[27,28] the electron cyclotron frequency ω_{He} (whistlers). We assume that all the stored charge in the experiments described in ref. 2 passes through a plasma bunch. Then

$$\omega_{He} = \mu_0 \frac{e}{m_e} H \simeq \mu_0 \frac{e}{m_e} \frac{CU_0}{2\pi t r}.$$

Assuming[2] $C \simeq 4 \cdot 10^{-11}$ F, $U_0 \simeq 10$ V, and $r \simeq 10^{-4}$ cm (the characteristic dimensions of the emitting point), we obtain $\omega_{He} \sim 10^{12}$ sec$^{-1} \sim \nu_e$. Consequently, the whistlers are strongly attenuated and stochastic acceleration of the electrons[2] can only be connected with the Langmuir turbulence.

Hence, the above estimates indicate that the nature of the fast electrons generated in nanosecond gas discharges may be related to stochastic acceleration of part of the electrons of the field-emission beams by turbulence excited by beams in the cathode plasma. To get better estimates it is necessary to determine experimentally the plasma electron temperature, for example, by investigating its radiation in the first nanoseconds of the discharge.

Nonlinear interaction between a monochromatic ion-acoustic wave and a plasma

V. P. Indykul

(Submitted July 4, 1973; resubmitted October 31, 1973)
Zh. Tekh. Fiz., 44, 1852-1856 (September 1974)

The nonlinear interaction between a monochromatic, finite-amplitude ion-acoustic wave and a collisionless nonisothermic plasma is considered. The nonlinear damping and frequency shift are obtained. The nonlinear damping of the ion-acoustic wave is due primarily to the ions, whose interaction with the wave is much stronger because the resonant-ion period is longer than the electron period. The nonlinear frequency shift of the ion-acoustic wave due to the interaction with the resonant plasma particles is determined primarily by the electrons.

1. The resonant interaction of waves with particles in a Maxwellian plasma underlies the collisionless damping – Landau damping. The interaction with the wave causes the distribution function in the resonant velocity region to become so distorted that energy exchange between the particles and the wave stops.

The equations of the quasilinear theory[1,2] can be used to study the damping of broad wave packets in a plasma. In this case the change in the distribution function associated with a particular harmonic is small, and the cumulative effect of all of the harmonics leads to diffusion of the resonant particles in velocity space. This diffusion is described by Fokker–Planck equations for the distribution functions.

The damping of a monochromatic wave of finite amplitude in a plasma is completely different. In this case the interaction between the resonant particles and the wave is completely nonlinear and leads to trapping of the resonant particles by the wave. An analytic solution for the problem of nonlinear Landau damping can be obtained when

$$\gamma^L \tau_0 \ll 1,$$

where γ^L is the linear damping and $\tau_0 = (keE_0/m)^{-1/2}$ is the characteristic oscillation period of particles trapped by the wave (k and E_0 are the wave number and amplitude of the monochromatic wave). The motion of the resonant particles is first considered in the field of a wave of constant amplitude; then the effect of the particles on the wave is taken into account. The earliest analyses of the damping of a monochromatic plasma wave are given in refs. 3-5.

An essential feature of the nonlinear interaction of monochromatic waves with a plasma is the presence of a large group of thermal (nonresonant) particles which determine the dispersion of the wave and whose motion in the field of the wave is linear. The interaction of a wave with a plasma is therefore usually studied under the assumption that the shape of the wave remains constant. It has been shown,[6] however, that the nonlinear interaction of the resonant particles with the wave causes a small nonlinear phase shift; this in turn causes a small nonlinear shift of the frequency of the plasma oscillations as compared to the frequency ω_L determined by the linear dispersion equation.

In the present work we consider the nonlinear interaction between a nonisothermal ($T_e \gg T_i$) plasma and a monochromatic ion-acoustic wave of finite amplitude whose electric field is

$$E(t,\ z) = E_0(t) \sin (kz - v_p t + \alpha). \tag{1}$$

Here, $v_p \simeq c_s = \sqrt{T_e/m_i}$ is the phase velocity of the wave, and α is the small nonlinear phase shift.

The nonlinear properties of an ion-acoustic wave are conveniently studied with the Poisson equation

$$\varepsilon(\omega_L + \Delta\hat{\omega}) \operatorname{div} \mathbf{E} + \text{c.c.} = 8\pi\rho, \tag{2}$$

which must be satisfied by the field given by Eq. (1). Here, ρ is the particle charge density,

$$\varepsilon(\omega_L) = 1 - \frac{\omega_{0i}^2}{\omega_L^2} + \frac{1}{k^2\lambda_{De}^2} = 0$$

is the linear dispersion equation for the longwave ion-acoustic mode, and $\Delta\hat{\omega}$ is a complex frequency shift operator, whose action on the field is defined by the equation

$$\Delta\hat{\omega} E = i \frac{\partial E}{\partial t}. \tag{3}$$

Utilizing the fact that $|\Delta\hat{\omega}|$ is small compared with ω_L, we can expand $\varepsilon(\omega_L + \Delta\hat{\omega})$ in powers of $\Delta\hat{\omega}/\omega_L$ (the zeroth-order term vanishes by virtue of the linear dispersion equation). Using this expansion and Eq. (3), and substituting (1) into (2), we obtain the result (in the wave reference frame)

$$\hat{\delta\omega} - i\gamma = \frac{8\pi e}{kE_0}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1} \int_{-\infty}^{\infty} dv_0 \int_{-\lambda/2}^{\lambda/2} \frac{dz_0}{\lambda} \{[f_{0i}(v_0 + v_p) - f_i^L(v_0 + v_p)] - [f_{0e}(v_0 + v_p) - f_e^L(v_0 + v_p)]\} e^{-ikz - i\alpha}, \tag{4}$$

where γ and $\delta\omega$ are the nonlinear damping and frequency shift of the ion-acoustic wave, and

$$f_{i,e}^L(v_0 + v_p) = \mp \frac{eE_0}{km_{i,e}} \frac{1}{v_0} \frac{\partial f_{0i,e}}{\partial v_0} \cos(kz + \alpha).$$

We assume that the following condition holds:

$$\frac{m_e}{m_i} \ll \frac{eE_0}{kT_e} \ll \left(\frac{T_i}{T_e}\right)^2. \tag{5}$$

The motions of the main nonresonant ions and electrons, which move with the thermal velocities, can be regarded as linear for these amplitudes. The nonlinear effects are due to the resonant particles, whose interaction with the wave is strong. The contribution of the linear approximation has therefore been subtracted from the right-hand side of Eq. (4).

By making use of the fact that the nonlinear damping and frequency shift are small compared with ω_L, we can make the approximation that $\alpha = 0$ in the right-hand side of Eq. (4). By separating the imaginary and real parts in Eq. (4), we obtain the following expressions for the nonlinear damping and frequency shift of the ion-acoustic wave:

$$\gamma=-\frac{8\pi e}{kE_0}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int\limits_{-\infty}^{\infty}dv_0\int\limits_{-\lambda/2}^{\lambda/2}\frac{dz_0}{\lambda}\left[f_{0i}(v_0+v_p)-f_{0e}(v_0+v_p)\right]\sin kz, \tag{6}$$

$$\delta\omega=\frac{8\pi e}{kE_0}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int\limits_{-\infty}^{\infty}dv_0\int\limits_{-\lambda/2}^{\lambda/2}\frac{dz_0}{\lambda}\{[f_{0i}(v_0+v_p)-f_i^L(v_0+v_p)]$$
$$-[f_{0e}(v_0+v_p)-f_e^L(v_0+v_p)]\}\cos kz. \tag{7}$$

If the particle velocity distribution is Maxwellian, making use of (5) we find

$$\left.\begin{aligned}f_{0i}(v_0+v_p)&\simeq\frac{n}{\sqrt{2\pi}\,v_{Ti}}e^{-v_p^2/2v_{Ti}^2}\left(1-\frac{v_0v_p}{v_{Ti}^2}-\frac{1}{2}\frac{v_0^2}{v_{Ti}^2}\right),\\ f_{0e}(v_0+v_p)&\simeq\frac{n}{\sqrt{2\pi}\,v_{Te}}\left(1-\frac{v_0v_p}{v_{Te}^2}-\frac{1}{2}\frac{v_0^2}{v_{Te}^2}\right).\end{aligned}\right\} \tag{8}$$

It is easy to show that the terms in Eq. (8) which are linear in v_0 contribute only to the damping; the quadratic terms contribute only to the nonlinear frequency shift. It then follows from Eqs. (6), (7), and (8) that

$$\gamma=\frac{8\pi}{\sqrt{2\pi}}\frac{en}{kE_0}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int\limits_{-\infty}^{\infty}dv_0\int\limits_{-\lambda/2}^{\lambda/2}\frac{dz_0}{\lambda}\left[\frac{v_pv_0}{v_{Ti}^3}\sin kz'+\frac{v_pv_0}{v_{Te}^3}\sin kz\right], \tag{9}$$

where $kz' = kz-\pi$ and

$$\delta\omega=-\frac{8\pi}{\sqrt{2\pi}}\frac{en}{kE_0}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int\limits_{-\infty}^{\infty}dv_0\int\limits_{-\lambda/2}^{\lambda/2}\frac{dz_0}{\lambda}\left\{\frac{1}{v_{Ti}^3}\left(\frac{v_0^2}{2}+v_i^2\cos kz'\right)\cos kz'\right.$$
$$\left.+\frac{1}{v_{Te}^3}\left(\frac{v_0^2}{2}+v_e^2\cos kz\right)\cos kz\right\}, \tag{10}$$

where $v_{i,e}^2 = eE_0/km_{i,e}$.

2. We first study the nonlinear damping of the ion-acoustic wave due to resonant ions. In order to solve the equations of motion for the ions, i.e., to find the dependence of $\sin kz'$ and $\cos kz'$ on z_0 and v_0, we divide the ions into two groups: those which are trapped and oscillate in the potential well, and those which are in transit. Integration of the equations of motion gives

$$F(\xi,\varkappa)=F(\xi_0,\varkappa)\pm\frac{t}{\varkappa\tau_{0i}},\quad \varkappa^2\equiv\frac{2eE_0}{kW+eE_0}<1 \tag{11}$$

for the transit ions, and

$$F\left(\zeta,\frac{1}{\varkappa}\right)=F\left(\zeta_0,\frac{1}{\varkappa}\right)\pm\frac{t}{\tau_{0i}},\quad \varkappa>1 \tag{12}$$

for the trapped ions. Here, W is the energy of the particles in the wave field (1), $\tau_{0i} = (ekE_0)/m_i)^{-1/2}$ is the period of oscillation of the particles in the potential well, $\xi = kz'/2$, F(x) is an elliptic integral of the first kind, and the quantities ξ and ζ are related by the equation $\varkappa \sin\xi = \sin\zeta$.

The upper sign in Eqs. (11) and (12) corresponds to ions with $v_0 > 0$, while the lower sign corresponds to ions with $v_0 < 0$. From Eqs. (11) and (12), it follows that

$$\left.\begin{aligned}\sin kz'&=2\,\mathrm{sn}\left(F\pm\frac{t}{\varkappa\tau_{0i}}\right)\mathrm{cn}\left(F\pm\frac{t}{\varkappa\tau_{0i}}\right),\quad \varkappa<1,\\ \sin kz'&=\frac{2}{\varkappa}\,\mathrm{sn}\left(F\pm\frac{t}{\tau_{0i}}\right)\mathrm{dn}\left(F\pm\frac{t}{\tau_{0i}}\right),\quad \varkappa>1,\end{aligned}\right\} \tag{13}$$

where snu, cnu, and dnu denote the elliptic sine and cosine and the Jacobi delta.

If we substitute Eqs. (13) into Eq. (9), integrate over $\varkappa$ and $F(\xi_0, \varkappa)$ for the particles in transit ($\varkappa < 1$) and over $1/\varkappa$ and $F(\zeta_0, 1/\varkappa)$ for the trapped particles ($\varkappa > 1$), and use the Fourier expansion of the elliptic functions,[7] the nonlinear damping due to the ions is found to be

$$\gamma_i=\gamma_i^L 128\pi\sum_{n=1}^{\infty}\int\limits_0^1 d\varkappa$$
$$\times\left\{\frac{nq^{2n}}{\varkappa^5K^2(1+q^{2n})^2}\sin\frac{n\pi t}{\varkappa K\tau_{0i}}+\frac{\varkappa\left(n-\frac{1}{2}\right)q^{2n-1}}{K^2(1+q^{2n-1})^2}\sin\frac{\left(n-\frac{1}{2}\right)\pi t}{K\tau_{0i}}\right\}, \tag{14}$$

where γ_i^L is the ion linear Landau damping, K is the total elliptic integral of the first kind, and $q = \exp\{-\pi K(\sqrt{1-\varkappa^2})\cdot[K(\varkappa)]^{-1}\}$.

It follows from Eq. (14) that for $t \ll \tau_{0i}$ the damping is identical with the linear damping; for $t \sim \tau_{0i}$ it oscillates about zero, causing oscillations of the wave amplitude. Since the period of the oscillations of the resonant particles which cause this temporal behavior of the wave is a function of their energy, a "phase mixing" of these particles occurs which results in damping of the oscillations after a long time $t \gg \tau_{0i}$. A stationary value of the field amplitude is thus established which is given by the equation

$$E(\infty)=E(0)\exp(-\Gamma),$$

where

$$\Gamma=\Gamma_i+\Gamma_e\equiv\int\limits_0^{\infty}\gamma_i(t)\,dt+\int\limits_0^{\infty}\gamma_e(t)\,dt.$$

The quantity $\Gamma_{i,e}$ is calculated by a method which has been previously discussed,[5] with the result that

$$\Gamma_{i,e}=\gamma_{i,e}^L\tau_{0i,e}\frac{64}{\pi}\int\limits_0^1 d\varkappa\left\{\frac{1}{\varkappa^4}\left[\frac{E}{\pi}-\frac{\pi}{4K}\right]+\frac{\varkappa}{\pi}[E-(1-\varkappa^2)K]\right\}, \tag{15}$$

where $E \equiv E(\varkappa)$ denotes the total elliptic integral of the second kind.

For realistic plasma parameters

$$\frac{\Gamma_i}{\Gamma_e}=\frac{m_i}{m_e}\left(\frac{T_e}{T_i}\right)^{3/2}\exp\left[-\frac{T_e}{2T_i}\right]\gg 1, \tag{16}$$

i.e., the ion contribution to the nonlinear damping of an ion-acoustic wave is much larger than the electron contribution. This fact can be explained as follows: Since τ_{0e} the period of the electron oscillations in the wave field is much smaller than the ion period τ_{0i}, the electron damping disappears after a time $\tau_{0e} \ll t \lessdot \tau_{0i}$; however, the ions continue to interact with the wave and determine the further evolution of the amplitude.

3. Let us now consider the nonlinear frequency shift caused by the interaction of the ion-acoustic wave with the resonant plasma particles. We first consider the effect of the electrons. From the electron equations of motion we have the following integral of the motion:

$$\frac{m_ev^2}{2}-m_ev_e^2\cos kz=W=\mathrm{const},$$

which is to be interpreted as the total energy of the electrons in the field (1) of the ion-acoustic wave. By taking this into account, it is easy to transform Eq. (10) to the form

$$\delta\omega_e = \frac{8}{\pi\sqrt{2\pi}}\frac{\omega_{0e}^2}{k^2 v_{Te}^2}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\left\{\int_0^1 \frac{d\varkappa}{\varkappa^2}\int_{-K}^{K} dF\,\mathrm{sn}^2 F\left[1 - 2\,\mathrm{sn}^2\left(F + \frac{t}{\varkappa T_{0e}}\right)\right]\right.$$
$$\left. + \int_0^1 \varkappa^3 d\varkappa \int_{-K}^{K} dF\,\mathrm{sn}^2 F\left[1 - 2\varkappa^2\,\mathrm{sn}^2\left(F + \frac{t}{\tau_{0e}}\right)\right]\right\}. \qquad (17)$$

If we now use the expansion[8]

$$\mathrm{sn}^2 u = \frac{K - E}{\varkappa^2 K} - \frac{2\pi^2}{\varkappa^2 K^2}\sum_{n=1}^{\infty}\frac{nq^n}{1 - q^{2n}}\cos\frac{n\pi u}{K}$$

we then obtain from Eq. (10)

$$\delta\omega_e = \frac{16}{\pi\sqrt{2\pi}}\frac{\omega_{0e}^2}{k^2 v_{Te}^2}\frac{v_e}{v_{Te}}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int_0^1 \frac{d\varkappa}{\varkappa^6 K}\left\{(K - E)\left[\varkappa^2 K + 2(E - K)\right]\right.$$
$$\left. - \frac{4\pi^4}{K^2}\sum_{n=1}^{\infty}\frac{n^2 q^{2n}}{(1 - q^{2n})^2}\cos\frac{n\pi t}{\varkappa K \tau_{0e}}\right\}$$
$$+ \frac{16}{\pi\sqrt{2\pi}}\frac{\omega_{0e}^2}{k^2 v_{Te}^2}\frac{v_e}{v_{Te}}\left(\frac{d\varepsilon}{d\omega_L}\right)^{-1}\int_0^1 \frac{\varkappa\, d\varkappa}{K}\left\{(K - E)(2E - K)\right.$$
$$\left. - \frac{4\pi^4}{K^2}\sum_{n=1}^{\infty}\frac{n^2 q^{2n}}{(1 - q^{2n})^2}\cos\frac{n\pi t}{K\tau_{0e}}\right\}. \qquad (18)$$

Here, the first term represents the contribution of the transiting particles and the second term represents the contribution of the trapped particles.

After a long interval of time $t \gg \tau_{0e}$, the nonlinear frequency shift becomes constant, being equal to

$$\delta\omega_e(\infty) = \frac{8}{\pi\sqrt{2\pi}}\,\omega\sqrt{\frac{eE_0}{kT_e}}\int_0^1 \frac{d\varkappa}{K}\left\{\frac{K - E}{\varkappa^6}\left[\varkappa^2 K\right.\right.$$
$$\left.\left. + 2(E - K)\right] + \varkappa(K - E)(2E - K)\right\}. \qquad (19)$$

It is easy to obtain expressions for the ions which are similar to Eqs. (18) and (19), and to show that

$$\frac{\delta\omega_e(\infty)}{\delta\omega_i(\infty)} = \left(\frac{T_i}{T_e}\right)^{1/2}\exp\left[\frac{T_e}{2T_i}\right] \gg 1. \qquad (20)$$

This means that the electronic contribution to the nonlinear change of the dispersion of an ion-acoustic wave is much larger than the ion contribution.

In conclusion, we thank V. D. Shapiro and V. I. Shevchenko for guidance.

High-frequency instabilities in an inhomogeneous, anisotropic finite-β plasma

V. D. Egorenkov and A. I. Pyatak

(Submitted July 30, 1973; resubmitted October 16, 1973)
Zh. Tekh. Fiz., 44, 1857-1861 (September 1974)

The electromagnetic instabilities in an inhomogeneous hot-electron ($T_e \gg T_i$) finite-β plasma with an anisotropic velocity distribution function are investigated. At frequencies $\omega_{Bi} \ll \omega \ll \omega_{Be}$ and wavelengths $v_{Te}/\omega_{Be} \ll \lambda_\perp \ll v_{Ti}/\omega_{Bi}$ firehose and mirror instabilities can develop in an anisotropic inhomogeneous plasma. In particular, the instabilities are related to the ion-acoustic mode and the whistler mode of a homogeneous plasma. The inhomogeneity in the plasma density and the external magnetic field has a strong effect on modes whose wavelength in the direction of the magnetic field $\lambda_\parallel$ is large compared to the inhomogeneity scale length for the equilibrium plasma parameters.

1. It is well-known[1-5] that in a homogeneous magnetoactive finite-β plasma anisotropies in the electron and ion pressures can produce firehose and mirror instabilities at frequencies $\omega \ll \omega_{Bi}$. It is shown in ref. 6 that these instabilities also develop in the frequency range $\omega_{Bi} \ll \omega \ll \omega_{Be}$. In a plasma with hot electrons and cold ions the long-wave modes ($kc \lesssim \omega_{pe}$), which correspond to ion-acoustic modes and whistler modes in an isotropic plasma, are unstable.

The papers cited above do not consider the inhomogeneity of the equilibrium plasma parameters (density, external magnetic field, etc.). It is clear, however, that the Larmor ($\nabla n_0 \neq 0$) and magnetic ($\nabla B \neq 0$) particle drifts can affect the dispersion properties of waves that propagate across the magnetic field. It will be shown in the present paper that this effect can be neglected if the wavelength along the magnetic field is smaller than the characteristic dimension of the inhomogeneity of the plasma parameters across the magnetic field.

In the present paper the stability of a finite-β plasma [$\beta = 4\pi n_0(T_e + T_i)/B_0^2 \sim 1$] with hot electrons and cold ions ($T_e \gg T_i$) is investigated in the frequency region $\omega_{Bi} \ll \omega$, $\gamma \ll \omega_{Be}$ for the case in which the wavelength along the magnetic field is of the same order as the characteristic scale size of the inhomogeneity. The inhomogeneity is to be assumed weak, i.e., the electron Larmor radius is assumed to be appreciably smaller than the characteristic dimension of the inhomogeneity. It is shown that the inhomogeneity has a strong effect on the dispersion properties; with a strong inhomogeneity the conditions for instability in a homogeneous plasma obtained in ref. 6 are modified.

2. We consider electromagnetic modes in a nonisothermal plasma with an anisotropic electron velocity distribution and cold ions. Let the external magnetic field be in the direction of the z axis, and let its magnitude vary slowly along the y axis. This variation will be considered small over distances of the order of the electron Larmor radius ($\varkappa_B v_e/\omega_{Be} \ll 1$, where $\varkappa_B = \partial \ln B_0/\partial y$ and v_e is the characteristic electron thermal velocity). Since we are interested in a finite-β plasma ($\beta \sim 1$) the condition for weak inhomogeneity of the magnetic field leads to a condition on weak inhomogeneity of the kinetic pressure. However, we assume a uniform plasma temperature and only consider the density inhomogeneity ($\varkappa_n v_e/\omega_{Be} \ll 1$, where $\varkappa_n = \partial \ln n/\partial y$). In describing the plasma we start with the kinetic equation for the electrons in the drift approximation and the hydrodynamic equations without a magnetic field for the ions together with Maxwell's equations.

We consider phase velocities that are appreciably smaller than the electron thermal velocity along the magnetic field and with wavelengths across the magnetic field that exceed the electron Larmor radius. We also assume $\varkappa \sim k_z \ll k$. Instead of using the vectors **E** and **H** of the electromagnetic field we introduce the scalar ψ and vector **A** potentials. Then the dispersion equation in the local approximation (see ref. 7) is

$$\varepsilon_{00}\frac{k^4c^4}{\omega^4} + [\varepsilon_{03}^2 - \varepsilon_{00}(\varepsilon_{33} + \varepsilon_{22}) - \varepsilon_{02}^2]\frac{k^2c^2}{\omega^2} + \varepsilon_{00}\varepsilon_{23}^2 + \varepsilon_{33}\varepsilon_{02}^2 + 2\varepsilon_{02}\varepsilon_{03}\varepsilon_{23} + \varepsilon_{22}(\varepsilon_{00}\varepsilon_{33} - \varepsilon_{03}^2) = 0, \tag{1}$$

$$\left.\begin{aligned}
\varepsilon_{00} &= \frac{\omega_{pi}^2}{k^2u_s^2} - \frac{\omega_{pi}^2}{\omega^2},\\
\varepsilon_{02} &= -i\frac{\omega_{pi}^2}{\omega\omega_{Bi}}\delta,\\
\varepsilon_{03} &= \frac{\omega_{pi}^2}{kk_zu_s^2} + \frac{\omega_{pi}^2}{\omega\omega_{Bi}}\frac{k_x\varkappa_B}{kk_z}\delta - \frac{\omega_{pi}^2}{\omega\omega_{Bi}}\frac{k_x\varkappa_n}{kk_z},\\
\varepsilon_{22} &= -\frac{\omega_{pi}^2}{\omega^2}\frac{k^2v_{2e}^2}{\omega_{Bi}^2},\\
\varepsilon_{23} &= i\frac{\omega_{pi}^2}{\omega\omega_{Bi}}\frac{k}{k_z}\lambda - i\frac{\omega_{pi}^2}{\omega^2}\frac{k}{k_z}\frac{k_x\varkappa_B(v_A^2 + v_{2e}^2)}{\omega_{Bi}^2},\\
\varepsilon_{33} &= \frac{\omega_{pi}^2}{k_z^2u_s^2} - \frac{\omega_{pi}^2}{\omega^2}\frac{k^2v_{1e}^2}{\omega_{Bi}^2} + \frac{\omega_{pi}^2}{\omega\omega_{Bi}}\frac{k_x\varkappa_B}{k_z^2}(\delta + \lambda)\\
&\quad - \frac{\omega_{pi}^2}{\omega\omega_{Bi}}\frac{k_x\varkappa_n}{k_z^2} - \frac{\omega_{pi}^2}{\omega^2}\frac{k_x^2\varkappa_B^2(v_A^2 + v_{2e}^2)}{k_z^2\omega_{Bi}^2},
\end{aligned}\right\} \tag{2}$$

where

$$\frac{1}{u_s^2} = -\frac{m_i}{m_e}\frac{1}{n_0}\int d\varepsilon_\perp dv_z\frac{\partial F}{\partial\varepsilon_z},\quad n_0 = \int d\varepsilon_\perp dv_z F,$$

$$\delta = \frac{1}{n_0}\int \varepsilon_\perp d\varepsilon_\perp dv_z\left(\frac{\partial F}{\partial\varepsilon_z} - \frac{\partial F}{\partial\varepsilon_\perp}\right),$$

$$\lambda = \frac{1}{n_0}\int \varepsilon_\perp d\varepsilon_\perp dv_z\frac{\partial F}{\partial\varepsilon_z},$$

$$v_{1,e}^2 = -\frac{m_e}{m_i}\frac{1}{n_0}\int \varepsilon_\perp d\varepsilon_\perp v_z^2 dv_z\left(\frac{\partial F}{\partial\varepsilon_z} - \frac{\partial F}{\partial\varepsilon_\perp}\right),$$

$$v_{2,e}^2 = \frac{m_e}{m_i}\frac{1}{n_0}\int \varepsilon_\perp^2 d\varepsilon_\perp dv_z\left(\frac{\partial F}{\partial\varepsilon_z} - \frac{\partial F}{\partial\varepsilon_\perp}\right),\quad v_A^2 = c^2\frac{\omega_{Bi}^2}{\omega_{pi}^2},$$

$$\varepsilon_\perp = \frac{v_\perp^2}{2},\quad \varepsilon_z = \frac{v_z^2}{2},\quad \omega_{pi}^2 = \frac{4\pi e^2n_0}{m_i},\quad \omega_{Bi} = \frac{|e|B_0}{m_ic},$$

and $F = F(v_\perp, v_z)$ is the electron velocity distribution function.

Solving Eq. (1) for the frequency ω we obtain the following expression for the normal modes of an inhomogeneous anisotropic finite-β plasma:

$$\omega^4 + m\omega^3 + p\omega^2 + n\omega + q = 0, \tag{3}$$

where

$$\left.\begin{aligned} m &= \sigma\frac{k_z k}{\omega_{Bi}\varkappa_n}\{(v_A^2+v_{2s}^2)(\varkappa_B+\varkappa_n)+u_s^2[\varkappa_B\delta^2+\varkappa_n\delta(\lambda-1)]\},\\ p &= -\frac{k_z^2k^2}{\omega_{Bi}^2}(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2+u_s^2\delta^2)\\ &\quad -k^2(v_A^2+v_{2s}^2+u_s^2\lambda^2)-\sigma^2\frac{k_z^2k^2}{\omega_{Bi}^2}u_s^2(v_A^2+v_{2s}^2),\\ n &= -\sigma\frac{k_z k}{\omega_{Bi}\varkappa_n}k^2u_s^2(v_A^2+v_{2s}^2)(\varkappa_B-\varkappa_n),\\ q &= k_z^2u_s^2\frac{k^4}{\omega_{Bi}^2}(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2),\quad \sigma\equiv\frac{k_x\varkappa_n}{k_z k}. \end{aligned}\right\}\quad(4)$$

The case of a homogeneous plasma corresponds to $\sigma = 0$. Here we obtain an equation that was investigated previously in ref. 6.

3. We now consider an inhomogeneous anisotropic plasma. We first consider short wavelengths ($k_z v_s/\omega_{Bi} \gg 1$). Equation (3) has the solutions

$$\omega^2 = k^2u_s^2\frac{(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2)}{(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2+u_s^2\delta^2)+\sigma^2u_s^2(v_A^2+v_{2s}^2)},\quad(5)$$

$$\begin{aligned}&\omega^2+\sigma\frac{k_z k}{\omega_{Bi}\varkappa_n}\{(v_A^2+v_{2s}^2)(\varkappa_B+\varkappa_n)+u_s^2[\varkappa_B\delta^2+\varkappa_n\delta(\lambda-1)]\}\,\omega\\ &-\sigma^2\frac{k_z^2k^2}{\omega_{Bi}^2}u_s^2(v_A^2+v_{2s}^2)-\frac{k_z^2k^2}{\omega_{Bi}^2}(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2+u_s^2\delta^2)=0.\quad(6)\end{aligned}$$

When the wavelength along the magnetic field is appreciably smaller than the characteristic dimensions of the inhomogeneities ($k_z \gg \varkappa_n$) the instability condition for the frequency, Eq. (5) becomes

$$-u_s^2\delta^2 < v_A^2+v_{2s}^2 < 0,\quad(7)$$

and the instability condition for (6) becomes

$$\left.\begin{aligned}&v_A^2+v_{1s}^2<0\\ \text{or}\quad&\\ &v_A^2+v_{2s}^2+u_s^2\delta^2<0.\end{aligned}\right\}\quad(8)$$

The homogeneous-plasma approximation is valid for these modes. However, when the wavelength along the magnetic field is much larger than the scale of the magnetic field inhomogeneity the instability condition for (5) becomes

$$v_A^2+v_{1s}^2<0,\quad(9)$$

and the instability condition for (6) becomes

$$\frac{1}{\varkappa_n^2}\{(v_A^2+v_{2s}^2)(\varkappa_B+\varkappa_n)+u_s^2[\varkappa_B\delta^2+\varkappa_n\delta(\lambda-1)]\}^2+4u_s^2(v_A^2+v_{2s}^2)<0.\quad(10)$$

To make conditions (9) and (10) more explicit we substitute a model electron velocity distribution function

$$F\sim\exp\left\{-\frac{mv_\perp^2}{2T_\perp}-\frac{mv_z^2}{2T_\parallel}\right\}$$

and introduce the following notation:

$$\beta_\perp=\frac{T_\perp}{m_iv_A^2},\quad \beta_\parallel=\frac{T_\parallel}{m_iv_A^2}.$$

Then, (9) takes the following form:

$$\beta_\parallel>1+\beta_\perp.\quad(11)$$

This is the usual condition for the firehose instability, which, in the given case, develops in an inhomogeneous plasma.

For explicitness in the case of an almost-isotropic plasma ($T_\perp \approx T_\parallel$) we write (10) near the limit of the necessary condition for instability as

$$1+\frac{v_{1s}^2}{v_A^2}=-\nu\quad(1\gg\nu>0).$$

Condition (10) is written in the following simple form:

$$\frac{1}{4}<\beta_\perp\nu<\frac{9}{4}.\quad(12)$$

We now consider long wavelengths ($k_z v_s/\omega_{Bi} \ll 1$). Equation (3) has the solutions

$$\omega^2=k^2(v_A^2+v_{2s}^2+u_s^2\lambda^2),\quad(13)$$

$$\begin{aligned}&-k^2(v_A^2+v_{2s}^2+u_s^2\lambda^2)\,\omega^2-\sigma\frac{k_z k}{\omega_{Bi}\varkappa_n}k^2u_s^2(v_A^2+v_{2s}^2)(\varkappa_B-\varkappa_n)\,\omega\\ &+k_z^2u_s^2\frac{k^4}{\omega_{Bi}^2}(v_A^2+v_{1s}^2)(v_A^2+v_{2s}^2)=0.\quad(14)\end{aligned}$$

Solution (13) does not depend on the inhomogeneity dimension. It has exactly the same form as the solution for a fast magnetosound mode obtained in ref. 6 for a homogeneous plasma and the same instability region. With regard to solution (14), the homogeneous-plasma approximation is valid for wavelengths along the magnetic field that are appreciably smaller than the dimension of the magnetic field inhomogeneity, and the instability^6 condition is

$$v_A^2+v_{1s}^2<0\quad(15)$$

or

$$-u_s^2\lambda^2<v_A^2+v_{2s}^2<0,\quad(16)$$

whereas for wavelengths along the magnetic field that appreciably exceed the dimension of magnetic field inhomogeneities, the modes for (14) are aperiodically stable ($\omega^2 > 0$).

Finally, we consider very long wavelengths ($k_z \ll \varkappa_n$) or fairly strong inhomogeneities, making no assumptions as to the magnitude of $k_z v_s/\omega_{Bi}$. In this case Eq. (3) splits into two equations, one of which is identical to the limiting equation (6) for $k_z \ll \varkappa_n$. This case has already been analyzed and the instability condition is expressed by (10). The second equation reads

$$\begin{aligned}&\Big[-\sigma^2\frac{k_z^2k^2}{\omega_{Bi}^2}u_s^2\omega^2-\sigma\frac{k_z k}{\omega_{Bi}\varkappa_n}k^2u_s^2(\varkappa_B-\varkappa_n)\,\omega\\ &+k_z^2u_s^2\frac{k^4}{\omega_{Bi}^2}(v_A^2+v_{1s}^2)\Big](v_A^2+v_{2s}^2)=0.\quad(17)\end{aligned}$$

In the limiting case $k_z v_s/\omega_{Bi} \gg 1$ this equation leads to aperiodically unstable oscillations, whose instability condition is determined by (9). In the opposite limiting case $k_z v_s/\omega_{Bi} \ll 1$ both solutions of (17) are aperiodically stable.

4. Thus it has been shown that it is important to take account of density and magnetic-field inhomogeneities for wavelengths along the magnetic field of the order of the inhomogeneity scale. For a plasma with $T_\perp < T_\parallel$ and $\omega_{Bi}/v_s \ll k_z \ll \varkappa_n$ the instability (5) is similar to the acoustic branch, and condition (9) coincides with the condition for generation of a firehose instability in a homogeneous plasma. For a plasma with $T_\perp > T_\parallel$ and $\omega_{Bi}/v_s \ll k_z \ll \varkappa_n$ the instability (6) develops from the whistler mode while condition (12) is somewhat more rigorous than the condition for the mirror instability in a homogeneous plas-

ma. A mirror instability develops in an inhomogeneous high-pressure plasma ($\beta \gg 1$) only for a low anisotropic temperature ($T_{\perp} \approx T_{\parallel}$) [see condition (12)]. If $k_z \ll \varkappa_n, \omega_{Bi}/v_s$, when $\varkappa_n v_s/\omega_{Bi} \gg 1$ the instability develops for (13), which coincides with the corresponding mode in a homogeneous plasma. When $\varkappa_n v_s/\omega_{Bi} \ll 1$ there is no instability.

In conclusion the authors thank K. N. Stepanov for guidance.

Modulation of microwaves by density fluctuations in a plasma

L. A. Dushin, A. V. Serikov, A. I. Skibenko, E. V. Krivorukov, and I. P. Fomin

(Submitted October 22, 1973)
Zh. Tekh. Fiz., 44, 1862-1870 (September 1974)

To determine the parameters of a fluctuating plasma from modulation of electromagnetic waves, we have investigated the frequency spectrum and the plasma particle density by spectral analysis of fluctuations in the level of a microwave signal transmitted through the plasma. Analytical relations are obtained for the partial and integrated modulation coefficients for the regular and random components of density and on the effective collisions frequency averaged over the path. The experimental arrangement allows investigation of the temporal variation of the spectrum and the level of the high-frequency signal transmitted through the plasma in the frequency range 0.05-5 MHz, by recording short samples at different time intervals of the pulse. Spectral analysis of fluctuations in the microwave signal level (λ = 8 mm) gives the spectrum and the level of plasma density oscillations whose mean value falls in the range 5.10^{11} to 10^{13} cm^{-5}. The range of characteristic frequencies of the density oscillations is 0.05 to 1 MHz. The level of relative density fluctuations in a 40 kHz band near the characteristic maxima of the oscillations is 2 to $7 \cdot 10^{-3}$. The high-frequency spectra are compared with the signal from a zero-bias double probe.

Probes[1] are frequently used to determine the intensity and spectral composition of fluctuations in a turbulent plasma. However, noncontact methods of measurement are to be preferred. Therefore, there is interest in investigating modulation of microwaves passing through a plasma with fluctuating parameters, both from the viewpoint of propagation of the electromagnetic oscillation, and from the viewpoint of noncontact diagnostics. However, the possibility of using modulation of a propagating wave for diagnostics of a dense plasma has only been investigated in the approximation in which the oscillation of the plasma parameters is monochromatic.[2,3] The spectrum of scattered radiation at large angles has been studied for diagnostic purposes.[4,5] An experimental investigation of modulation of microwave signals inside a tube has been performed by us (see ref. 6). The present paper is a continuation of ref. 6 with the objective of developing a method of determining the spectral distribution of the fluctuations of the plasma parameters from the fluctuation in the level of a microwave signal passing through the plasma.

1. DERIVATION OF THE BASIC RELATIONS

If the density N and the effective collision frequency ν in a plasma are random functions of time we can write[7]

$$N(t) = N_0(t) + \int\limits_{\Omega'_m}^{\Omega''_m} N(\Omega_m)\, e^{i(\Omega_m t + \varphi_{0m})} d\Omega, \tag{1}$$

$$\nu(t) = \nu_0(t) + \int\limits_{\Omega'_n}^{\Omega''_n} \nu(\Omega_n)\, e^{i(\Omega_n t + \varphi_{0n})} d\Omega, \tag{2}$$

where $N(\Omega_m)$ and $\nu(\Omega_n)$ are the spectral densities of the random functions $\overset{\circ}{N}(t)$ and $\overset{\circ}{\nu}(t)$; $N_0(t)$ and $\nu_0(t)$ are slow functions of time as compared with $\exp[i(\Omega_m(t) + \varphi_{0m})]$ and $\exp[i(\Omega_n t + \varphi_{0n})]$, respectively; φ_{0m}, φ_{0n} are the initial phases.

In the linear approximation the plasma must have components of the high-frequency complex conductivity σ_ω and $\sigma_{\omega \pm \Omega_{m,n}}$, corresponding to the probe frequency ω and the sideband components $\omega \pm \Omega_{m,n}$. Under the assumption that $\Omega_m \ll \omega$, $\Omega_n \ll \omega$, and

$$\left| \int\limits_{\Omega'_m}^{\Omega''_m} \frac{N(\Omega_m)}{N_0} e^{i(\Omega_m t + \varphi_{0m})} d\Omega \right| \ll 1, \quad \left| \int\limits_{\Omega'_n}^{\Omega''_n} \frac{\nu(\Omega_n)}{i\omega + \nu_0} e^{i(\Omega_n t + \varphi_{0n})} d\Omega \right| \ll 1,$$

neglecting second-order quantities we can write the conductivity components in the form

$$\sigma_\omega = \sigma_0 \left[1 + \int\limits_{\Omega'_m}^{\Omega''_m} \frac{N(\Omega_m)}{N_0} e^{i(\Omega_m t + \varphi_{0m})} d\Omega - \int\limits_{\Omega'_n}^{\Omega''_n} \frac{\nu(\Omega_n)}{i\omega + \nu_0} e^{i(\Omega_n t + \varphi_{0n})} d\Omega \right], \tag{3a}$$

$$\sigma_{\omega \pm \Omega_{m,n}} = \sigma_\omega \left[1 \mp \frac{i\Omega_{m,n}}{i\omega + \nu} \right], \tag{3b}$$

where $\sigma_0 = e^2 N_0 / m(i\omega + \nu_0)$ is the conductivity of the unperturbed plasma at frequency ω. A plane electromagnetic wave propagating through the plasma will have components of electric field

$$\left. \begin{array}{c} E_0 \exp\{i(\omega t + \varphi_0)\};\ E_m(\omega) \exp\{i[(\omega \pm \Omega_m) t + \varphi_0 \pm \varphi_{0m}]\} d\omega, \\ E_n(\omega) \exp\{i[(\omega \pm \Omega_n) t + \varphi_0 \pm \varphi_{0n}]\} d\omega, \end{array} \right\} \tag{4}$$

where $E_m(\omega)$ and $E_n(\omega)$ are the spectral densities of the components of the electric field, and φ_0 is the initial phase of the plane monochromatic wave incident on the plasma.

The analytical dependence of the fluctuations of the electromagnetic wave passing through the plasma on the parameters of the turbulent plasma can be obtained by solving the wave equation

$$\frac{\partial^2 E}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} = \frac{4\pi}{c^2} \frac{\partial J}{\partial t} \tag{5}$$

taking account of the fact that the wave propagates in the positive 0x direction, and that $\partial/\partial y = \partial/\partial z = 0$. Substituting the conductivity values from Eqs. (3a) and (3b) and values of the electric field components from Eq. (4) into Eq. (5), we obtain linear second-order differential equations for the field components:

$$\frac{\partial^2 \varepsilon_0}{\partial x^2} + b_0^2 \varepsilon_0 = 0, \tag{6a}$$

$$\frac{\partial^2 \varepsilon_{1,2m,n}(\omega)}{\partial x^2} + b_{1,2m,n}^2 \varepsilon_{1,2m,n}(\omega) = d_{1,2m,n} \varepsilon_0, \tag{6b}$$

where

$$b_0^2 = \left(1 - \frac{4\pi i \sigma_0}{\omega}\right) k^2; \quad k = \frac{\omega}{c},$$

$$b^2_{1,2m,n}=\left[\frac{(\omega\pm\Omega_{m,n})^2}{\omega^2}-\frac{4\pi i\,(\omega\pm\Omega_{m,n})}{\omega^2}\sigma_{\omega\pm\Omega_{m,n}}\right]k^2,$$

$$d_{1m,n}=\frac{2\pi i\,(\omega+\Omega_{m,n})}{\omega^2}a_{m,n}k^2;\quad d_{2m,n}=\frac{2\pi i\,(\omega-\Omega_{m,n})}{\omega^2}\tilde{a}_{m,n}k^2,$$

$$a_m=\frac{N(\Omega_m)}{N_0}\sigma_0;\quad \tilde{a}_m=\frac{N(\Omega_m)}{N_0}\sigma_0\exp[i2(\Omega_m t+\varphi_{0m})],$$

$$a_n=\frac{\nu(\Omega_n)}{i\omega+\nu_0}\sigma_0;\quad \tilde{a}_n=\frac{\nu(\Omega_n)}{i\omega+\nu_0}\sigma_0\exp[i2(\Omega_n t+\varphi_{0n})],$$

$$\varepsilon_0=\frac{E_0}{E_{00}};\quad \varepsilon_{1,2m,n}(\omega)=\frac{E_{1,2m,n}(\omega)}{E_{00}},$$

ω is the frequency of the probe wave; c is the speed of light in vacuum; E_{00} is the electric field wave incident on the plasma.

The solution of Eq. (5) with $m \neq 0$, $n = 0$ or $m = 0$, $n \neq 0$ and the initial conditions

$$\varepsilon_{1,2m,n}(\omega)|_{x=0}=0,\quad \left.\frac{\partial\varepsilon_{1,2m,n}(\omega)}{\partial x}\right|_{x=0}=0$$

has the form

$$\varepsilon_0=D_0e^{ib_0x}, \tag{7a}$$

$$\varepsilon_{1,2m,n}(\omega)=\frac{d_{1,2m,n}D_0}{b_0^2-b_{1,2m,n}^2}[e^{ib_{1,2m,n}x}-e^{ib_0x}]. \tag{7b}$$

Taking account of Eqs. (1), (2), (7a), and (7b) we write the normalized field in the plasma in the form

$$\varepsilon(t)=\varepsilon_0e^{i(\omega t+\varphi_0)}+\int\limits_{\omega'_{1m}}^{\omega''_{1m}}\varepsilon_{1m}(\omega)\,e^{i(\omega_{1m}t+\varphi_{1m})}d\omega+\int\limits_{\omega''_{2m}}^{\omega'_{2m}}\varepsilon_{2m}(\omega)\,e^{i(\omega_{2m}t+\varphi_{2m})}d\omega$$
$$+\int\limits_{\omega'_{1n}}^{\omega''_{1n}}\varepsilon_{1n}(\omega)\,e^{i(\omega_{1n}t+\varphi_{1n})}d\omega+\int\limits_{\omega''_{2n}}^{\omega'_{2n}}\varepsilon_{2n}(\omega)\,e^{i(\omega_{2n}t+\varphi_{2n})}d\omega$$
$$=\varepsilon_0[1+\dot{M}(t)]\,e^{i(\omega t+\varphi_0)}, \tag{8}$$

where

$$\omega_{1n,m}=\omega+\Omega_{m,n};\ \omega_{2m,n}=\omega-\Omega_{m,n};$$

$$\varphi_{1m,n}=\varphi_0+\varphi_{0m,n};\ \varphi_{2m,n}=\varphi_0-\varphi_{0m,n}.$$

The instantaneous value of the complex modulation amplitude of the electromagnetic wave passing through the plasma is a random quantity

$$\dot{M}(t)=\int\limits_{\Omega'_m}^{\Omega''_m}\dot{M}(\Omega_m)\,e^{i(\Omega_m t+\varphi_{0m})}d\Omega+\int\limits_{\Omega'_n}^{\Omega''_n}\dot{M}(\Omega_n)\,e^{i(\Omega_n t+\varphi_{0n})}d\Omega. \tag{9}$$

The spectral distribution of the modulation coefficients can be represented by the expressions

$$\dot{M}(\Omega_m)=\left\{\frac{(\omega+\Omega_m)}{b_0^2-b_{1m}^2}[e^{i(b_{1m}-b_0)x}-1]\right.$$
$$\left.+\frac{(\omega-\Omega_m)}{b_0^2-b_{2m}^2}[e^{i(b_{2m}-b_0)x}-1]\right\}\frac{2\pi i\sigma_0}{\omega^2}k^2\frac{N(\Omega_m)}{N_0}, \tag{10}$$

$$\dot{M}(\Omega_n)=\left\{\frac{(\omega+\Omega_n)}{b_0^2-b_{1n}^2}[e^{i(b_{1n}-b_0)x}-1]\right.$$
$$\left.+\frac{(\omega-\Omega_n)}{b_0^2-b_{2n}^2}[e^{i(b_{2n}-b_0)x}-1]\right\}\frac{2\pi i\sigma_0}{\omega^2}k^2\frac{\nu(\Omega_n)}{i\omega+\nu_0}. \tag{11}$$

If we neglect the collision frequency and assume that the plasma oscillations are of low frequency, and that their level is low, i.e., $\nu \ll \omega$, $\Omega_m \ll \omega$, $|i(b_m-b_0)x| \ll 1$, then, taking into account Eqs. (3a), (3b), (5a), (5b), (9), and (10), the modulus of the spectral distribution of the modulation coefficient can be represented by the expression

$$|\dot{M}(\Omega_m)|=\frac{1}{2}\frac{\omega}{c}x\left(1-\frac{N_0}{N_{cr}}\right)^{-1/2}\frac{N_0}{N_{cr}}\frac{N(\Omega_m)}{N_0}. \tag{12}$$

The modulus of the modulation coefficient is then equal to

$$M=\frac{1}{2}\frac{\omega}{c}x\frac{N_0}{N_{cr}}\left(1-\frac{N_0}{N_{cr}}\right)^{-1/2}\left\{\left[\int\limits_{\Omega'_m}^{\Omega''_m}\frac{N(\Omega_m)}{N_0}\sin(\Omega_m t+\varphi_{0m})\,d\Omega\right]^2\right.$$
$$\left.+\left[\int\limits_{\Omega'_m}^{\Omega''_m}\frac{N(\Omega_m)}{N_0}\cos(\Omega_m t+\varphi_{0m})\,d\Omega\right]^2\right\}^{1/2}. \tag{13}$$

Replacing the random functions by their variances we write the expression for the mean-square value of the modulation amplitude in the form

$$\overline{M}=\frac{1}{2}\frac{\omega}{c}x\frac{N_0}{N_{cr}}\left(1-\frac{N_0}{N_{cr}}\right)^{-1/2}\frac{\sqrt{\overline{N}^2}}{N_0}, \tag{14}$$

where $\overline{N}^2$ is the variance of the density fluctuation. Thus, by measuring the spectral distribution of the fluctuations in the level of a microwave signal, we can determine the spectrum of density fluctuations; from the variance of the signal level fluctuations we can determine the mean-square deviation of density from its mean value.

2. MEASUREMENT TECHNIQUE AND RESULTS

An experimental investigation of the modulation of an electromagnetic wave caused by a spectrum of plasma oscillations has been carried out on the high-power cold cathode reflex discharge facility described in ref. 6. The discharge takes place in hydrogen at 10^{-2} torr in a mag-

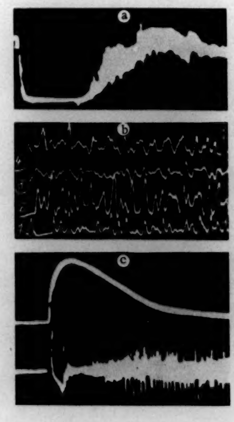

Fig. 1. a) Microwave signal passed through the plasma, with sweep length 2 μsec; b) microwave signals delayed by 1.2, 1.4, 1.6, and 1.8 μsec relative to the start of the discharge (curves 1-4, respectively), length 50 μsec; c) discharge current and signal from the zero-bias twin electrical probe (sweep is 2 μsec).

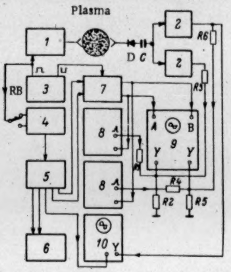

Fig. 2. Schematic diagram of the measurement system. 1) Microwave generator; 2) amplifier; 3) G5-15 generator; 4) individual record trigger; 5) triggering unit; 6) electrical circuit; 7) matched electronic gates; 8) sawtooth voltage generator; 9) S1-33 oscilloscope; 10) S1-16 oscilloscope.

netic field. The plasma is probed by means of electromagnetic waves at λ = 8 mm, with $E \parallel H_{ext}$. Horns mounted in matched diagnostic ports are used to form beams of the order of the antenna aperture.

It has been noted earlier[6] that for certain conditions in a discharge of this type there are intense low-frequency oscillations of the plasma, whose spectrum varies during the discharge. In order to study the temporal variation of the spectrum of the oscillations the spectral composition is investigated for samples of a given length ($\Delta t = 50$ μsec), these being chosen by introducing a different delay relative to the start of the discharge (Fig. 1).

To carry out these measurements a system (Fig. 2) has been developed to allow recording of both the random fluctuations of the microwave signal level, and also the mean value. To determine the level of the signal a continuous sequence of pulses is fed from a reference oscillator 3 to the reflector of the klystron oscillator 1, the pulse length being t_p, and the repetition period T_p. The mean level of the signal passing through the plasma is determined from the cutoff (Fig. 1b). To record the short samples of the progress of the process, multiple recordings are taken on two channels of oscilloscope 9, with independent sweeps. To do this a signal is fed from oscillator 3 to the matched "electronic gates" 7 (Fig. 3) and through the record button RB to the separate record trigger 4. The first pulse to pass through after the contact RB closes flips the trigger 4. A positive pulse appears at the trigger output which arrives at the input to the multichannel generator of synchropulses with a controlled delay. At a given time relative to the start of the discharge the first channel of the electronic gate 7 is recorded by unit 5, and at its output a sequence of pulses appears which gives a multiple sweep of the first channel beam on the oscilloscope 9. Similarly, the second channel of unit 7 gives a multiple recording of the sweep of the second beam of oscilloscope 9 at later times than for the first channel. Vertical displacement of the beams during the multiple recording on oscilloscope 9 is achieved by sawtooth voltage pulses of length $t_{sp} \geq (n-1)T_n$, which come from generator 8 synchronously with the oscilloscope recording. The resistor networks, R1, R2, R3, and R4, R5, R6 allow decoupling of the output of the amplifiers 2 and the generators 8. Oscilloscope 10 is used to record variation in the level of the microwave that is passed through the plasma during the entire process (Fig. 1a).

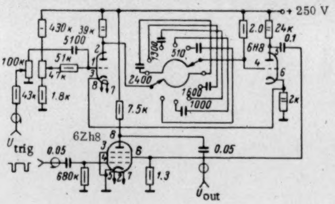

Fig. 3. Circuit diagram of the electronic gates.

A similar arrangement is also used to record the signals from the zero-bias electrical double probe. The coupling element between the probe and amplifiers 2 is a wideband symmetric transformer with a 3 dB band from 0.01 to 10 MHz. An oscillogram of the probe signal is shown in Fig. 1c.

The level of the signal that is passed through the plasma can be represented by the function

$$A(t) = A_0(t) + \tilde{A}(t), \tag{15}$$

where $A_0(t)$ is a slowly varying function of time; $\tilde{A}(t)$ is a centered random function, describing random fluctuations of the level.

The recorded signal oscillograms (Fig. 1b) are processed and a continuous sample is transformed into a random sequence. Digitalization and measurement of the samples is semiautomatic. The initial sequence of points thus obtained, measured in an arbitrary manner along the time axis, is transformed following interpolation into an equidistant sequence of the desired size.

Following transformation of the random function into a stationary centered sequence, the mathematic expectation, the variance, and the autocorrelation function can be represented, respectively, in the form[9]

$$A_0^* = \frac{1}{n} \sum_{j=1}^{n} A_j^{1/\gamma}, \tag{16}$$

$$\bar{A}_d^{*2} = \frac{1}{n} \sum_{j=1}^{n} [A_j^{1/\gamma} - A_0^*]^2, \tag{17}$$

$$R_A = \frac{1}{n} \sum_{j=1}^{n-k} A_j^{1/\gamma} A_{j+k}^{1/\gamma} \tag{18}$$

(k = 0, 1, 2, ... is the number of intervals of the digitalization, A_j is the deviation of the j-th point from the zero level; and γ is the exponent determining the volt–ampere characteristic of the sensor). The spectral density of the level fluctuations in the interval $0 \leq f \leq 1/2\Delta$ is[8]

$$\bar{A}^{*2}(f) = 2\Delta \sum_{k=0}^{p-1} R_A e^{-i2\pi k\Delta f}$$

($f = \Omega/2\pi$; Δ is the digitalization interval).

Thus, the mean-square value of the modulation coefficient and its spectral distribution in the interval Δt has the form

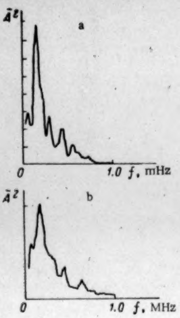

Fig. 4. Spectral distributions of oscillations of a microwave signal transmitted through a plasma (a), and of a probe signal (b), for a time t = 1.6 μsec relative to the start of the discharge.

$$\bar{M}=\frac{(\bar{A}_{\sim}^{*2})^{1/2}}{A_0^*}, \tag{19}$$

$$M^2(f)=\frac{\bar{A}^{*2}(f)}{A_0^{*2}}. \tag{20}$$

By recording and processing oscillograms of the fluctuations in the signal level (Fig. 1b) in the above manner, using a type M-220 computer, we have been able to determine the spectral distribution at different times (Fig. 4a) and the mean value of the transmitted signal. Thus we find the spectral distribution of the modulation coefficient and its integrated value, both in a narrow frequency range near the characteristic frequency, and also in the wide range of frequencies investigated (Fig. 5). From these relationships and the time variation of the mean density (Fig. 6) we have calculated the time (Fig. 7) and frequency (Fig. 8) dependences of the relative density fluctuations $\bar{N}(t)/N_0$ and $\bar{N}(f)/N_0$.

Comparison of Figs. 6 and 7 shows that, as the density N_0 decreases, the level of $\bar{N}(t)/N_0$ first increases, reaches a maximum, and then decreases. The value of $\bar{N}(f)/N_0$ decreases as the frequency f increases, and the position of the maximum is displaced towards lower densities (at later time). The cause of the observed fluctuations in the signal level, besides low-frequency large-scale density oscillations, may also be other factors; fluctuations in the frequency of collisions, regular refraction, scattering of the wave at large angles, followed by reflection and combination with the transmitted wave.

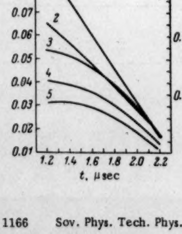

Fig. 5. Time dependence of the integral (1) and partial modulation coefficients in a 40 kHz band near the characteristic plasma oscillation frequencies: 2) 200; 3) 300; 4) 400; 5) 500 kHz.

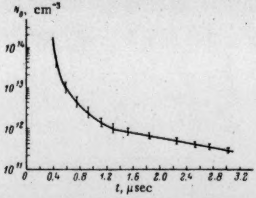

Fig. 6. Time dependence of the mean plasma density across the probe section. p = 10^{-2} torr, H = 320 kA/m, U_{el} = 3.6 kV.

It can be shown from Eqs. (10) and (11) that the ratio of the modulation coefficients due to fluctuations in the frequency of collisions and of the density is

$$\frac{M_\nu}{M_N}=\frac{\nu_0}{\omega}\frac{\tilde{\nu}}{\nu_0}\left(\frac{\bar{N}}{N_0}\right)^{-1}. \tag{21}$$

In our case ($\nu \leqslant 0.04\ \omega$) for the same level of fluctuations of the two parameters, $M_\nu \leq 0.04\ M_N$. Calculation of the refraction shows that the increase in dispersion of the ray tube due to this factor is less than 1° for $N \leq 0.1\ N_{cr}$.

It is known that the integrated scattering coefficient is[11]

$$\Gamma=\frac{\pi^3 d}{\lambda^2}\left(\frac{\bar{N}}{N_{cr}}\right)^2\left[1-\exp\left\{-\left(\frac{2\pi d}{\lambda}\right)^2\right\}\right], \tag{22}$$

where d is the scale of the nonuniformity. Assuming d ≈ 1 cm, and $\bar{N}/N_{cr} \approx 0.5$, and that the fraction of the scattered flux reaching the receiving antenna is proportional to the ratio of the area of the antenna aperture (0.8 Δb^2) to the area of the part of the chamber reflecting the scattered radiation, equal to $2\pi R\Delta b$ (Δb is the width of the antenna aperture), we obtain a modulation coefficient of 0.06.

Taking into account that, for the plasma parameters chosen and for a single transmission, the radiation is attenuated roughly by a factor of 2, the effect of large-scale scattering will be less than the modulation level in the ray tube by a factor of roughly 3 to 4.

Simultaneously with measurement of the spectrum of signal level fluctuations, a study is made of the spectrum of current fluctuations in the zero-bias electrical double

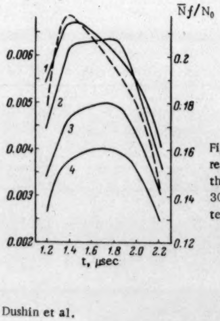

Fig. 7. Temporal dependence of the relative fluctuations of density near the characteristic frequency 1) 200; 2) 300; 3) 400; 4) 500 kHz, and their integrated value (dashed line).

probe, which is mounted in the same section at a distance of (1/3)R from the discharge axis (Fig. 4). A comparison of the fluctuations in the level and in the probe signals shows that their spectra coincide. Therefore, we can consider that the fluctuations in signal level are due to fluctuations of parameters in the plasma volume, and do not result from interference by multiple reflection in the chamber. The two sensors do not record oscillations when the discharge current duration is small. The nature of the time variations in the probe signal fluctuations is qualitatively similar to the fluctuation in the signal level.

Thus, large-scale low-frequency oscillations predominate in the discharge; their intensity decreases linearly as frequency increases.

An analysis of the time dependence of the fluctuations in signal level and of the probe signal (Fig. 1, a and c) shows that the fluctuations are generated at the density growth stage and are attenuated when the discharge current and the density have their maximum values. At the density decrease stage the amplitude of the oscillations increases to a maximum and again decreases. When the oscillations are attenuated the plasma decays more slowly.

Preliminary investigations of the dependence of the fluctuation spectrum on the level of the external magnetic field, and estimates of the temperature gradients and the density support the view that the observed plasma oscillations can be interpreted as drift oscillations of a nonuniform plasma with an isotropic particle distribution function in the presence of an external magnetic field; these oscillations exist in a nonisothermal plasma[10] with $T_e \gg T_i$. Since the drift oscillations are generated at density gradients, the size of a nonuniformity must be less than the radius of the plasma (R = 100 mm), and the least size of nonuniformity for which radiation does not emerge from the ray tube is of the order[6] of 24 mm.

Thus, spectral analysis of fluctuations of the level of microwaves used to probe a plasma has generated the spectral distribution and the value of large-scale low-frequency density fluctuations in the vicinity of the characteristic frequencies of plasma oscillations, as well as the integral value of plasma oscillations over the entire frequency range.

The experimental technique used has allowed investigation of the time variation of the spectrum of plasma oscillations in a single discharge.

In conclusion the authors thank A. Ya. Omel'chenko and B. I. Smerdov for useful comments.

Measurement of plasma density distribution with a rectangular microwave cavity

I. N. Moskalev

(Submitted September 25, 1973)
Zh. Tekh. Fiz., 44, 1871-1876 (September 1974)

The feasbility of using multimode microwave cavities with a rectangular cross section to measure an arbitrary plasma density distribution n (r, φ) is investigated. It is shown that the loss of information associated with the odd harmonics of the Fourier expansion of the function n (r, φ) makes it impossible to measure an arbitrary distribution.

The feasibility of measuring the spatial density distribution n(r, φ, z) of a plasma by the cavity method is well known in the literature.[1–4] When a plasma is introduced into a cavity the cavity eigenfrequencies are shifted; the amount of the shift is known to be proportional to the average density of the plasma in the region occupied by the electric field. The distribution and absolute value of the plasma density can be found by determining the frequency shifts of the cavity in several modes with different electric field configurations. In most of the papers devoted to this problem for simplicity the density distribution is assumed to be axisymmetric and independent of the longitudinal coordinate. In many practical situations, however, these assumptions are not justified. For example, the plasma in a stellerator or tokamak is not axisymmetric; the plasma distribution in devices with magnetic mirrors has a strong dependence on z, etc. The density distribution with respect to z can almost always be determined by means of a cavity with small longitudinal dimensions (such as a Fabry–Perot cavity or an open beer-barrel cavity) such that the density gradient is negligible. It is not yet clear how the dependence on r and φ can be determined or whether it is even possible to do so. An analysis has shown[5] that axisymmetric cavities do not respond to the odd harmonics of the Fourier expansion of the function n(r, φ) with respect to φ. This means that such cavities cannot be used, in principle, to determine an arbitrary distribution n(r, φ), regardless of what modes or how many of them are used for the measurements.

The insensitivity of axisymmetric cavities to odd harmonics of an azimuthal perturbation (in particular, to a slight displacement of the plasma column) is a consequence of the specific form of the azimuthal dependence of the electric fields. The latter, in turn, are determined by the cavity eigenfunctions, i.e., primarily by the cavity configuration. It is reasonable to ask, therefore, whether the indicated insensitivity of such cavities to odd harmonics is not a result of their axial symmetry. If this is true, it should be possible to obtain an arbitrary distribution n(r, φ) by means of cavities with a different configuration. Since rectangular cavities are the simplest and therefore the most widely used next to the axisymmetric type, they deserve the greatest attention.

In this paper we consider the possibility of using rectangular cavities (it is immaterial whether they are open or closed) to determine an arbitrary plasma density distribution n(r, φ).

Without sacrificing generality we consider the TM_{mnq} modes of a rectangular cavity with longitudinal index q = 1 (Fig. 1). The principal field component E_z in a rectangular coordinate system associated with one of the cavity angles has the form

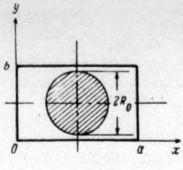

Fig. 1

$$E_z = E_0 \sin\left(\frac{\pi m}{a}x\right)\sin\left(\frac{\pi n}{b}y\right)f(z), \tag{1}$$

where $f(z)$ is the longitudinal field distribution function, which is unimportant for our problem.

Let a plasma cylinder of radius R_0 with an arbitrary density distribution with respect to the coordinates n(x, y, z) be located at the center of the cavity, i.e., at the point $\{a/2, b/2\}$.

The resonance shift of a cavity operating in the TM_{mn} mode when a plasma is introduced is given by the expression (see, e.g., ref. 4)

$$\left(\frac{\Delta\omega}{\omega}\right)_{mn} = \frac{1}{2n_{cr}}\frac{\int\limits_V E_{mn}^2(V)\,n(V)\,dV}{\int\limits_V E_{mn}^2(V)\,dV}. \tag{2}$$

Here n_{cr} is the critical density, and V is the volume of the cavity. Since we are assuming that the relative variation of the density over the length of the cavity is small and the principal field component is E_z, we can write the expression (2) for the shift in the form

$$\left(\frac{\Delta\omega}{\omega}\right)_{mn} = \frac{1}{2n_{cr}}\frac{\int\limits_S E_z^2(x, y)\,n(x, y)\,dS}{\int\limits_S E_z^2(x, y)\,dS}, \tag{3}$$

where S is the cross section of the cavity.

We introduce a cylindrical coordinate systm r, φ, z* whose center coincides with the center of the cavity, where the z* axis is parallel to the original z axis and the direction φ = 0 corresponds to the positive direction of the x axis. Expressing the variables x, y, and z in terms of r, φ, and z* = Z, substituting the resulting expression for the electric field into (3), and carrying out suitable transformations, we obtain

$$\int\limits_0^{2\pi}\int\limits_0^{R_0} E_0^2 \sin^2\left[\frac{\pi m}{a}\left(r\cos\varphi - \frac{a}{2}\right)\right]\sin^2\left[\frac{\pi n}{b}\left(r\sin\varphi - \frac{b}{2}\right)\right] n(r, \varphi)\,r\,dr\,d\varphi = B_{mn}\left(\frac{\Delta\omega}{\omega}\right)_{mn}. \tag{4}$$

Here, the constant B_{mn} includes all other quantities irrelevant to our problem.

We separate the variables in the integrand of (4). We note, accordingly, that by rewriting

$$\sin^2\left[\frac{\pi m}{a}\left(r\cos\varphi-\frac{a}{2}\right)\right] \text{ as } \frac{1}{2}\left[1-(-1)^m\cos\left(\frac{2\pi m}{a}r\cos\varphi\right)\right]$$

we can write the electric field in (4) in the form

$$\begin{aligned}E_z^2(r,\varphi)&=\frac{1}{4}\left[1-(-1)^m\cos\frac{2\pi m}{a}(r\cos\varphi)\right]\left[1-(-1)^n\cos\frac{2\pi n}{b}(r\sin\varphi)\right]\\&=\frac{1}{4}\left[1-(-1)^m\cos\left(\frac{2\pi m}{a}r\cos\varphi\right)-(-1)^n\cos\left(\frac{2\pi n}{b}r\sin\varphi\right)\right.\\&\quad\left.+(-1)^{m+n}\cos\left(\frac{2\pi n}{a}r\cos\varphi\right)\cos\left(\frac{2\pi n}{b}r\sin\varphi\right)\right].\end{aligned}\tag{5}$$

(We drop E_0^2 from now on as an inessential constant.)

We rewrite the last term in (6):

$$\begin{aligned}&(-1)^{m+n}\frac{1}{2}\left\{\cos\left[2\pi r\left(\frac{m}{a}\cos\varphi-\frac{n}{b}\sin\varphi\right)\right]\right.\\&\quad\left.+\cos\left[2\pi r\left(\frac{m}{a}\cos\varphi+\frac{n}{b}\sin\varphi\right)\right]\right\}\\&=(-1)^{m+n}\frac{1}{2}\left\{\cos\left[2\pi r\sqrt{\left(\frac{m}{a}\right)^2+\left(\frac{n}{b}\right)^2}\sin(\varphi+\varphi_0)\right]\right.\\&\quad\left.+\cos\left[2\pi r\sqrt{\left(\frac{m}{a}\right)^2+\left(\frac{n}{b}\right)^2}\sin(\varphi_0-\varphi)\right]\right\}\\&=(-1)^{m+n}\frac{1}{2}\{\cos[M(r)\sin(\varphi+\varphi_0)]+\cos[M(r)\sin(\varphi_0-\varphi)]\},\end{aligned}$$

where

$$M(r)=\cos\left[2\pi r\sqrt{\left(\frac{m}{a}\right)^2+\left(\frac{n}{b}\right)^2}\right],$$

$$\varphi_0=\operatorname{arc\,tg}\frac{mb}{na}.$$

Introducing the notation

$$\frac{2\pi m}{a}r=U(r) \text{ and } \frac{2\pi n}{b}r=W(r),$$

we write (5) in the form

$$\begin{aligned}E_z^2=E_{mn}^2=\frac{1}{4}&\left\{1-(-1)^m\cos[U(r)\cos\varphi]-(-1)^n\cos[W(r)\sin\varphi]\right.\\&+(-1)^{m+n}\frac{1}{2}\cos[M(r)\sin(\varphi+\varphi_0)]\\&\left.+(-1)^{m+n}\frac{1}{2}\cos[M(r)\sin(\varphi_0-\varphi)]\right\}.\end{aligned}\tag{6}$$

Using the relations

$$\cos(U\sin\varphi)=J_0(U)+2\sum_{p=1}^{\infty}J_{2p}(U)\cos 2p\varphi$$

and

$$\cos(U\cos\varphi)=J_0(U)+2\sum_{p=1}^{\infty}(-1)^pJ_{2p}(U)\cos 2p\varphi,$$

in which $J_p(U)$ is the Bessel function of order p, we find

$$\begin{aligned}E_{mn}^2=\frac{1}{4}&\left\{1-(-1)^m\left[J_0(U)+2\sum_{p=1}^{\infty}J_{2p}(U)\cos 2p\varphi\right]\right.\\&-(-1)^n\left[J_0(W)+2\sum_{p=1}^{\infty}(-1)J_{2p}(W)\cos 2p\varphi\right]+\frac{1}{2}(-1)^{m+n}\\&\times\left[J_0(M)+2\sum_{p=1}^{\infty}(-1)^pJ_{2p}(M)\cos 2p(\varphi+\varphi_0)\right]-\frac{1}{2}(-1)^{m+1}\\&\left.\times\left[J_0(M)+2\sum_{p=1}^{\infty}(-1)^pJ_{2p}(M)\cos 2p(\varphi-\varphi_0)\right]\right\}.\end{aligned}\tag{7}$$

Consequently, E_m^2 can be represented as a linear combination of functions depending only on one variable, r or φ.

We expand the function $n(r, \varphi)$ in a Fourier series in the interval $[0, 2\pi]$:

$$n(r,\varphi)=\frac{a_0}{2}+\sum_{k=1}^{\infty}(a_k\cos k\varphi+b_k\sin k\varphi),\tag{8}$$

where a_k and b_k are the coefficients of the expansion.

We now substitute Eqs. (7) and (8) into (4) and integrate with respect to φ from 0 to 2π. Using relations of the type

$$\int_0^{2\pi}\cos 2p\varphi\cos k\varphi d\varphi\begin{cases}0 & \text{for } k\neq 2p\\ \pi & \text{for } k=2p\end{cases} \text{ and } \int_0^{2\pi}\cos 2p\varphi\times$$

$$\times\sin k\varphi d\varphi \text{ for any integers p and k,}$$

we infer that

$$\left.\begin{aligned}&\left(\frac{\Delta\omega}{\omega}\right)_{mn}=\pi\int_0^{R_0}\left(a_0A+2\sum_{p=1}^{\infty}a_{2p}C_{2p}\right)rdr,\\&\text{where}\\&A=1-(-1)^mI_0(U)-(-1)^nI_0(W)+(-1)^{m+n}I_{2p}(M)\cos 2p\varphi_0,\\&C_{2p}=-(-1)^{m+p}I_{2p}(U)-(-1)^nI_{2p}(W)\\&\qquad+(-1)^{m+n}I_{2p}(M)\cos 2p\varphi_0.\end{aligned}\right\}\tag{9}$$

The dependence of the right-hand side on the indices m and n is contained here in the functions U(r, m), W(r, n), and M(r, m, n).

As is evident from (9), the expression for the frequency shift does not include odd harmonics of the expansion (8); consequently, the "rectangular" cavity, like the "axisymmetric" type, does not respond to these density perturbations, and this information is therefore lost in cavity measurements.

It is interesting to note that not only are the odd harmonics of the expansion (8) missing from expression (9); all terms of the form $b_k\sin k\varphi$ are also missing; this fact seems strange because it implies, at first glance, that the x axis ($\varphi = 0$) is special by comparison with the y axis ($\varphi = \pi/2$). This cannot be the case since the electric fields are symmetric with respect to the coordinate axes.

To understand the reason for the foregoing result, i.e., to ascertain its physical meaning, we refer to Fig. 2, which shows various deformations of a plasma. We assume for simplicity that the plasma cylinder is homogeneous in its cross section and that the coefficients a_k and b_k are much smaller than a_0. The electric field E_{mn} is perpendicular to the plane of the figure (TM_{mn} modes), and the density of the contours (solid lines) is proportional to the field. Small values of m and n are used (m = 2, n = 1). The variation $\delta(\Delta\omega/\omega)_{mn}$ of the frequency shift due to perturbations of the plasma is proportional in the figure to the variation of the field flux across the plasma cross section after superposition of their perturbations.

We consider the simplest perturbations of the plasma density, $n = a_0 + a_1\cos\varphi$ and $n = n_0 + b_1\sin\varphi$, which represent, to a first approximation, displacements of the plasma

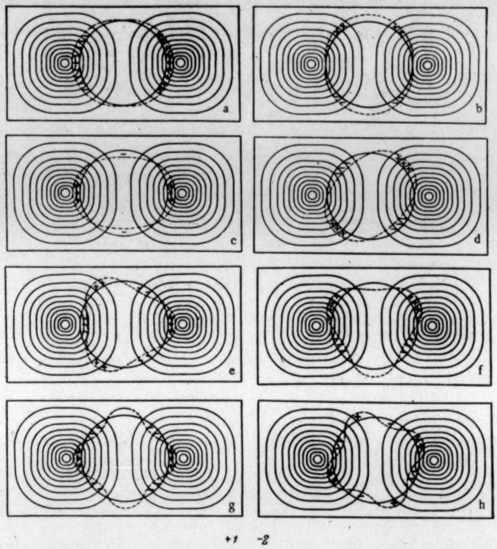

Fig. 2. Response of a cavity to various perturbations of a plasma filament. a) $n = a_0 + a_1 \cos\varphi$, $\delta(\Delta\omega) = 0$; b) $n = a_0 + b_1 \sin\varphi$, $\delta(\Delta\omega) = 0$; c) $n = a_0 + a_2 \cos 2\varphi$, $\delta(\Delta\omega) \neq 0$; d) $n = a_0 + b_2 \sin 2\varphi$, $\delta(\Delta\omega) = 0$; e) $n = a_0 + a_3 \cos 3\varphi$, $\delta(\Delta\omega) = 0$; f) $n = a_0 + b_3 \sin 2\varphi$, $\delta(\Delta\omega) = 0$; g) $n = a_0 + a_4 \cos 4\varphi$, $\delta(\Delta\omega) \neq 0$; h) $n = a_0 = b_4 \sin 4\varphi$, $\delta(\Delta\omega) = 0$. An increase in the frequency shift due to deformation of the filament is indicated by a plus sign, a decrease by a minus sign [the number of signs is proportional to the contribution to $\delta(\Delta\omega)$].

column along the x and y axes, respectively (Figs. 2a and 2b). As the figure shows, with these displacements the positive increment of the frequency shift due to entry of the plasma into the electric field domain 1 is offset by the negative increment of the shift due to its departure from the other domain 2, so that the resultant effect, i.e., the total variation $\delta(\Delta\omega)$ is equal to zero. The cavity is therefore insensitive to plasma density variation of the type $a_1 \cos\varphi$ or $b_1 \sin\varphi$.

Next we consider the perturbations $a_2 \cos\varphi$ and $b_2 \cdot \sin\varphi$ illustrated in Figs. 2c and 2d; they transform the axisymmetric plasma cylinder into an elliptical cylinder. In the case of a cosine perturbation the positive increment of $\Delta\omega$ induced by the flux across domain 1 is greater than the negative increment due to the departure of the plasma from domain 2, so that the net effect is no longer zero. A sine perturbation in this case, on the other hand, again does not change the value of $\Delta\omega$, because the positive variation $\delta(\Delta\omega)$, due to domain 1 is exactly equal to the opposite variation induced by domain 2. Accordingly, expression (9) includes the term $a_2 \sin 2\varphi$ of the expansion and not the term $b_2 \sin 2\varphi$.

A further examination of the figures (2f, 2g, and 2h) shows that the cavity has a nonzero response only for the density perturbation $a_4 \cos 4\varphi$ and, as is immediately apparent, for all perturbations symmetric with respect to both the x and the y axis simultaneously.

Therefore, contrary to first appearances based on expression (9), the cavity is actually not selective with respect to one of the directions (x or y).

The fact that the two largest and most thoroughly investigated classes of cavities, axisymmetric and rectangular, do not respond to odd harmonics of the density perturbation still does not imply that cavities should be dismissed for density distribution measurements. Under certain assumptions with respect to the form of the function $n(r, \varphi)$ [for example, if the shape of the cross section of the surfaces on which the density has the same value ("equidensity lines") is known] such multimode measurements will yield complete information about the required distribution.[5]

I wish to thank A. M. Stefanovskii and E. I. Dobrokhotov for a discussion.

The penetration times for quasistationary magnetic fields in a conducting cylindrical shell and in a solid conducting cylinder are computed. In both cases, the penetration time of the field is determined by the conducting properties of the material and the spatial periods of the currents that excite the field.

The investigation of the diffusion of quasistationary magnetic fields into regions bounded by conductors is of interest in many problems. The increasing interest in such studies stems from the need for effective magnetic configurations for plasma confinement. The most widespread and promising of these are magnetic systems which utilize uniform and spatially periodic fields of quasistationary currents that flow inside or outside of a conducting chamber.

In the first part of this work[1] we have investigated diffusion of uniform fields. In the second part we consider the diffusion of helical magnetic fields into the interior of hollow and solid conducting cylinders.

1. DIFFUSION OF HELICAL MAGNETIC FIELDS INTO THE INTERIOR OF CONDUCTING CYLINDERS

Consider a magnetic field created by spatially periodic quasistationary currents that flow along the outer surface of a hollow conducting cylinder of radius a. In a cylindrical coordinate system (r, φ, z) with z axis directed along the cylinder axis, with periodically distributed currents with period $2\pi/l$ relative to φ and L relative to z, the components of the magnetic field can be represented by a double Fourier series in φ and z. We limit ourselves to the case of helical symmetry, in which the current components are periodic functions of the period 2π relative to the combination $\theta = l\varphi - hz$, where $h = 2\pi/L$.

Despite these constraints, the case under consideration remains fairly general, and from it for $l = 0$ we obtain the case of a "corrugated" magnetic field and for $h = 0$ the case of a field of periodically distributed longitudinal currents.

We represent the components of the helical currents by a Fourier series in complex form:

$$\left.\begin{aligned} j_z(\theta, t) &= \sum_{n=-\infty}^{n=+\infty} j_{nz}(t)\, e^{in\theta}, \\ j_\varphi(\theta, t) &= \sum_{n=-\infty}^{n=+\infty} j_{n\varphi}(t)\, e^{in\theta}. \end{aligned}\right\} \tag{1.1}$$

The condition that the current density be continuous (div j = 0) implies that

$$j_{n\varphi}(t) = \frac{ha}{l} j_{nz}(t) \equiv j_n(t), \tag{1.2}$$

i.e., the helical currents can be specified by one component. The ratio ha/l represents the tangent of the angle between the direction of the current and the generator of the cylinder ($\tan \vartheta = ha/l$).

The components of the magnetic field with helical symmetry can also be represented by a Fourier series:

$$\left.\begin{aligned} H_r(r, \theta, t) &= \sum_n f_n(r, t)\, e^{in\theta}, \\ H_\varphi(r, \theta, t) &= \sum_n g_n(r, t)\, e^{in\theta}, \\ H_z(r, \theta, t) &= \sum_n q_n(r, t)\, e^{in\theta}. \end{aligned}\right\} \tag{1.3}$$

To be specific we consider the case of positive n ($n > 0$). Because the components of the magnetic field are real, the Fourier coefficients with negative n must be the complex conjugates of the corresponding coefficient with positive n. The case $n = 0$ has been considered earlier.[1]

The Laplace transformations with respect to time for the Fourier coefficients of the magnetic field components $\bar{f}_n(r)$, $\bar{g}_n(r)$, $\bar{q}_n(r)$ can be found from the solution of Maxwell's equations ((1.5)-(1.7) in ref. 1).

The solutions for Maxwell's equations for the Fourier coefficients inside a cylindrical shell that are finite on the cylinder axis and outside the cylinder that are finite at infinity can be written in the form

$$\left.\begin{aligned} \bar{f}_n^{(i)}(r) &= iC_n^{(i)} I'_{nl}(nhr), \\ \bar{q}_n^{(i)}(r) &= -\frac{hr}{l} \bar{g}_n^{(i)}(r) = C_n^{(i)} I_{nl}(nhr), \\ \bar{f}_n^{(e)}(r) &= iC_n^{(e)} K'_{nl}(nhr), \\ \bar{q}_n^{(e)}(r) &= -\frac{hr}{l} \bar{g}_n^{(e)} = C_n^{(e)} K_{nl}(nhr). \end{aligned}\right\} \tag{1.4}$$

Here, the prime denotes derivatives with respect to the argument.

Inside the cylinder walls, the Fourier coefficients are related by the expressions

$$\left.\begin{aligned} \bar{f}_n(r) + i\bar{g}_n(r) &= A_{1n} I_{nl+1}(\varkappa_n r) + B_{1n} K_{nl+1}(\varkappa_n r), \\ \bar{f}_n(r) - i\bar{g}_n(r) &= A_{2n} I_{nl-1}(\varkappa_n r) + B_{2n} K_{nl-1}(\varkappa_n r), \\ \bar{q}_n(r) &= \frac{i\varkappa_n}{2nh}[-(A_{1n} + A_{2n}) I_{nl}(\varkappa_n r) + (B_{1n} + B_{2n}) K_{nl}(\varkappa_n r)], \end{aligned}\right\} \tag{1.5}$$

where $\varkappa_n^2 = q^2 + n^2h^2$, $q^2 = p/\chi^2$, $\chi^2 = c^2/4\pi\sigma$. As before,[1] we assume that $\mu = 1$.

The constants $C_n^{(i)}$, $C_n^{(e)}$, A_{1n}, A_{2n}, B_{1n}, and B_{2n} depend on n, l, h, and $\varkappa_n$, and can be found from the continuity conditions for the magnetic field components on the inner side of the cylindrical shell ($r = b = a - \Delta$):

$$\bar{f}_n^{(i)}(b) = \bar{f}_n(b), \quad \bar{g}_n^{(i)}(b) = \bar{g}_n(b), \quad \bar{q}_n^{(i)}(b) = \bar{q}_n(b) \tag{1.6}$$

and the boundary conditions on the interior side of the cylinder, which allow for the discontinuity in the tangential components of the magnetic field as a result of the surface current:

$$\left.\begin{array}{c}\bar f_n^{(e)}(a)=\bar f_n(a),\quad \bar g_n^{(e)}(a)=\bar g_n(a)+\frac{4\pi l}{cha}\bar j_n,\\ \bar q_n^{(e)}(a)=\bar q_n(a)-\frac{4\pi}{c}\bar j_n,\end{array}\right\}\qquad(1.7)$$

where $\bar{j}_n$ is the Laplace transformation of the Fourier coefficient of the current $j_n(t)$.

We omit the calculations and give expressions for the coefficients $C_n^{(i)}$, $C_n^{(e)}$ and the determinant $D_n(p)$. To abbreviate the notation we introduce functions which represent combinations of cylindrical functions:

$$\left.\begin{array}{l}M_{n,m}\equiv M_{n,m}(a,\ b)=I_n(\varkappa_n a)K_m(\varkappa_n b)-I_m(\varkappa_n b)K_n(\varkappa_n a),\\ N_{n,m}\equiv N_{n,m}(a,\ b)=I_n(\varkappa_n a)K_m(\varkappa_n b)+I_m(\varkappa_n b)K_n(\varkappa_n a).\end{array}\right\}(1.8)$$

Then these coefficients can be written in the form

$$\left.\begin{array}{l}C_n^{(i)}=-\frac{4\pi}{c}\bar j_n nhaG_n^{(i)}(p)D_n^{-1}(p)K'_{nl}(nha),\\ C_n^{(e)}=-\frac{4\pi}{c}\bar j_n nhaG_n^{(e)}(p)D_n^{-1}(p)I'_{nl}(nha),\end{array}\right\}\qquad(1.9)$$

where

$$G_n^{(i)}(p)=\frac{1}{2n^2h^2ab}\left(M_{nl-1,\,nl-1}+M_{nl+1,\,nl+1}+\frac{2l^2}{h^2ab}M_{nl,\,nl}\right),\qquad(1.10)$$

$$G_n^{(e)}(p)=\frac{I'_{nl}(nhb)}{nhaI'_{nl}(nha)}\Big\{\Big[M_{nl-1,\,nl-1}M_{nl+1,\,nl+1}$$
$$+\frac{\varkappa_n^2}{4n^2h^2}(M_{nl+1,\,nl+1}-M_{nl-1,\,nl-1})^2$$
$$-\frac{\varkappa_n l^3}{2nh^4a^2b}(N_{nl,\,nl+1}-N_{nl,\,nl-1})^2\Big]\frac{I_{nl}(nhb)}{I'_{nl}(nhb)}+\frac{\varkappa_n}{2nh}\Big[N_{nl+1,\,nl}M_{nl-1,\,nl-1}$$
$$+N_{nl-1,\,nl}M_{nl+1,\,nl+1}+\frac{l^2}{h^2a^2}M_{nl,\,nl}(N_{nl,\,nl+1}+N_{nl,\,nl-1})\Big]\Big\}.\qquad(1.11)$$

The determinant is

$$D_n(p)=M_{nl-1,\,nl-1}M_{nl+1,\,nl+1}I_{nl}(nhb)K_{nl}(nha)+\frac{\varkappa_n}{2nh}[N_{nl,\,nl+1}I_{nl}(nhb)$$
$$\times K_{nl+1}(nha)+N_{nl+1,\,nl}I_{nl+1}(nhb)K_{nl}(nha)]M_{nl-1,\,nl-1}+\frac{\varkappa_n}{2nh}M_{nl+1,\,nl+1}$$
$$\times[N_{nl,\,nl-1}I_{nl}(nhb)K_{nl-1}(nha)+N_{nl-1,\,nl}I_{nl-1}(nhb)K_{nl}(nha)]+$$
$$+\frac{\varkappa_n^2}{4n^2h^2}M_{nl,\,nl}[M_{nl+1,\,nl-1}I_{nl+1}(nhb)K_{nl-1}(nha)+M_{nl-1,\,nl+1}I_{nl-1}(nhb)$$
$$\times K_{nl+1}(nha)+M_{nl-1,\,nl-1}I_{nl+1}(nhb)K_{nl+1}(nha)+M_{nl+1,\,nl+1}$$
$$\times I_{nl-1}(nhb)K_{nl-1}(nha)].\qquad(1.12)$$

For $a = b$ or $\sigma = 0$ ($\varkappa_n = nh$) the products $G_n^{(i)}(p)D_n^{-1}(p)$ and $G_n^{(e)}(p)D_n^{-1}(p)$ become unity and the values of the coefficients $C_n^{(i)}$ and $C_n^{(e)}$, as expected, are equal to their values when there is no conducting medium.

Let us first investigate the transient process. The roots of the determinant (1.12) in the general case of arbitrary a_n and Δ can be determined by numerical methods.

For thin walls, where the condition $nh\Delta \ll 1$ holds, the minimum root of the determinant that satisfies the condition $\varkappa_n\Delta \ll 1$ can be found by series expansion of the determinant in powers of $nh\Delta$ and $\varkappa_n\Delta$.

Using the series expansion of Bessel function we obtain the following expression for the determinant:

$$D_n(p)=\frac{\Delta}{n^2h^2a^3}\left[1+\frac{l^2}{h^2a^2}-\frac{pa\Delta}{\chi^2}I'_{nl}(nha)K'_{nl}(nha)\right].\qquad(1.13)$$

The unique root of the determinant in this approximation is

$$p=\frac{\chi^2}{a\Delta}\left(1+\frac{l^2}{h^2a^2}\right)\frac{1}{I'_{nl}(nha)K'_{nl}(nha)}.\qquad(1.14)$$

The applicability condition for the expansion in powers of $\varkappa_n\Delta \ll 1$ yields a constraint on the ratio Δ/a of the form

$$\frac{\Delta}{a}\ll\frac{h^2a^2}{l^2+h^2a^2}I'_{nl}(nha)\,|K'_{nl}(nha)|.\qquad(1.15)$$

When this condition is not observed other roots of the equation $D_n(p) = 0$ appear, but the minimum root, which essentially determines the diffusion time of the field, remains (1.14), as before. Equation (1.14) is valid for arbitrary nha. If $nha \ll 1$, we have

$$p=-\frac{2\chi^2}{a\Delta}nl=-\frac{2\chi^2}{a\Delta}nha\operatorname{ctg}\vartheta\qquad(1.16)$$

for nonzero l values, and

$$p=-\frac{2\chi^2}{a\Delta}\qquad(1.17)$$

for $l = 0$.
